# Chapter 1. SQL programming

You can use the HCL Informix® implementation of the SQL language to develop applications for Informix® database servers.

## Guide to SQL: Syntax

The *Informix® Guide to SQL: Syntax* describes the syntax of the statements, data types, expressions, operators, and built-in functions of the Informix® dialect of the SQL language.

This information is intended for the following users:

- Database users
- Database administrators
- Database security administrators
- Database application programmers.

This information assumes that you have the following background:

- A working knowledge of your computer, your operating system, and the utilities that your operating system provides
- Some experience working with relational databases or exposure to database concepts
- Some experience with computer programming.

## Overview of SQL syntax

These topics provide an overview about how to use the SQL statements, SPL statements, and syntax segments.

The topics in this chapter are organized into the following sections.

| Section   | Scope   |
|---|---|
| <a href="#">How to Enter SQL Statements on page 1</a>         | How to use syntax diagrams and descriptions to enter SQL statements correctly |
| <a href="#">How to Enter SQL Comments on page 3</a>           | How to enter comments in SQL statements                                       |
| <a href="#">Categories of SQL Statements on page 6</a>        | The SQL statements, listed by functional category                             |
| <a href="#">ANSI/ISO Compliance and Extensions on page 12</a> | The SQL statements, listed by degree of ANSI/ISO compliance                   |

## How to Enter SQL Statements

SQL is a free-form language, like C or PASCAL, that generally ignores white-space characters like TAB, LINEFEED, and extra blank spaces between statements or statement elements. At least one blank character or other delimiter, however, must separate keywords and identifiers from other syntax tokens.

SQL is lettercase insensitive, except within quoted strings; see also [Identifier on page 1456](#). In an ANSI-compliant database, if you do not delimit the *owner* of an object by double ( " ) quotation marks, and the **ANSIOWNER** environment variable was not set to 1 when the database server was initialized, the database server stores the *owner* name in uppercase letters.

Statement descriptions are provided in this publication to help you to enter SQL statements successfully. A statement description includes this information:

- A brief introduction that explains what the statement does
- A syntax diagram that shows how to enter the statement correctly
- A syntax table that explains each input parameter in the syntax diagram
- Rules of usage, typically with examples that illustrate these rules

For some statements, this information is provided for individual clauses.

Most statement descriptions conclude with references to related information in this publication and in other publications.

[SQL statements on page 16](#) provides descriptions of each SQL statement, arranged in alphabetical order. [SPL statements on page 1081](#) describes each of the SPL statements, using the same format.

The major aids for entering SQL statements include:

- The combination of the syntax diagram and syntax table
- The examples of syntax that appear in the rules of usage
- The references to related information

## Using Syntax Diagrams and Syntax Tables

Before you try to use the syntax diagrams in this chapter, it is helpful to read the syntax diagram section of the Introduction. This section is the key to understanding the syntax diagrams and explains the elements that can appear in a syntax diagram and the paths that connect the elements to each other. This section also includes an example that illustrates the elements of typical syntax diagrams. The narrative that follows the example diagram shows how to read the diagram in order to enter the statement successfully.

Notes@ to the diagram can reference other syntax segments or can specify various restrictions. If you are using an application programming interface, such as ESQL/C, only the SQL syntax rules that both your client application and the database server support are valid.

When a syntax diagram includes input specifications that are not keywords, syntax segments, nor punctuation symbols, such as identifiers, expressions, filenames, or host variables, the syntax diagram is followed by a table that describes how to enter the term without generating errors. Each syntax table includes four columns:

- The **Element** column lists each variable term in the syntax diagram.
- The **Description** column briefly describes the term and identifies the default value, if the term has one.
- The **Restrictions** column summarizes the restrictions on the term, such as acceptable ranges of values. (For some diagrams, restrictions that cannot be tersely summarized appear in the **Usage** notes, rather than in this column.)
- The **Syntax** column points to the SQL segment that gives the detailed syntax for the term. For a few terms, such as the names of host variables, pathnames, or literal characters, no page reference is provided.

The diagrams generally provide an intuitive notation for what is valid in a given SQL statement, but for some statements, dependencies or restrictions among syntax elements are identified only in the text of the Usage section.

## Using Examples

To understand the main syntax diagram and subdiagrams for a statement, study the examples of syntax that appear in the rules of usage for each statement. These examples have two purposes:

- To show how to accomplish specific tasks with the statement or its clauses
- To show how to use syntax of the statement or its clauses in a concrete way

**Tip:** An efficient way to understand a syntax diagram is to find an example of the syntax and compare it with the keywords and parameters in the syntax diagram. By mapping the concrete elements of the example to the abstract elements of the syntax diagram, you can understand the syntax diagram and use it more effectively.

For an explanation of the conventions used in the examples in this publication, see the syntax diagram section of the Introduction.

These code examples are program fragments to illustrate valid syntax, rather than complete SQL programs. In some code examples, ellipsis ( . . . ) symbols indicate that additional code has been omitted. To save space, however, ellipses are not shown at the beginning or end of the program fragments.

## Using Related Information

For help in understanding concepts and terms in the SQL statement description, check the “Related Information” section at the end of each statement.

This section points to related information in this publication and other publications to help you understand the statement in question. The section provides some or all of the following information:

- The names of related statements that might contain a fuller discussion of topics in this statement
- The titles of other publications that provide extended discussions of topics in this statement

**Tip:** If you do not have extensive knowledge and experience with SQL, the *Informix® Guide to SQL: Tutorial* gives you the basic SQL knowledge that you need to understand and use the statement descriptions in this document.

## How to Enter SQL Comments

You can add comments to clarify the purpose or effect of particular SQL statements. You can also use comment symbols during program development to disable individual statements without deleting them from your source code.

Your comments can help you or others to understand the role of the statement within a program, SPL routine, or command file. The code examples in this document sometimes include comments that clarify the role of an SQL statement within the code, but your own SQL programs will be easier to read and to maintain if you document them with frequent comments.

The following table shows the SQL comment indicators that you can enter in your code. Here a *Y* in a column signifies that you can use the symbol with the product or with the type of database identified in the column heading. An *N* in a column signifies that you cannot use the symbol with the indicated product or with a database of the indicated ANSI-compliance status.

| <b>Comment Symbol</b>        | <b>ESQL/C</b> | <b>SPL Routine</b> | <b>DB-Access</b> | <b>ANSI-Compliant Databases</b> | <b>Databases Not ANSI Compliant</b> | <b>Description</b>   |
|------------------------------|---------------|--------------------|------------------|---------------------------------|-------------------------------------|--|
| double hyphen (--)           | Y             | Y                  | Y                | Y                               | Y                                   | The double hyphen precedes a comment within a single line. To comment more than one line, put double hyphen symbols at the beginning of each comment line.   |
| braces ( {... })             | N             | Y                  | Y                | Y                               | Y                                   | Braces enclose the comment. The { precedes the comment, and the } follows it. Braces can delimit single- or multiple-line comments, but comments cannot be nested.   |
| slash and asterisk /* ... */ | Y             | Y                  | Y                | Y                               | Y                                   | C-language style slash and asterisk ( /* */ ) paired delimiters enclose the comment. The /* precedes the comment, and the */ follows it. These can delimit single-line or multiple-line comments, but comments cannot be nested. |

Characters within the comment are ignored by the database server.

The section [Optimizer Directives on page 1472](#) describes a context where information within comments can influence query plans of Informix®.

If the product that you use supports all of these comment symbols, your choice of a comment symbol depends on requirements for ANSI/ISO compliance:

- Double hyphen ( -- ) complies with the ANSI/ISO standard for SQL.
- Braces ( { } ) are the Informix® extension to the ANSI/ISO standard.
- C-style slash-and-asterisk ( /\* ... \*/ ) comply with the SQL-99 standard.

If ANSI/ISO compliance is not an issue, your choice of comment symbols is a matter of personal preference.

In DB-Access, you can use any of these comment symbols when you enter SQL statements with the SQL editor and when you create SQL command files with the SQL editor or with a system editor.

An SQL command file is an operating-system file that contains one or more SQL statements. Command files are also known as command scripts. For more information about command files, see the discussion of command scripts in the *Informix® Guide to SQL: Tutorial*. For information on how to create and modify command files with the SQL editor or a system editor in DB-Access, see the *Informix® DB-Access User's Guide*.

You can use any of these comment symbols in any line of an SPL routine. See the discussion of how to comment and document an SPL routine in the *Informix® Guide to SQL: Tutorial*.

In Informix® ESQL/C, the double hyphen ( -- ) can begin a comment that extends to the end of the same line. For information on language-specific comment symbols in Informix® ESQL/C programs, see the *Informix® ESQL/C Programmer's Manual*.

## Examples of SQL Comments

These examples illustrate different ways to use the SQL comment indicators.

The following examples use each style of comment indicator, including the double hyphen ( -- ), braces ( { } ), and C-style ( /\* . . . \*/ ) comment delimiters to include a comment after an SQL statement. The comment appears on the same line as the statement.

```
SELECT * FROM customer; -- Selects all columns and rows

SELECT * FROM customer; {Selects all columns and rows}

SELECT * FROM customer; /*Selects all columns and rows*/
```

The next three examples use the same SQL statement and the same comments as in the preceding examples, but place the comment on a separate line:

```
SELECT * FROM customer;
  -- Selects all columns and rows

SELECT * FROM customer;
  {Selects all columns and rows}

SELECT * FROM customer;
  /*Selects all columns and rows*/
```

In the following examples, the user enters the same SQL statement as in the preceding example but now a multiple-line comment (or for the double-hyphen indicator, two comments) follows each statement:

```
SELECT * FROM customer;
  -- Selects all columns and rows
  -- from the customer table

SELECT * FROM customer;
  {Selects all columns and rows
  from the customer table}

SELECT * FROM customer;
```

```
/*Selects all columns and rows
from the customer table*/
```

Comments in any of these styles can also appear within an SQL statement:

```
SELECT *          -- Selects all columns and rows
FROM customer;  -- from the customer table

SELECT *          {Selects all columns and rows}
FROM customer;  {from the customer table}

SELECT *          /*Selects all columns and rows*/
FROM customer;  /*from the customer table*/
```

If you use braces or C-style comments that are delimited by paired opening and closing indicators, the closing comment indicator must be in the same style as the opening comment indicator.

## Non-ASCII Characters in SQL Comments

You can enter non-ASCII characters (including multibyte characters) in SQL comments if the database locale supports the non-ASCII characters. For further information on the GLS aspects of SQL comments, see the *Informix® GLS User's Guide*.

## Categories of SQL Statements

SQL statements are traditionally divided into the following logical categories:

### **Data definition statements**

These data definition language (DDL) statements can declare, rename, modify, or destroy objects in the local database.

### **Data manipulation statements**

These data manipulation language (DML) statements can retrieve, insert, delete, or modify data values.

### **Cursor manipulation statements**

These statements can declare, open, and close cursors, which are data structures for operations on multiple rows of data.

### **Dynamic management statements**

These statements support memory management and allow users to specify at runtime the details of DML operations.

### **Data access statements**

These statements specify discretionary access privileges and support concurrent access to the database by multiple users.

### **Data integrity statements**

These implement transaction logging and support the referential integrity of the database.

**Optimization statements**

These can be used to improve the performance of operations on the database.

**Routine definition statements**

These can declare, define, modify, execute, or destroy user-defined routines that the database stores.

**Client/server connection statements**

These can open or close a connection between a database and a client application.

**Auxiliary statements**

These can provide information about the database. (This is also a residual category for statements that are not closely related to the other statement categories.)

## Data Definition Language Statements

The data definition language (DDL) statements of SQL create, modify, rename, or destroy database objects, and make corresponding changes to rows in the system catalog tables of the database.

- ALTER ACCESS\_METHOD
- ALTER FRAGMENT
- ALTER FUNCTION
- ALTER INDEX
- ALTER PROCEDURE
- ALTER ROUTINE
- ALTER SECURITY LABEL COMPONENT
- ALTER SEQUENCE
- ALTER TABLE
- ALTER TRUSTED CONTEXT
- ALTER USER
- CLOSE DATABASE
- CREATE ACCESS\_METHOD
- CREATE AGGREGATE
- CREATE CAST
- CREATE DATABASE
- CREATE DEFAULT USER
- CREATE DISTINCT TYPE
- CREATE EXTERNAL TABLE
- CREATE FUNCTION
- CREATE FUNCTION FROM
- CREATE INDEX
- CREATE OPAQUE TYPE
- CREATE OPCLASS

- CREATE PROCEDURE
- CREATE PROCEDURE FROM
- CREATE ROLE
- CREATE ROUTINE FROM
- CREATE ROW TYPE
- CREATE SCHEMA
- CREATE SECURITY LABEL
- CREATE SECURITY LABEL COMPONENT
- CREATE SECURITY POLICY
- CREATE SEQUENCE
- CREATE SYNONYM
- CREATE TABLE
- CREATE TEMP TABLE
- CREATE TRIGGER
- CREATE TRUSTED CONTEXT
- CREATE USER
- CREATE VIEW
- CREATE XADATASOURCE
- CREATE XADATASOURCE TYPE
- DROP ACCESS\_METHOD

- DROP TRIGGER
- DROP TRUSTED CONTEXT
- DROP TYPE
- DROP USER
- DROP VIEW
- DROP XADATASOURCE
- DROP XADATASOURCE TYPE
- RENAME COLUMN

- RENAME DATABASE
- RENAME INDEX
- RENAME SECURITY
- RENAME SEQUENCE
- RENAME TABLE
- RENAME TRUSTED CONTEXT
- RENAME USER
- TRUNCATE
- UPDATE STATISTICS

## Data Manipulation Language Statements

- DELETE
- INSERT
- LOAD
- MERGE
- SELECT
- UNLOAD
- UPDATE

**Note:** DELETE, INSERT, MERGE, SELECT, and UPDATE are DML statements in the ANSI/ISO standard for SQL, where MERGE can emulate INSERT and DELETE or UPDATE. Although LOAD and UNLOAD resemble DML in their functionality, these DB-Access macros are out-of-scope for most references in this document to "DML statements."

## Data Integrity Statements

- BEGIN WORK
- COMMIT WORK
- SAVEPOINT
- RELEASE SAVEPOINT
- ROLLBACK WORK
- SET Database Object Mode
- SET LOG
- SET Transaction Mode
- START VIOLATIONS TABLE
- STOP VIOLATIONS TABLE

## Cursor Manipulation Statements

- CLOSE
- DECLARE
- FETCH
- FLUSH
- FREE
- OPEN
- PUT
- SET AUTOFREE

## Dynamic Management Statements

- ALLOCATE COLLECTION
- ALLOCATE DESCRIPTOR
- ALLOCATE ROW
- DEALLOCATE COLLECTION
- DEALLOCATE DESCRIPTOR
- DEALLOCATE ROW
- DESCRIBE
- DESCRIBE INPUT
- EXECUTE
- EXECUTE IMMEDIATE
- FREE
- GET DESCRIPTOR
- INFO
- PREPARE
- SET DEFERRED\_PREPARE
- SET DESCRIPTOR

## Data Access Statements

- GRANT
- GRANT FRAGMENT
- LOCK TABLE
- REVOKE
- REVOKE FRAGMENT

- SET SESSION AUTHORIZATION
- SET TRANSACTION
- SET Transaction Mode
- UNLOCK TABLE

## Optimization Statements

- SAVE EXTERNAL DIRECTIVES
- SET ENVIRONMENT
- SET EXPLAIN
- SET OPTIMIZATION
- SET PDQPRIORITY
- SET STATEMENT CACHE

## Routine Definition Statements

- ALTER FUNCTION
- ALTER PROCEDURE
- ALTER ROUTINE
- CREATE FUNCTION
- CREATE FUNCTION FROM
- CREATE PROCEDURE
- CREATE PROCEDURE FROM
- CREATE ROUTINE FROM
- DROP FUNCTION
- DROP PROCEDURE
- DROP ROUTINE
- EXECUTE FUNCTION
- EXECUTE PROCEDURE
- SET DEBUG FILE TO

## Auxiliary Statements

- GET DIAGNOSTICS
- INFO
- OUTPUT
- SET COLLATION
- SET DATASKIP
- SET ENCRYPTION PASSWORD
- SET USER PASSWORD
- WHENEVER

## Client/Server Connection Statements

- CONNECT
- DATABASE
- DISCONNECT
- SET CONNECTION

## ANSI/ISO Compliance and Extensions

Lists that follow show statements that match the ANSI SQL-92 standard at the entry level, statements that are ANSI compliant but include Informix® extensions, and statements that are Informix® extensions to the ANSI/ISO standard.

## ANSI/ISO-Compliant Statements

- CLOSE
- COMMIT WORK
- RELEASE SAVEPOINT
- SET CONSTRAINTS (See [SET Transaction Mode statement on page 1007](#))
- SET SESSION AUTHORIZATION
- SET TRANSACTION

## ANSI/ISO-Compliant Statements with Informix® Extensions

- ALLOCATE DESCRIPTOR
- ALTER TABLE
- CONNECT
- CREATE FUNCTION
- CREATE PROCEDURE
- CREATE TRIGGER
- CREATE SCHEMA
- CREATE TABLE
- CREATE TEMP TABLE
- CREATE VIEW
- DEALLOCATE DESCRIPTOR
- DECLARE
- DELETE
- DESCRIBE
- DESCRIBE INPUT
- DISCONNECT
- EXECUTE

- EXECUTE IMMEDIATE

- SET COLLATION
- SET CONSTRAINTS (See [SET Database Object Mode statement on page 871.](#))
- SET Database Object Mode
- SET DATASKIP
- SET DEBUG FILE TO
- SET DEFERRED\_PREPARE
- SET ENCRYPTION PASSWORD
- SET ENVIRONMENT
- SET EXPLAIN
- SET INDEXES (See [SET Database Object Mode statement on page 871.](#))
- SET ISOLATION
- SET LOCK MODE
- SET LOG

- SET OPTIMIZATION
- SET PDQPRIORITY
- SET ROLE
- SET STATEMENT CACHE
- SET TRIGGERS (See [SET Database Object Mode statement on page 871.](#))
- SET USER PASSWORD
- START VIOLATIONS TABLE
- STOP VIOLATIONS TABLE
- TRUNCATE
- UNLOAD
- UNLOCK TABLE
- UPDATE STATISTICS

## SQL statements

This chapter describes the syntax and semantics of SQL statements that are recognized by Informix®.

The SQL statement names that appear as the title to each statement description in this chapter are listed in alphabetical order.

For some statements, important details of the semantics appear in other volumes of this documentation set, as indicated by cross-references.

For many statements, the syntax diagram, or the table of terms immediately following the diagram, or both, includes references to syntax segments in [Data types and expressions on page 1139](#) or in [Other syntax segments on page 1433](#).

When the name of an SQL statement includes lowercase characters, such as SET Database Object Mode, it means that the first mixed-lettercase string in the statement name is not an SQL keyword, but that two or more different SQL keywords can follow the preceding uppercase keyword.

For an explanation of the structure of statement descriptions, see [Overview of SQL syntax on page 1](#).

## ALLOCATE COLLECTION statement

Use the ALLOCATE COLLECTION statement to allocate memory for a variable of a collection data type (such as LIST, MULTiset, or SET) or for an untyped collection variable.

### Syntax

**ALLOCATE COLLECTION***variable*

| Element         | Description  | Restrictions  | Syntax                            |
|-----------------|--|---|-----------------------------------|
| <i>variable</i> | Name of the typed or untyped collection variable to allocate | Must be an unallocated Informix® ESQL/C collection-type host variable | Language-specific rules for names |

## Usage

This statement is an extension to the ANSI/ISO standard for SQL. Use this statement with ESQL/C.

The ALLOCATE COLLECTION statement allocates memory for an ESQL/C variable that can store the value of a collection data type.

To create a collection variable for Informix® ESQL/C programs:

1. Declare the collection variable as a client collection variable in the Informix® ESQL/C program.  
The collection variable can be a typed or untyped collection variable.
2. Allocate memory for the collection variable with the ALLOCATE COLLECTION statement.

The ALLOCATE COLLECTION statement sets **SQLCODE** (that is, **sqlca.sqlcode**) to zero (0) if the memory allocation was successful, or to a negative error code if the allocation failed.

When you no longer need the collection variable, you must explicitly release the memory that it occupies with the DEALLOCATE COLLECTION statement. After the DEALLOCATE COLLECTION statement executes successfully, you can reuse the collection variable.

**Tip:** The ALLOCATE COLLECTION statement allocates memory for Informix® ESQL/C collection variables only. To allocate memory for Informix® ESQL/C row variables, use the ALLOCATE ROW statement.

## Examples

The following example shows how to allocate resources with the ALLOCATE COLLECTION statement for the untyped collection variable, **a\_set**:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection a_set;
EXEC SQL END DECLARE SECTION;
. . .
EXEC SQL allocate collection :a_set;
```

The following example uses ALLOCATE COLLECTION to allocate resources for a typed collection variable, **a\_typed\_set**:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection set(integer not null) a_typed_set;
EXEC SQL END DECLARE SECTION;
. . .
EXEC SQL allocate collection :a_typed_set;
```

---

[Inserting into a Collection Cursor on page 705](#)

## ALLOCATE DESCRIPTOR statement

Use the ALLOCATE DESCRIPTOR statement to declare the name and allocate memory for a system-descriptor area (SDA). Use this statement with ESQL/C.

### Syntax

#### ALLOCATE DESCRIPTOR

*'descriptor' descriptor\_var*

#### WITH MAX

*items items\_var*

| Element               | Description   | Restrictions   | Syntax                                      |
|-----------------------|---|--|---|
| <i>descriptor</i>     | Name that you declare here for an unallocated system-descriptor area    | Enclose in single ( ' ) quotation marks.<br>Must be unique among SDA names | <a href="#">Quoted String on page 1424.</a> |
| <i>descriptor_var</i> | Host variable that stores the name of a system-descriptor area          | Must contain name of unallocated system-descriptor area                    | Language specific                           |
| <i>items</i>          | Number of item descriptors in <i>descriptor</i> . Default value is 100. | Must be an unsigned INTEGER greater than zero                              | <a href="#">Literal Number on page 1419</a> |
| <i>items_var</i>      | Host variable that contains the number of items                         | Data type must be INTEGER or SMALLINT                                      | Language specific                           |

### Usage

The ALLOCATE DESCRIPTOR statement creates a new *system-descriptor area*, which is a location in memory that holds information that the DESCRIBE statement can display, or that holds information about the WHERE clause of a query.

A system-descriptor area (SDA) contains one or more fields called *item descriptors*. Each item descriptor holds a data value that the database server can receive or send. The item descriptors also contain information about the data, such as data type, length, scale, precision, and support for NULL values.

A system-descriptor area holds information that a DESCRIBE ... USING SQL DESCRIPTOR statement obtains or that holds information about the WHERE clause of a dynamically executed query.

If the name that ALLOCATE DESCRIPTOR declares for a system-descriptor area matches the name of an existing system-descriptor area, the database server returns an error. After you free the specified descriptor with the DEALLOCATE DESCRIPTOR statement, however, the ALLOCATE DESCRIPTOR statement can reuse the same descriptor name.

## WITH MAX Clause

You can use the WITH MAX clause to indicate the maximum number of item descriptors that the new system-descriptor area can include.

When you use this clause, the COUNT field value of the system-descriptor area is set to the number of *items* that you specify here. If you do not specify the WITH MAX clause, the default value of the COUNT field is 100 items. You can use the SET DESCRIPTOR statement to change the value of the COUNT field.

### Examples of ALLOCATE DESCRIPTOR statements

The following examples show valid ALLOCATE DESCRIPTOR statements that include the WITH MAX clause. This example uses embedded variable names to identify the system-descriptor area and to specify the maximum number of item descriptors:

```
EXEC SQL allocate descriptor :descname with max :occ;
```

The next example uses a quoted string to declare desc1 as the identifier of the system-descriptor area, and uses an unsigned integer to specify 3 as the maximum number of item descriptors in the desc1 area:

```
EXEC SQL allocate descriptor 'desc1' with max 3;
```

## ALLOCATE ROW statement

Use the ALLOCATE ROW statement to allocate memory for a *row* variable. This statement is an extension to the ANSI/ISO standard for SQL. Use this statement with ESQL/C.

### Syntax

**ALLOCATE ROW***variable*

| Element         | Description  | Restrictions   | Syntax            |
|-----------------|--|--|-------------------|
| <i>variable</i> | Name of a typed or untyped <i>row</i> variable to allocate | Must be an unallocated Informix® ESQL/C row-type host variable | Language specific |

## Usage

The ALLOCATE ROW statement allocates memory for a host variable that stores row-type data. To create a **row** variable, an ESQL/C program must do the following:

1. Declare the *row* variable. The row variable can be a typed or untyped *row* variable.
2. Allocate memory for the *row* variable with the ALLOCATE ROW statement.

The following example shows how to allocate resources with the ALLOCATE ROW statement for the typed *row* variable,

`a_row`:

```
EXEC SQL BEGIN DECLARE SECTION;
    row (a int, b int) a_row;
EXEC SQL END DECLARE SECTION;
. . .
EXEC SQL allocate row :a_row;
```

The ALLOCATE ROW statement sets **SQLCODE** (the contents of `sqlca.sqlcode`) to zero (0) if the memory allocation operation was successful, or to a negative error code if the allocation failed.

You must explicitly release memory with the DEALLOCATE ROW statement. Once you free the *row* variable with the DEALLOCATE ROW statement, you can reuse the *row* variable.

**Tip:** The ALLOCATE ROW statement allocates memory for the Informix® ESQL/C *row* variable only. To allocate memory for the Informix® ESQL/C *collection* variable, use the ALLOCATE COLLECTION statement.

When you use the same *row* variable in multiple function calls without deallocating it, a memory leak on the client computer results. Because there is no way to determine if a pointer is valid when it is passed, Informix® ESQL/C assumes that the pointer is not valid and assigns it to a new memory location.

## ALTER ACCESS\_METHOD statement

Use the ALTER ACCESS\_METHOD statement to change one or more attributes of a user-defined primary or secondary access method in the **sysams** system catalog table.

## Syntax

### ALTER ACCESS\_METHOD

*owner* .

*access\_method*

,

### MODIFY ADD

Purpose Option<sup>1</sup>

**DROP** *purpose\_keyword*

| Element                | Description  | Restrictions  | Syntax  |
|------------------------|--|---|---|
| <i>access_method</i>   | Name of the access method to modify                | Access method must be registered in the <b>sysams</b> system catalog table by a previous CREATE ACCESS_METHOD statement | <a href="#">Identifier on page 1456</a>                           |
| <i>owner</i>           | Name of the owner of the access method             | Must own the access method  | <a href="#">Owner name on page 1488</a>                           |
| <i>purpose_keyword</i> | A keyword that indicates which attribute to change | Keyword must be associated with the access method by a previous CREATE or ALTER ACCESS_METHOD statement                 | <a href="#">Purpose Functions, Flags, and Values on page 1495</a> |

## Usage

This statement is an extension to the ANSI/ISO standard for SQL. This statement cannot modify a built-in access method.

Use ALTER ACCESS\_METHOD to modify the definition of a user-defined access method. You cannot modify a built-in access method.

You must own the access method or hold the DBA privilege to alter a user-defined access method. In an ANSI-compliant database, the DBA must qualify the name of the access method with the *owner* name if another user is the owner of the access method.

When you alter an access method, you change the purpose-option specifications (purpose functions, purpose methods, purpose flags, or purpose values) that define the access method. For example, you might alter an access method to declare a new user-defined function or method name, or to provide a multiplier for the scan cost on a table.

If a transaction is in progress, the database server waits to modify the access method until after the transaction is committed or rolled back. No other users can execute the access method until the transaction has completed.

## Examples

The following statement alters the **remote** user-defined access method:

```
ALTER ACCESS_METHOD remote
  ADD am_scancost = FS_scancost,
  ADD am_rowids,
  DROP am_getbyid,
  MODIFY am_costfactor = 0.9;
```

1. See [Purpose Options on page 1493](#)

The preceding example makes the following changes to the access method:

- Adds a user-defined function or method named **FS\_scancost( )**, which is associated in the **sysams** table with the **am\_scancost** keyword
- Sets (adds) the **am\_rowids** flag
- Drops the user-defined function or method associated with the **am\_getbyid** keyword
- Modifies the **am\_costfactor** value

## ALTER FRAGMENT statement

Use the ALTER FRAGMENT statement to change the distribution strategy or the storage location of an existing table or index. This statement is an extension to the ANSI/ISO standard for the SQL language.

**Syntax****ALTER FRAGMENT**<sup>8</sup>**ONLINE****ON TABLE***surviving\_table*ATTACH Clause<sup>2</sup>DETACH Clause<sup>3</sup>INIT Clause<sup>4</sup>ADD Clause<sup>5</sup>DROP Clause<sup>6</sup>MODIFY Clause<sup>7</sup>**ON INDEX***surviving\_index*INIT Clause<sup>4</sup>ADD Clause<sup>5</sup>DROP Clause<sup>6</sup>MODIFY Clause<sup>7</sup>

| Element                | Description  | Restrictions  | Syntax                                  |
|------------------------|--|---|---|
| <i>surviving_index</i> | Index on which to modify the distribution or storage | Must exist when the statement executes  | <a href="#">Identifier on page 1456</a> |
| <i>surviving_table</i> | Table on which to modify the distribution or storage | Must exist. See <a href="#">Restrictions on the ALTER FRAGMENT Statement on page 25</a> . | <a href="#">Identifier on page 1456</a> |

**Usage**

The ALTER FRAGMENT statement applies only to table fragments or index fragments that are located at the current site. No remote information is accessed or updated.

You must have the Alter privilege or the DBA privilege to change the fragmentation strategy of a table. You must have the Index privilege or the DBA privilege to alter the fragmentation strategy of an index.

**Attention:** This statement can cause indexes to be dropped and rebuilt. Before undertaking alter operations, check corresponding sections in your *Informix® Performance Guide* to review effects and strategies.

Clauses of the ALTER FRAGMENT statement support the following tasks.

**Clause**

2. See [ATTACH Clause on page 27](#)
3. See [DETACH Clause on page 36](#)
4. See [INIT Clause on page 40](#)
5. See [ADD Clause on page 47](#)
6. See [DROP Clause on page 51](#)
7. See [MODIFY Clause on page 53](#)
8. Only with ATTACH, DETACH, or MODIFY on tables fragmented by interval

**Effect**

**ATTACH**

Combines two or more tables that have the same schema into a single fragmented table

**DETACH**

Detaches one fragment from a fragmented table, and creates a new nonfragmented table to store the rows in the fragment.

**INIT**

Provides the following options:

- Defines and initializes a fragmentation strategy on a nonfragmented table
- Changes the order of evaluation of fragment expressions
- Changes the fragmentation strategy of a fragmented table or index
- Changes the storage location of an existing table
- Moves data from an existing table fragment into a new nonfragmented table
- Changes the storage location of fragments that the database generates for a table or index
- Changes the fragmentation key or fragmentation expression for a table or index

**ADD**

Adds an additional fragment to an existing fragmentation list

**DROP**

Drops an existing fragment from a fragmentation list

Remove one or more dbspaces from the list of dbspaces where interval fragments are created.

**MODIFY**

Changes an existing interval, list, or expression-based fragmentation expression

Moves an existing fragment to a different dbspace

Replaces with a new list the current list of dbspaces where interval fragments are created.

Enables or disables automatic creation of interval fragments

Use the CREATE TABLE statement or the INIT clause of the ALTER FRAGMENT statement to create fragmented tables.

After a dbspace has been renamed successfully by the **onspaces** utility, only the new name can reference the renamed dbspace. The database server automatically updates existing fragmentation strategies for tables or indexes in the system catalog, however, to replace the old dbspace name with the new name. You do not need to take any additional action to update a distribution strategy or storage location that was defined using the old dbspace name, but you must use the new name if you reference the dbspace in an ALTER FRAGMENT or ALTER TABLE statement.

If you omit the optional ONLINE keyword, the ALTER FRAGMENT operation requires exclusive access and exclusive locks on all of the tables involved in the operation. If you enable the FORCE\_DDL\_EXEC session environment option, you can

force out other transactions that have opened a table involved in an ALTER FRAGMENT ON TABLE operation, or that have placed locks on any of those tables. If the server is unable to get exclusive access and exclusive locks on the table, the server starts rolling back the transactions that are open or that have locks on the table, until the value specified with the FORCE\_DDL\_EXEC option is reached. (For more information, see [FORCE\\_DDL\\_EXEC session environment option on page 921](#).)

---

[CREATE INDEX statement on page 253](#)

[ALTER TABLE statement on page 99](#)

## Restrictions on the ALTER FRAGMENT Statement

You cannot use the ALTER FRAGMENT statement on a view, on a temporary table, or on a table that is not registered in the current database.

If your table or index is not already fragmented, the only clauses available to you are ATTACH and INIT.

You cannot use ALTER FRAGMENT on a typed table that is part of a table hierarchy.

## ALTER FRAGMENT and Transaction Logging

If your database supports transaction logging, ALTER FRAGMENT is executed within a single transaction. If the fragmentation strategy uses large numbers of records, you might run out of log space or disk space. (To alter a fragmentation strategy, the database server requires extra disk space that it later frees.)

If you run out of log space or disk space, try one of the following procedures to reduce your log-space or disk-space requirements:

- Turn off logging and turn it back on again at the end of the operation. This procedure indirectly requires a backup of the **root** dbspace.
- Split the operations into multiple ALTER FRAGMENT statements, moving a smaller portion of records each time.

For information about log-space requirements and disk-space requirements, see your *Informix® Administrator's Guide*. That guide also contains detailed instructions about how to turn off logging. For information about backups, refer to your *Informix® Backup and Restore Guide*.

---

## Determining the Number of Rows in the Fragment

### About this task

You can place as many rows into a fragment as the available space in the dbspace allows.

To find out how many rows are in a fragment:

1. Run the UPDATE STATISTICS FORCED statement on the table. This step fills the **sysfragments** system catalog table with the current table information.
2. Query the **sysfragments** system catalog table to examine the **npused** and **nrows** values. The **npused** column shows the number of data pages used in the fragment, and the **nrows** column shows the number of rows in the fragment.

## The ONLINE keyword in ALTER FRAGMENT operations

The ONLINE keyword instructs the database server to modify the storage of the table in the background, while other concurrent users can continue to access the table.

The DBA can reduce the risk of nonexclusive access errors, and can increase the availability of the fragmented table, by including the ONLINE keyword in the ALTER FRAGMENT statement. This instructs the database server to commit the work in ATTACH, DETACH, and MODIFY operations internally, if there are no errors, and to apply an intent exclusive lock to the table, rather than an exclusive lock.

In DETACH and MODIFY operations, the ONLINE keyword can reduce the risk of -710 errors when either of the following is true:

- the AUTO\_REPREPARE configuration parameter is set to `1`,
- the IFX\_AUTO\_REPREPARE session environment variable is set to `1`.

The following restrictions apply to the ALTER FRAGMENT ONLINE FOR TABLE statement:

- Only the ATTACH, DETACH, and MODIFY options to ALTER FRAGMENT ONLINE are valid.
- The FOR TABLE clause must specify a table that is fragmented by a range interval scheme.
- The table that is being altered cannot be locked explicitly by the LOCK TABLE statement.
- The ALTER FRAGMENT ONLINE operation must be the first statement in the transaction that modifies any database object or table.
- No other operation that modifies an object in the database can follow the ALTER FRAGMENT ONLINE statement in the same transaction.

For additional information, see the following topics:

- [Using the ONLINE keyword in ATTACH operations on page 31](#)
- [Using the ONLINE keyword in DETACH operations on page 38](#)
- [Using the ONLINE keyword in MODIFY operations on page 68](#)

## Automatic renaming of interval fragment identifiers

Some ALTER FRAGMENT operations can change the positional order of existing interval fragments within the fragment list. In these cases, the database server automatically updates the system-defined names of the affected interval fragments.

For tables partitioned by an interval fragmentation scheme, ALTER FRAGMENT operations that add, drop, attach, or detach fragments, or that modify the transition value of the table, can change the **sysfragments.evalpos** values for existing interval fragments, or can change an interval fragment to a range fragment. To avoid creating new interval fragments with the same system-generated name as an interval fragment that the ALTER FRAGMENT statement has repositioned within the fragment list, the database server automatically replaces the original system-defined names with new identifiers that will not match the names of subsequently created interval fragments of the same table.

The general rules used for system generated range and interval fragment names are as follows:

- For interval fragments: `sys_evalpos`
- For range fragments: `sys_evalposrg`

Here `evalpos` is the numeric (ordinal) value of **sysfragments.evalpos**, where `0` is the `evalpos` value for the first fragment in the fragment list.

During a fragment renaming operation, an exclusive lock is placed on the fragment while the **sysfragments** system catalog is being updated with the new **partition** names, and with new **evalpos** values for any fragments whose ordinal positions within the fragment list changed during the ALTER FRAGMENT operation.

To avoid declaring non-unique fragment names when new interval fragments are created, the database server renames only system-generated identifiers of interval fragment that are repositioned during ALTER FRAGMENT operations. Automatic renaming does not occur for user-defined identifiers of repositioned fragments.

If you wish to avoid having existing fragments automatically renamed during ALTER FRAGMENT ONLINE ATTACH statements, or during other ALTER FRAGMENT operations on tables that use interval partitioning, you can first use the ALTER FRAGMENT MODIFY statement to rename with user-defined names the interval fragments whose system-generated names might otherwise be changed by the ALTER FRAGMENT operation. User-defined fragment names cannot begin with the string `sys_`.

## ATTACH Clause

Use the ATTACH clause of the ALTER FRAGMENT ON TABLE statement to combine tables that have identical structures into a table with the same fragmentation strategy.

You can use this syntax, for example, to combine a fragment that has been detached from a table with an archival table that has the same distributed storage scheme.

ATTACH Clause

**ATTACH**

,  
<sup>9</sup>*surviving\_table*  
*consumed\_table*

AS Clause

AS Clause

**VALUES** < *range\_expr*<sup>9</sup>**VALUES IS NULL**

List Expression

**VALUES**

(  
, *const\_expr*  
)

<sup>9</sup>**IS NULL**

| Element               | Description  | Restrictions  | Syntax  |
|-----------------------|--|---|---|
| <i>const_expr</i>     | Constant expression that defines the list of values for a fragment to store                  | Must be a quoted string or a literal value. Each value in the list must be unique among the lists for fragments of the same object.   | <a href="#">Constant Expressions on page 1235</a> |
| <i>consumed_table</i> | Table that loses its identity, to be merged with <i>surviving_table</i>                      | Schema must match that of <i>surviving_table</i> . Cannot include serial columns, nor unique, referential, or primary key constraints. See also <a href="#">General Restrictions for the ATTACH Clause on page 29</a> . | <a href="#">Identifier on page 1456</a>           |
| <i>expr</i>           | Expression defining which rows are stored in a fragment of a table partitioned by expression | Can include only columns from the current table and only data values from a single row. See also  | <a href="#">Condition on page 1144</a> ;          |

9. Use path no more than once

10. Required if another *surviving\_table* fragment has the same name as *dbspace*

11. Required for fragmentation by expression; optional for round-robin and list fragmentation; not valid for range interval fragmentation

| Element                | Description   | Restrictions  | Syntax  |
|------------------------|---|---|---|
|                        |   | <a href="#">General Restrictions for the ATTACH Clause on page 29.</a>  | <a href="#">Expression on page 1193</a>           |
| <i>new_frag</i>        | Name declared here for a <i>consumed_table</i> fragment. Default is the dbspace name.           | Must be unique among the names of fragments of <i>surviving_table</i>   | <a href="#">Identifier on page 1456</a>           |
| <i>old_frag</i>        | Fragment or dbspace name for a <i>surviving_table</i> fragment                                  | Must exist. Cannot be a range or interval fragment.   | <a href="#">Identifier on page 1456</a>           |
| <i>range_expr</i>      | Constant expression that defines the upper bound for fragment key values stored in the fragment | Must be a constant literal expression that evaluates to a numeric, DATETIME, or DATE data type compatible with the data type of the fragment key expression | <a href="#">Constant Expressions on page 1235</a> |
| <i>surviving_table</i> | Table on which to modify the distribution or storage location                                   | Must exist. Cannot have any constraints. See also <a href="#">Restrictions on the ALTER FRAGMENT Statement on page 25.</a>                                  | <a href="#">Identifier on page 1456</a>           |

When a new expression fragment is attached to table that is fragmented by list or by range interval, the data from the consumed table and the affected fragments in the surviving table are scanned and moved into appropriate partitions, because these strategies are not overlapping.

If the automatic mode for updating distribution statistics is enabled, and the table being attached to has fragmented distribution statistics, the database server calculates the distribution statistics of the new fragment. Stale distribution statistics of existing fragments are also recalculated at this point. This recalculation of fragment statistics runs in the background. After the database server has calculated the fragment statistics, it merges them to form table distribution statistics, and stores the results in the system catalog.

To use this clause, you must have the DBA privilege or else be the owner of the specified tables. The ATTACH clause supports the following tasks:

- Creates a single fragmented table by combining two or more identically-structured, nonfragmented tables  
(See [Combining Nonfragmented Tables to Create a Fragmented Table on page 31.](#))
- Attaches one or more tables to a fragmented table  
(See [Attaching a Table to a Fragmented Table on page 31.](#))

## General Restrictions for the ATTACH Clause

This clause is not valid in ALTER FRAGMENT ON INDEX statements.

Any tables that you attach must have been created previously in separate partitions. You cannot attach the same table more than once.

All consumed tables listed in the ATTACH clause must have the same structure as the surviving table. The number, names, data types, and relative position of the columns must be identical.

The *expression* cannot include aggregates, subqueries, or variant functions.

## Additional Restrictions on the ATTACH Clause

User-defined routines and references to fields of a ROW-type column are not valid. You cannot attach a fragmented table to another fragmented table.

All of the dbspaces that store the fragments must have the same page size.

An ATTACH operation on two nonfragmented tables cannot produce a surviving table that is fragmented by interval or by list. (If you want to attach two nonfragmented tables, use the INIT option of ALTER FRAGMENT to define an interval or list fragmentation scheme for one of the nonfragmented tables, and then use the ATTACH option to attach the second table to it.)

For surviving tables that are fragmented by interval, the following restrictions apply:

- Because the database server determines the ordinal position of interval fragments, BEFORE and AFTER specifications are not valid.
- You cannot attach a fragment whose expression matches an existing interval fragment expression.
- While you attach fragments above the transition value, the upper limit of the fragment being attached must align at an interval fragment boundary. That is, the upper limit of the fragment must equal the transition value plus an integer multiple of the interval value.

For fragmented tables that are protected by a security policy, attaching a fragment to the table fails if any of the following conditions are not satisfied:

- The source table and the target table are both protected by the same security policy;
- Both tables have the same protection granularity (either row-level, or column-level, or both row-level and column-level);
- In both tables, the same set of protected columns is protected by the same security labels. If there is more than one protected column, there can be more than one security label in each table, but the same label must protect the same column in both tables.

If the ATTACH operation fails because one or more of these conditions are not satisfied, you can use the ALTER TABLE statement to make the schemas of the two tables identical, and then repeat the ALTER FRAGMENT ATTACH statement on the modified tables

Only a user who holds the DBSECADM role can reference a protected table in the ALTER FRAGMENT statement.

## Using the BEFORE, AFTER, and REMAINDER options

The BEFORE and AFTER options allow you to place a new fragment either before or after an existing fragment. You cannot use the BEFORE and AFTER options when the distribution scheme is round-robin or range interval..

When you attach a new list or expression fragment without specifying an explicit BEFORE or AFTER keyword option, the database server places the added fragment at the end of the fragment list, unless a remainder fragment exists. If a

remainder fragment exists, the new fragment, by default, is placed just before the remainder fragment. You cannot attach a new fragment after the remainder fragment.

You cannot define a remainder fragment when the distribution scheme is round-robin or range interval.

If you omit the AS PARTITION *fragment* specification, the default name of the fragment is the name of the dbspace where it is stored. If another fragment of the same table already has the same name as the dbspace, the database server issues an exception, and the ALTER FRAGMENT ATTACH operation fails.

## Combining Nonfragmented Tables to Create a Fragmented Table

When you transform tables with identical table structures into fragments into a single table, you allow the database server to manage the fragmentation instead of allowing the application to manage the fragmentation. The distribution scheme can be round-robin or expression based.

To make a single, fragmented table from two or more identically-structured, nonfragmented tables, the ATTACH clause must include the surviving table in the *attach list*. The attach list is the specified list of tables in the ATTACH clause.

To include a **rowid** column in the newly-created single, fragmented table, attach all tables first and then add the **rowid** with the ALTER TABLE statement.

## Attaching a Table to a Fragmented Table

### About this task

To attach a nonfragmented table to an already fragmented table, the nonfragmented table must have been created in a separate dbspace and must have the same table structure as the fragmented table. In the following example, a round-robin distribution scheme fragments the table **cur\_acct**, and the table **old\_acct** is a nonfragmented table that resides in a separate dbspace. The following example shows how to attach (as the consumed table) **old\_acct** to **cur\_acct** (as the surviving table):

```
ALTER FRAGMENT ON TABLE cur_acct ATTACH old_acct;
```

When you attach one or more tables to a fragmented table, a *consumed\_table* must be nonfragmented.

## Using the ONLINE keyword in ATTACH operations

The ONLINE keyword instructs the database server to commit the ALTER FRAGMENT ATTACH work internally, if there are no errors, and to apply an intent exclusive lock to the surviving table, rather than an exclusive lock. An exclusive lock is applied to the consumed table, which must be a nonfragmented table.

### Requirements for ONLINE ATTACH operations

You can use the ATTACH option to the ALTER FRAGMENT ONLINE ON TABLE statement only if the *surviving table* is fragmented by an interval fragmentation scheme. The consumed table must be nonfragmented.

All indexes on the surviving table must have the same fragmentation scheme as the table. (That is, any indexes must be attached.) For this reason, if there is a primary key constraint or other referential constraints on the table, it is recommended

that you first create an attached index for the constraint, and then use the ALTER TABLE statement to add the constraint. (By default, system-created indexes for primary key constraints and for other referential constraints are detached.)

For each index on the surviving table, there must be a matching index on the same set of columns of the consumed table. The matching indexes on the consumed table will be recycled as index fragments on the surviving table during the ATTACH operation. Any additional indexes on the consumed table are dropped during the ATTACH operation. The indexes on the consumed table that will be recycled must each be detached in a single dbspace, and the dbspace that stores the recycled index must be same dbspace that stores the consumed table.

If the index on the surviving table is unique, the corresponding matching index on the consumed table must also be unique.

The consumed table must have a check constraint that satisfies the following two conditions:

- It must exactly match the expression for the fragment that is being attached.
- It must span a single interval only.

This last requirement, that rows in the consumed table span only a single interval within the range interval fragmentation scheme of the surviving table, is necessary to prevent data movement. Data movement is not allowed in ALTER FRAGMENT ATTACH operations that include the ONLINE keyword.

Only one consumed table can be specified in the ONLINE ATTACH operation.

All other restrictions that apply to the ATTACH option also apply to ONLINE ATTACH operations. For those restrictions, see [General Restrictions for the ATTACH Clause on page 29](#) and [Additional Restrictions on the ATTACH Clause on page 30](#).

### Example of ALTER FRAGMENT ONLINE ATTACH

The following SQL statements define a fragmented **employee** table that uses a range-interval storage distribution scheme, with a unique index **employee\_id\_idx** on the column **emp\_id** (that is also the fragmentation key) and another index **employee\_dept\_idx** on the column **dept\_id**.

```
CREATE TABLE employee
  (emp_id INTEGER, name CHAR(32),
   dept_id CHAR(2), mgr_id INTEGER, ssn CHAR(12))
FRAGMENT BY RANGE (emp_id)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3, dbs4)
  PARTITION p0 VALUES < 200 IN dbs1,
  PARTITION p1 VALUES < 400 IN dbs2;
CREATE UNIQUE INDEX employee_id_idx ON employee(emp_id);
CREATE INDEX employee_dept_idx ON employee(dept_id);
```

The last two statements insert rows with fragment key values above the upper limit of the transition fragment, causing the database server to generate two new interval fragments, so that the resulting fragment list consists of four fragments:

```
Fragments in surviving table before ALTER FRAGMENT ONLINE:
p0    VALUES < 200                - range fragment
p1    VALUES < 400                - range fragment (transition fragment)
sys_p2 VALUES >= 400 AND VALUES < 500 - interval fragment
sys_p4 VALUES >= 600 AND VALUES < 700 - interval fragment
```

The next SQL statements define a nonfragmented **employee2** table with the same column schema as the **employee** table, and with single-column indexes on the two corresponding columns (**emp\_id** and **dept\_id**) that were indexed in the **employee**

table, but also defines a unique index **employee2\_ssn\_idx** on the column **emp\_ssn** and another index **employee\_dept\_idx** on the column **name**. All four of these indexes are stored in the dbspace **db4**. The CREATE TABLE statement also specifies a check constraint (`(emp_id >=500 AND emp_id <600)`) that exactly matches the fragment expression for a consumed table that will be attached, and that exactly spans a single interval of the range interval fragmentation scheme for the **employee** table.

```
CREATE TABLE employee2
  (emp_id INTEGER, name CHAR(32),
   dept_id CHAR(2), mgr_id INTEGER, ssn CHAR(12),
   CHECK (emp_id >=500 AND emp_id <600)) in db4;
CREATE UNIQUE INDEX employee2_id_idx ON employee2(emp_id) in db4;
CREATE INDEX employee2_dept_idx ON employee2(dept_id) in db4;
CREATE UNIQUE INDEX employee2_ssn_idx ON employee2(ssn) in db4;
CREATE INDEX employee2_name_idx ON employee2(name) in db4;
```

The following statement returns an error because the fragment being attached is a range fragment (a fragment that stores rows with fragmentation key values below the transition value of 400 for the **employee** table). Only interval fragments can be attached online.

```
ALTER FRAGMENT ONLINE ON TABLE employee
  ATTACH employee2 AS PARTITION p3 VALUES < 300;
```

The following statement runs successfully, and creates a new **p3** interval fragment:

```
ALTER FRAGMENT ONLINE ON TABLE employee
  ATTACH employee2 AS PARTITION p3 VALUES < 600;
```

Fragments in surviving table after ALTER FRAGMENT ONLINE:

|        |                                |                     |
|--------|--------------------------------|---------------------|
| p0     | VALUES < 200                   | - range fragment    |
| p1     | VALUES < 400                   | - range fragment    |
| sys_p2 | VALUES >= 400 AND VALUES < 500 | - interval fragment |
| sys_p3 | VALUES >= 500 AND VALUES < 600 | - interval fragment |
| sys_p4 | VALUES >= 600 AND VALUES < 700 | - interval fragment |

Note that the successful ALTER FRAGMENT ONLINE . . . ATTACH operation above required multiple correspondences among specifications in the DDL statements that defined the surviving and consumed tables, including their columns, indexes, constraints, index storage location, and the interval fragmentation strategy of the surviving table:

- The check constraint on the consumed table spans a single interval only. The interval value is 100 for the surviving table, and the check constraint is `>= 500 and < 600`.
- The conditional expression being attached (`< 600`) is internally converted to the interval fragment expression format (`>= 500 and < 600`) which matches the check constraint.
- The indexes on the surviving table are attached (that is, they are fragmented by the same fragmentation scheme as the table) because no fragmentation strategy was specified explicitly in their CREATE INDEX statements.
- The indexes on the consumed table are detached in a single dbspace (**db4**), which is the same dbspace that stored the consumed table.
- For each index on the surviving table, there is a matching index on the consumed table.
- The extra indexes on the consumed table (**employee2\_ssn\_idx** and **employee2\_name\_idx**) that do not correspond to indexes on the surviving **employee** table are dropped during the ONLINE ATTACH operation.

## Effect of the ATTACH Clause

After an ATTACH operation, all consumed tables no longer exist. Any CHECK constraints or NOT NULL constraints on the consumed tables also no longer exist. You must reference the records that were in the consumed tables through the surviving table.

## What Happens to Indexes?

A detached index on the surviving table retains its same fragmentation strategy. That is, a detached index does not automatically adjust to accommodate the new fragmentation of the surviving table. For more information on what happens to indexes, see the discussion about altering table fragments in your *Informix® Performance Guide*.

In a database that supports transaction logging, an ATTACH operation extends any attached index on the surviving table according to the new fragmentation strategy of the surviving table. All rows in the consumed table are subject to these automatically adjusted indexes. For information on whether the database server completely rebuilds the index on the surviving table or reuses an index that was on the consumed table, see your *Informix® Performance Guide*.

In a nonlogging database of Informix®, an ATTACH operation does not extend indexes on the surviving table according to the new fragmentation strategy of the surviving table. To extend the fragmentation strategy of an attached index according to the new fragmentation strategy of the surviving table, you must drop the index and re-create it on the surviving table.

Some ALTER FRAGMENT ... ATTACH operations to attach a fragment can cause the database server to update the index structure. When an index is rebuilt in those cases, the associated column distribution is automatically recalculated, and is available to the query optimizer when it designs query plans for the table on which the fragment was attached.

- For an indexed column (or a set of columns) on which ALTER FRAGMENT ... ATTACH automatically rebuilds a B-tree index, the recalculated column distribution statistics are equivalent to distributions created by the UPDATE STATISTICS statement in HIGH mode.
- If the rebuilt index is not a B-tree index, the automatically recalculated statistics correspond to distributions created by the UPDATE STATISTICS statement in LOW mode.

See also the section [Automatic Calculation of Distribution Statistics on page 280](#) in the description of the CREATE INDEX statement for additional information about statistical distributions that are produced automatically when an index or constraint is created on an existing table.

---

## What Happens to BYTE and TEXT Columns?

When an ATTACH occurs, BYTE and TEXT fragments of the consumed table become part of the surviving table and continue to be associated with the same rows and data fragments as they were before the ATTACH operation.

Each BYTE and TEXT column in every table that is specified in the ATTACH clause must have the same storage type, either blobspace or tblspace. If the BYTE or TEXT column is stored in a blobspace, the same column in all tables must be in the same blobspace. If the BYTE or TEXT column is stored in a tblspace, the same column must be stored in a tblspace in all tables.

## What Happens to Triggers and Views?

When you attach tables, triggers on the surviving table survive the ATTACH, but triggers on the consumed table are automatically dropped. No triggers are activated by the ATTACH clause, but subsequent data-manipulation operations on the new rows can activate triggers.

Views on the surviving table survive the ATTACH operation, but views on the consumed table are automatically dropped.

## What Happens with the Distribution Scheme?

You can attach a nonfragmented table to a table with any type of supported distribution scheme. In general, the resulting table has the same fragmentation strategy as the prior fragmentation strategy of the surviving table.

When you attach two or more nonfragmented tables, however, the distribution scheme can either be based on expression or round-robin.

Only the following distribution schemes can result from combining the distribution schemes of the tables in the ATTACH clause.

| Prior Distribution Scheme of Surviving Table | Prior Distribution Scheme of Consumed Table | Resulting Distribution Scheme |
|--|---|-------------------------------|
| None   | None  | Round-robin or expression     |
| Round-robin                                  | None  | Round-robin                   |
| Expression                                   | None  | Expression                    |

## Round-Robin Distribution Scheme

The following example combines nonfragmented tables **pen\_types** and **pen\_makers** into a single, fragmented table, **pen\_types**. Table **pen\_types** resides in dbspace **dbsp1**, and table **pen\_makers** resides in dbspace **dbsp2**. Table structures are identical in each table.

```
ALTER FRAGMENT ON TABLE pen_types ATTACH pen_types, pen_makers;
```

After you execute the ATTACH clause, the database server fragments the table **pen\_types** using a round-robin scheme into two dbspaces: the dbspace that contained **pen\_types** and the dbspace that contained **pen\_makers**. Table **pen\_makers** is consumed and no longer exists; all rows that were in table **pen\_makers** are now in table **pen\_types**.

## Expression Distribution Scheme

Consider the following example that combines tables **cur\_acct** and **new\_acct** and uses an expression-based distribution scheme. Table **cur\_acct** was originally created as a fragmented table and has fragments in dbspaces **dbsp1** and **dbsp2**. The first statement of the example shows that table **cur\_acct** was created with an expression-based distribution scheme. The

second statement of the example creates table **new\_acct** in **dbsp3** without a fragmentation strategy. The third statement combines the tables **cur\_acct** and **new\_acct**. Table structures (columns) are identical in each table.

```
CREATE TABLE cur_acct (a int) FRAGMENT BY EXPRESSION
  a < 5 in dbsp1, a >= 5 and a < 10 in dbsp2;
CREATE TABLE new_acct (a int) IN dbsp3;
ALTER FRAGMENT ON TABLE cur_acct ATTACH new_acct AS a>=10;
```

When you examine the **sysfragments** system catalog table after you alter the fragment, you see that table **cur\_acct** is fragmented by expression into three dbspaces. For additional information about the **sysfragments** system catalog table, see the *Informix® Guide to SQL: Reference*.

In addition to simple range rules, you can use the ATTACH clause to fragment by expression with hash or arbitrary rules. For a discussion of all types of expressions that you can use in an expression-based distribution scheme, see [Expression Fragment Clause on page 385](#).

**Warning:** When you specify a date value as the default value for a parameter, make sure to specify 4 digits instead of 2 digits for the year. If you specify a 2-digit year, the setting of the **DBCENTURY** environment variable can affect how the database server interprets the date value. For more information, see the *Informix® Guide to SQL: Reference*.

## DETACH Clause

Use the DETACH clause of the ALTER FRAGMENT ON TABLE statement to detach a table fragment from a storage distribution scheme and place the contents into a new nonfragmented table.

This clause is not valid in ALTER FRAGMENT ON INDEX statements.

For an explanation of distribution schemes, see [FRAGMENT BY clause on page 382](#).

DETACH Clause

**DETACH**

**PARTITION**

*fragmentnew\_table*

| Element         | Description  | Restrictions  | Syntax                                  |
|-----------------|--|---|---|
| <i>fragment</i> | Named fragment or dbspace that contains the table fragment to be detached. | Must exist at the time of execution. For list or range- interval fragments, the PARTITION keyword | <a href="#">Identifier on page 1456</a> |

| Element          | Description   | Restrictions                      | Syntax                                  |
|------------------|---|-----------------------------------|---|
|                  |   | must precede<br><i>fragment</i> . |   |
| <i>new_table</i> | Name that you declare here for a nonfragmented table that results after you execute the ALTER FRAGMENT statement. | Must not exist before execution   | <a href="#">Identifier on page 1456</a> |

## Usage

The new table that results from executing the DETACH clause does not inherit any indexes or constraints from the original table. Only data values remain.

Similarly, the new table does not inherit any access privileges from the original table. Instead, the new table has the default privileges of any new table. For further information on default table-level privileges, see the description in the GRANT statement of [Table-Level Privileges on page 597](#).

The DETACH clause cannot be applied to a table that has any of the following attributes:

- a ROWID column
- a column or columns defined as the primary key of a referential constraint
- an Enterprise Replication replicate is defined on the table
- a detached index (that is, an index whose storage distribution scheme is not identical to the fragmentation strategy of the table).

If you omit the PARTITION keyword, the name of the fragment must be the name of the dbspace where the fragment is stored.

In the following example, a system-generated range interval fragment **sys\_pt1** is detached from table **T1** and placed in a new unfragmented table **detacht1**:

```
ALTER FRAGMENT ON TABLE T1 DETACH PARTITION sys_pt1 detacht1;
```

The next example detaches a list fragment **part2** from table **T2** and places its data in a new unfragmented table **detacht2**:

```
ALTER FRAGMENT ON TABLE T2 DETACH PARTITION part2 detacht2;
```

## Distribution statistics after DETACH operations

Some ALTER FRAGMENT . . . DETACH operations can cause the database server to update the index structure of the original table. When an index is rebuilt in those cases, the database server also recalculates the associated column distributions, and these statistics are available to the query optimizer when it designs query plans for the table from which the fragment was detached:

- For an indexed column (or for a set of columns) on which ALTER FRAGMENT . . . DETACH automatically rebuilds a B-tree index, the recalculated column distribution statistics are equivalent to distributions created by the UPDATE STATISTICS statement in HIGH mode.
- If the rebuilt index is not a B-tree index, the automatically recalculated statistics correspond to distributions created by the UPDATE STATISTICS statement in LOW mode.

If the automatic mode for updating column-distribution statistics is enabled, and the table from which the fragment is being detached has fragment-level distribution statistics, the database server uses the statistics of the detached fragment as distribution statistics for the new table. The database server also merges the data distribution statistics of the remaining fragments to calculate new table distribution statistics for the original table, and stores these results in the **sysdistrib** system catalog table. This registration of distribution statistics for the new table and recalculation of table distribution statistics for the old table runs in the background.

See also the section [Automatic Calculation of Distribution Statistics on page 280](#) in the description of the CREATE INDEX statement for additional information about statistical distributions that are produced automatically when an index or constraint is created on an existing table.

## Using the ONLINE keyword in DETACH operations

The ONLINE keyword instructs the database server to commit the ALTER FRAGMENT ... DETACH work internally, if there are no errors, and to apply an intent exclusive lock to the table from which the fragment was detached, rather than an exclusive lock. An exclusive lock is applied to the table that is created from the detached fragment.

You can use the DETACH option to the ALTER FRAGMENT ONLINE ON TABLE statement only for a table that uses a range interval fragmentation scheme.

A table that uses a range interval storage distribution scheme can have two types of fragments:

- *range* fragments, which are defined by the user in the FRAGMENT BY or PARTITION BY clause of the CREATE TABLE or ALTER TABLE statement, and
- *interval* fragments, which are generated automatically by the database server during INSERT and UPDATE operations, if a row has a fragment key values above the upper limit of the transition fragment (the last range fragment).

Only an interval fragment can be detached in an ONLINE DETACH operation.

If the detached interval fragment that is not the last fragment, the database server modifies the fragment names for any system-generated interval fragments that follow the detached fragment in the fragment list to match their new **sysfragments.evalpos** values in the surviving table. During this fragment renaming operation, an exclusive lock is placed on the fragments while the **sysfragments** system catalog is being updated with the new **partition** names (and with new **evalpos** values for any fragments whose ordinal positions within the fragment list changed during the ALTER FRAGMENT DETACH operation).

All indexes on the surviving table must have the same fragmentation scheme as the table. (That is, any indexes must be attached.) For this reason, if there is a primary key constraint or other referential constraints on the table, it is recommended

that you first create an attached index for the constraint, and then use the ALTER TABLE statement to add the constraint. (By default, system-created indexes for primary key constraint and for other referential constraints are detached.)

If there are sessions accessing the same partition that is being detached, it is recommended that you issue the SET LOCK MODE TO WAIT statement for enough seconds to prevent nonexclusive access errors.

All other restrictions that apply to the DETACH option also apply to ONLINE DETACH operations. For those restrictions, see [Restrictions on the ALTER FRAGMENT Statement on page 25](#) and [DROP Clause on page 51](#).

## Example of ALTER FRAGMENT ONLINE ... DETACH

The following SQL statements define a fragmented **employee** table that uses a range-interval storage distribution scheme, with a unique index **employee\_id\_idx** on the column **emp\_id** (that is also the fragmentation key) and another index **employee\_dept\_idx** on the column **dept\_id**.

```
CREATE TABLE employee (emp_id INTEGER, name CHAR(32), dept_id CHAR(2),
                        mgr_id INTEGER, ssn CHAR(12))
  FRAGMENT BY RANGE (emp_id)
    INTERVAL (100) STORE IN (dbs1, dbs2, dbs3, dbs4)
    PARTITION p0 VALUES < 200 IN dbs1,
    PARTITION p1 VALUES < 400 IN dbs2;
CREATE UNIQUE INDEX employee_id_idx ON employee(emp_id);
CREATE INDEX employee_dept_idx ON employee(dept_id);

INSERT INTO employee VALUES (401, "Susan", "DV", 101, "123-45-6789");
INSERT INTO employee VALUES (601, "David", "QA", 104, "987-65-4321");
```

The last two statements insert rows with fragment key values above the upper limit of the transition fragment, causing the database server to generate two new interval fragments, so that the resulting fragment list consists of four fragments:

```
Fragments in surviving table before ALTER FRAGMENT ONLINE:
p0      VALUES < 200           - range fragment
p1      VALUES < 400           - range fragment (transition fragment)
sys_p2  VALUES >= 400 AND VALUES < 500 - interval fragment
sys_p4  VALUES >= 600 AND VALUES < 700 - interval fragment
```

The following statement returns an error, because the specified fragment to be detached is a range fragment (a fragment that stores rows with fragmentation key values below the transition value of 400). Only interval fragments can be detached online.

```
ALTER FRAGMENT ONLINE ON TABLE employee
  DETACH PARTITION p0 employee3;
```

The following statement runs successfully, and creates a new **employee3** table to store the data in the detached fragment.

```
ALTER FRAGMENT ONLINE ON TABLE employee
  DETACH PARTITION sys_p2 employee3;
```

If there are concurrent sessions accessing **sys\_p2**, set the lock mode to WAIT (for a number of seconds sufficient for the ONLINE DETACH operation to be committed) to prevent nonexclusive access errors:

```
SET LOCK MODE TO WAIT 300;
ALTER FRAGMENT ONLINE ON TABLE employee DETACH PARTITION sys_p2 employee3;

Fragments in surviving table after ALTER FRAGMENT ONLINE:
p0      VALUES < 200           - range fragment
```

```
p1      VALUES < 400          - range fragment
sys_p4  VALUES >= 600 AND VALUES < 700 - interval fragment.
```

## Detach with BYTE and TEXT Columns

If the DETACH clause specifies the first fragment of a table that includes simple large objects of data type BYTE or TEXT, the database server applies locks on the blobspaces of every fragment of the table. To detach any other fragment of the table locks only the blobspaces of the specified fragment, rather than the blobspaces of all fragments, so fewer locks are required if the fragment is not the first.

## Detach from a Protected Table

If a successfully executed DETACH clause specifies a table that is protected by a security policy, the database server creates a new table that is protected by the same security policy.

If the original table has both row-level and column-level protection,

- the new table has the same IDSSecurityLabel column, and the same label, for row-level security,
- and the same set of protected columns secured by the same labels as the original table for column-level protection.

For tables with row-level protection, the IDSSecurityLabel column has a NOT NULL constraint by default. Only a user who holds the DBSECADM role can reference a protected table in the ALTER FRAGMENT statement.

## Detach That Results in a Nonfragmented Table

The following example uses the table **cur\_acct** fragmented into two dbspaces, **dbsp1** and **dbsp2**:

```
ALTER FRAGMENT ON TABLE cur_acct DETACH dbsp2 accounts;
```

This example detaches **dbsp2** from the distribution scheme for **cur\_acct** and places the rows in a new table, **accounts**. Table **accounts** now has the same structure (column names, number of columns, data types, and so on) as table **cur\_acct**, but the table **accounts** does not contain any indexes or constraints from the table **cur\_acct**. Both tables are now nonfragmented. The following example shows a table that contains three fragments:

```
ALTER FRAGMENT ON TABLE bus_acct DETACH dbsp3 cli_acct;
```

This statement detaches **dbsp3** from the distribution scheme for **bus\_acct** and places the rows in a new table, **cli\_acct**. Table **cli\_acct** now has the same structure (column names, number of columns, data types, and so on) as **bus\_acct**, but the table **cli\_acct** does not contain any indexes or constraints from the table **bus\_acct**. Table **cli\_acct** is a nonfragmented table, but table **bus\_acct** remains fragmented.

## INIT Clause

The INIT clause of the ALTER FRAGMENT statement can define or modify the fragmentation strategy or the storage location of an existing table or an existing index.

The INIT clause has the following syntax.

INIT Clause

**INIT**

**WITH ROWIDS**

FRAGMENT BY Clause for Tables <sup>12</sup>

**PARTITION***fragment*

**IN** *dbspace*

FRAGMENT BY Clause for Indexes <sup>13</sup>

| Element         | Description                      | Restrictions                     | Syntax                                  |
|-----------------|----------------------------------|----------------------------------|---|
| <i>dbspace</i>  | Dbospace storing fragmented data | Must exist at time of execution  | <a href="#">Identifier on page 1456</a> |
| <i>fragment</i> | Name of fragment                 | No more than 2048 for same table | <a href="#">Identifier on page 1456</a> |

The INIT clause can accomplish tasks that include the following:

- Move a nonfragmented table from one dbospace to a named fragment or to another dbospace.
- Convert a fragmented table to a nonfragmented table.
- Fragment an existing non-fragmented table without redefining it.
- Convert a fragmentation strategy to another fragmentation strategy.
- Fragment an existing index that is not fragmented without redefining the index.
- Convert a fragmented index to a nonfragmented index.
- Add a new **rowid** column to the table definition.

When you use the INIT clause to modify a table, the **tabid** value in the system catalog tables changes for the affected table. The **constrid** value of all unique and referential constraints on the table also changes.

For more information about the storage spaces in which you can store a table, see [Using the IN Clause on page 377](#).

**Attention:** When you execute the ALTER FRAGMENT statement with this clause, it results in data movement if the table contains any data. If data values move, the potential exists for significant logging, for the transaction being aborted as a long transaction, and for a relatively long exclusive lock being held on the affected tables. Use this statement when it does not interfere with day-to-day operations.

12. See [FRAGMENT BY Clause for Tables on page 42](#)

13. See [FRAGMENT BY clause for indexes on page 45](#)

## WITH ROWIDS Option

Nonfragmented tables contain a hidden column called **rowid**. Its integer value defines the physical location of a row. To include a **rowid** column in a fragmented table, you must explicitly request it by using the WITH ROWIDS clause in CREATE TABLE (or ADD ROWIDS in ALTER TABLE, or WITH ROWIDS in ALTER FRAGMENT INIT).

The **rowid** in a row of a fragmented table does not identify a physical location for the row in the same way that a **rowid** in a non-fragmented table does.

When you use the WITH ROWIDS option to add a new **rowid** column to a fragmented table, the database server assigns a unique **rowid** number to each row and creates an index that it can use to find the physical location of the row. Performance using this access method is comparable to using a SERIAL, BIGSERIAL, or SERIAL8 column. The **rowid** value of a row cannot be updated, but remains stable during the existence of the row. Each row requires an additional four bytes to store the **rowid** column after you specify the WITH ROWIDS option.

**Recommendation:** When creating new applications, use primary keys as a method of row identification instead of using **rowid** values.

## Converting a Fragmented Table to a Nonfragmented Table

You might decide that you no longer want a table to be fragmented. You can use the INIT clause to convert a fragmented table to a nonfragmented table. The following example shows the original fragmentation definition, as well as how to use the INIT clause of the ALTER FRAGMENT statement to convert the table to a nonfragmented table:

```
CREATE TABLE checks (col1 INT, col2 INT)
  FRAGMENT BY ROUND ROBIN IN dbsp1, dbsp2, dbsp3;

ALTER FRAGMENT ON TABLE checks INIT IN dbsp1;
```

You must use the IN *dbspace* clause to place the table in a dbspace explicitly.

When you use the INIT clause to change a fragmented table to a nonfragmented table, all attached indexes become nonfragmented indexes. In addition, constraints that do not use existing user-defined indexes (detached indexes) become nonfragmented indexes. All newly nonfragmented indexes exist in the same dbspace as the new nonfragmented table.

Using the INIT clause to change a fragmented table to a nonfragmented table has no effect on the fragmentation strategy of detached indexes, nor of constraints that use detached indexes.

## FRAGMENT BY Clause for Tables

Use the FRAGMENT BY option of the INIT clause of the ALTER FRAGMENT statement to fragment an existing nonfragmented table, or to convert one table fragmentation strategy to another.

The PARTITION BY keywords are a synonym for the FRAGMENT BY keywords in this context.

FRAGMENT BY Clause for Tables

**FRAGMENT BY PARTITION BY**

**ROUND ROBIN**

**IN**

**RANGE**( *fragment\_key*)

Interval Fragment Clause<sup>15</sup>

**LIST**( *fragment\_key*)List Fragment Clause<sup>16</sup>

Fragment List

,

**PARTITION***part*

(*expr*)

<sup>14</sup>**REMAINDER**

**IN***dbspace*

| Element        | Description                              | Restrictions  | Syntax                                  |
|----------------|--|---|---|
| <i>column</i>  | Column to which the strategy applies     | Must exist in the table   | <a href="#">Identifier on page 1456</a> |
| <i>dbspace</i> | Dbpace that contains the table fragment  | Must specify at least 2 but no more than 2,048 dbspaces   | <a href="#">Identifier on page 1456</a> |
| <i>expr</i>    | Expression that defines a table fragment | Must evaluate to a Boolean value (Ⓣ or Ⓛ)   | <a href="#">Expression on page 1193</a> |
| <i>part</i>    | Name of a fragment                       | Required for any named fragment in the same dbspace as another named fragment of the same table. Name must be unique among fragments of the same table. | <a href="#">Identifier on page 1456</a> |

This supports the same syntax as the FRAGMENT BY (or PARTITION BY) clause of the CREATE TABLE statement. For more information on the fragmentation strategies available for tables, see the [FRAGMENT BY clause on page 382](#) of the CREATE TABLE statement.

14. If included, must be the last item in fragment list

15. See

16. See [List fragment clause on page 388](#)

## Examples of range interval fragmentation

These examples define statement define range interval fragmentation strategies for an existing table. The following ALTER FRAGMENT statement defines three fragments of a range interval fragmentation strategy that includes no NULL fragment, where numeric column **c1** is the fragmentation key:

```
ALTER FRAGMENT ON TABLE T1 INIT
  FRAGMENT BY RANGE(c1)
  INTERVAL (100+100) STORE IN (dbs3, dbs4, dbs5, dbs6, dbs7, dbs8)
  PARTITION part0 VALUES < 0 IN dbs0,
  PARTITION part1 VALUES < 1000 IN dbs1,
  PARTITION part2 VALUES < 2000 IN dbs2;
```

Here the interval value expression of `(100+100)` defines the interval fragment size as 200 within the range of column **c1**. No fragment is defined for fragmentation key values of 2000 or greater. If this were still the storage distribution when a row with **c1** equal to or greater than 2000 is inserted, the database server automatically creates a new fragment to store that row, which was outside the range of any existing fragment. Interval partitions are stored in the dbspaces `dbs2`, `dbs3`, `dbs4`, `dbs5`, `dbs6`, `dbs7`, and `dbs8` in round-robin fashion.

The following statement similarly defines three fragments of a range interval fragmentation strategy that includes no NULL fragment, and where the DATE or DATETIME column **c2** is the fragmentation key:

```
ALTER FRAGMENT ON TABLE T1 INIT
  FRAGMENT BY RANGE(c2)
  INTERVAL (NUMTOYMINTERVAL(1, 'MONTH'))
  PARTITION part0 VALUES < DATE('01/01/2009') IN dbs0,
  PARTITION part1 VALUES < DATE('07/01/2009') IN dbs1,
  PARTITION part2 VALUES < DATE('01/01/2010') IN dbs2;
```

Here the interval value expression of `NUMTOYMINTERVAL(1, 'MONTH')` defines the interval fragment size as a single month within the range of column **c2**. The PARTITION list defines three fragments: `part0` for December of 2008, `part1` for June of 2008, and `part2` for December of 2009. If rows are inserted whose **c2** value is not in one of these months, the database server will create new fragments for those rows. Because no STORE IN clause is specified, the database server will store these new range interval fragments in a round-robin fashion in the dbspaces `dbs0`, `dbs1`, and `dbs2` that this example lists after the IN keywords of the three PARTITION specifications.

## Changing an Existing Fragmentation Strategy on a Table

You can redefine a fragmentation strategy on a table if you decide that your initial strategy does not fulfill your needs. When you alter a fragmentation strategy, the database server discards the existing fragmentation strategy and moves records to fragments as defined in the new fragmentation strategy.

The following example shows the statement that originally defined the fragmentation strategy on the table **account** and then shows an ALTER FRAGMENT statement that redefines the fragmentation strategy:

```
CREATE TABLE account (col1 INT, col2 INT)
  FRAGMENT BY ROUND ROBIN IN dbsp1, dbsp2;
ALTER FRAGMENT ON TABLE account
  INIT FRAGMENT BY EXPRESSION
  col1 < 0 IN dbsp1,
  col2 >= 0 IN dbsp2;
```

If an existing dbspace is full when you redefine a fragmentation strategy, you must not use it in the new fragmentation strategy.

## Defining a Fragmentation Strategy on a Nonfragmented Table

The INIT clause can define a fragmentation strategy on a nonfragmented table, regardless of whether the table was created with a storage option.

```
CREATE TABLE balances (col1 INT, col2 INT) IN dbsp1;
ALTER FRAGMENT ON TABLE balances INIT
  FRAGMENT BY EXPRESSION col1 <= 500 IN dbsp1,
  col1 > 500 AND col1 <=1000 IN dbsp2, REMAINDER IN dbsp3;
```

When you use the INIT clause to fragment an existing nonfragmented table, all indexes on the table become fragmented in the same way as the table.

## FRAGMENT BY clause for indexes

Use the FRAGMENT BY clause to redefine the storage distribution strategy of an index without redefining the index. The keywords FRAGMENT BY and PARTITION BY are synonyms in this context.

| Element        | Description                                      | Restrictions  | Syntax                                  |
|----------------|--|---|---|
| <i>dbspace</i> | Dbspace that contains the fragmented information | Must specify at least one (but no more than 2,048) dbspaces of the same page size | <a href="#">Identifier on page 1456</a> |

17. See

18. See [List fragment clause on page 388](#)

| Element             | Description   | Restrictions   | Syntax   |
|---------------------|---|--|--|
| <i>expr</i>         | Expression defining an index fragment   | Must be unique among fragmentation expressions for the same index, and must return a Boolean value   | <a href="#">Condition on page 1144</a> ; <a href="#">Expression on page 1193</a> |
| <i>fragment_key</i> | Constant expression, based on a column value. The index is fragmented on this expression. | Any column must be in the current table.   | <a href="#">Expression on page 1193</a>  |
| <i>part</i>         | Name that you declare here for the fragment. Default is the <i>dbspace</i> name.          | Required for fragments in the same <i>dbspace</i> as another fragment of the same index. Must be unique among fragments of the same index. | <a href="#">Identifier on page 1456</a>  |

The INIT FRAGMENT BY clause for indexes of the ALTER FRAGMENT statement can accomplish any of the following operations on the storage distribution scheme of an existing index, without redefining the index:

- Change an existing fragmented index to a nonfragmented index.
- Change the distribution scheme of an existing fragmented index to another distribution scheme of the same expression, list, or range interval type, or to a different type of distribution scheme.
- Change the interval value or the interval fragment key (or both) of a range interval distribution scheme for an existing index.

To change the interval value expression or the fragment key expression for an existing index that is fragmented by a range interval strategy, you must use the INIT FRAGMENT BY RANGE option (rather than the MODIFY clause) of the ALTER FRAGMENT statement. When you change either or both of those expressions, the Interval Fragment clause in the ALTER FRAGMENT ON INDEX statement must also define at least one range fragment.

When you use the FRAGMENT BY or PARTITION BY clause to convert an existing storage fragmentation strategy to another fragmentation strategy, Informix® discards the existing fragmentation strategy and moves the data records to fragments that you define in the new fragmentation strategy. Data movement similarly occurs when you convert a nonfragmented index to a fragmented index, and when you convert a fragmented index to a nonfragmented index.

To convert an existing fragmented index to a nonfragmented index, you can use the INIT clause to specify IN *dbspace* (or else PARTITION *partition* IN *dbspace*) as the only storage specification for a previously fragmented index.

Just as for an expression-based index fragmentation scheme that the CREATE INDEX statement defines, restrictions apply to each expression (*expr*) that you specify in the ALTER FRAGMENT ON INDEX . . . INIT FRAGMENT BY EXPRESSION statement, including these:

- Any column that the expression references must be from the current table.
- Those columns must be the indexed columns, or a subset of the indexed columns.
- The expression cannot reference fields of a column of type ROW.
- Any data values in the expression must be from only a single row.

- No subqueries, aggregates, nor **CURRVAL** or **NEXTVAL** sequence object expressions are allowed.
- The built-in **CURRENT**, **DATE**, **DBINFO**, **DBSERVERNAME**, **ROWID**, **SITENAME**, **SYSDATE**, **TODAY**, **CURRENT\_USER**, and **USER** expressions are not valid in the expression.

The restrictions above also apply to fragment key expressions for list and for range interval index fragmentation schemes, including fragmentation strategies that are defined in the **FRAGMENT BY** clause of the **CREATE INDEX** statement.

## Detaching an Index from a Table-Fragmentation Strategy

You can detach an index from a table-fragmentation strategy with the **INIT** clause of the **ALTER FRAGMENT ON INDEX** statement, so that an attached index becomes a detached index. This breaks any dependency of the index on the table fragmentation strategy. If the **INIT** clause specifies only **IN *dbspace*** or **PARTITION *fragment* IN *dbspace*** for a previously fragmented index, or if it specifies an index fragmentation strategy that differs from the storage option of the table, then the index becomes a detached index.

## Fragmenting Unique and System Indexes

You can fragment unique indexes on a table that uses a round-robin or expression-based distribution scheme, but any columns referenced in the fragment expression must be indexed columns. If your index fragmentation strategy violates this restriction, the **ALTER FRAGMENT INIT** statement fails, and work is rolled back.

You might have an attached unique index on a table fragmented by **Column A**. If you attempt to use **ALTER FRAGMENT INIT** to change the table fragmentation to **Column B**, the statement fails because the unique index is defined on **Column A**. To resolve this issue, use the **INIT** clause on the index to detach it from the table fragmentation strategy and fragment it separately.

System indexes (such as those used in referential constraints and unique constraints) use user-defined indexes if the indexes exist. If no user-defined indexes can be used, system indexes remain nonfragmented and are moved to the *dbspace* where the database was created. To fragment a system index, create the fragmented index on the constraint columns and then use the **ALTER TABLE** statement to add the constraint.

## ADD Clause

Use the **ADD** clause to add another fragment to a list of fragments of an existing table or index.

21. List or expression fragmentation only

22. List fragmentation only

| Element           | Description   | Restrictions   | Syntax  |
|-------------------|---|--|---|
| <i>expression</i> | Expression that defines the new fragment that is to be added                            | Must return a Boolean value (t or f)   | <a href="#">Condition on page 1144</a> ;<br><a href="#">Expression on page 1193</a> |
| <i>fragment</i>   | Name of an existing fragment  | Must exist   | <a href="#">Identifier on page 1456</a>   |
| <i>new_dspace</i> | Name of a dspace being added to store new interval fragments                            | Must exist<br><br>If the table is in a tenant database, the <i>new_dspace</i> must be a dedicated dspace in the tenant database properties list.<br><br>If the table is not in a tenant database, the <i>new_dspace</i> cannot be the name of a dspace that is dedicated to a tenant database. | <a href="#">Identifier on page 1456</a>   |
| <i>part</i>       | Name that you declare here for the new fragment. The default is the name of the dspace. | Required if another fragment in the fragment list is stored in the same dspace. Must be unique among names of fragments of the index.  | <a href="#">Identifier on page 1456</a>   |

The *expression* can contain *column* names only from the current table, and data values only from a single row. No subqueries or aggregates are allowed. In addition, the built-in **CURRENT**, **DATE**, **DBINFO**, **SYSDATE**, and **TODAY** expressions are not valid in this context.

## Adding a New Dspace to a Round-Robin Distribution Scheme

You can add more dspsaces to a round-robin distribution scheme. The following example shows the original round-robin definition:

```
CREATE TABLE book (col1 INT, col2 INT)
  FRAGMENT BY ROUND ROBIN IN dbsp1, dbsp4;
```

To add another dspace, use the **ADD** clause, as in this example:

```
ALTER FRAGMENT ON TABLE book ADD dbsp3;
```

## Adding a New Named Fragment to a Round-Robin Distribution Scheme

In Informix®, you can add a named fragment to an existing round-robin distribution scheme. The name must be unique within the distribution among fragments of the same dspace. The following example specifies the same original round-robin fragmentation definition as in the previous section:

```
CREATE TABLE book (col1 INT, col2 INT)
  FRAGMENT BY ROUND ROBIN IN dbsp1, dbsp4;
```

To add a new named fragment, you can use the ADD clause, as in the following example:

```
ALTER FRAGMENT ON TABLE book
  ADD PARTITION chapter3 IN dbsp1;
```

The new distribution uses **dbsp1**, **dbsp4**, and **chapter3** as storage locations for a 3-part round-robin fragmentation scheme. The records in the fragment **chapter3** are stored separately in the dbspace **dbsp1** from the records in the first fragment, which is identified only by the dbspace name: **dbsp1**. The newly-added **chapter3** fragment will be favored exclusively by inserts and loads until it no longer has the fewest rows among the table's fragments.

## Adding an expression-based fragment

Adding a fragment expression to the fragmentation list of an expression-based distribution scheme can relocate records from existing fragments into the new fragment. When you insert a new fragment into the fragmentation list, the database server reevaluates all the data in the existing fragments that follow the new fragment. (The **evalpos** column value for any fragment in the **sysfragments** system catalog table indicates the ordinal position of that fragment within the fragmentation list.)

The next statement fragment shows the original expression definition:

```
FRAGMENT BY EXPRESSION
  c1 < 100 IN dbsp1, c1 >= 100 AND c1 < 200 IN dbsp2,
  REMAINDER IN dbsp3
```

To add another named fragment in dbspace **dbsp2** to hold rows for column **c1** values between 200 and 299, use the following ALTER FRAGMENT statement:

```
ALTER FRAGMENT ON TABLE news
  ADD PARTITION century3 (c1 >= 200 AND c1 < 300) IN dbsp2;
```

Any rows that were formerly in the remainder fragment but that fit the criteria (**c1 >= 200 AND c1 < 300**) move to the new **century3** fragment in dbspace **dbsp2**.

If the ALTER FRAGMENT ADD operation results in the redistribution of data rows while the automatic mode for updating distribution statistics is enabled, the database server drops the distribution statistics of the affected fragments, but the table statistics are not dropped. The next query on the table will cause the database server to recalculate the statistics for the same fragments.

## Using the BEFORE and AFTER Options

The BEFORE and AFTER options can position the new fragment either before or after an existing fragment within the fragmentation list. The name of a fragment is the name of the dbspace or the name declared in the PARTITION clause. You cannot use the BEFORE and AFTER options if the distribution scheme is round-robin or range interval.

When you attach a new fragment without an explicit BEFORE or AFTER option, the database server places the added fragment at the end of the fragmentation list, unless a remainder fragment exists. If a remainder fragment exists, the new fragment is placed immediately before the remainder fragment. You cannot position a new fragment after the remainder fragment.

## Using the REMAINDER Option

You cannot add a remainder fragment if one already exists. If you add a new fragment when a remainder exists, the database server retrieves and reevaluates all records in the remainder fragment; some records might move to the new fragment. The remainder fragment is always the last item in the fragment list.

You cannot add a remainder fragment to the fragmentation list of a range interval fragmentation scheme.

## DROP Clause

Use the DROP clause to remove an existing fragment from the fragmentation list of a table or index that is fragmented by round-robin. For a table or index that is fragmented by range interval, you can use this clause to drop one or more dbspaces from the list of dbspaces that store system-generated interval fragments.

Use the DETACH clause, rather than the DROP clause, to remove an existing fragment from a table that uses range-interval fragmentation, such as a rolling window table.

DROP Clause

### DROP

**PARTITION***fragment*

<sup>23</sup>**INTERVAL STOREIN**(

, *dbspace*

)

| Element         | Description                                   | Restrictions   | Syntax                                  |
|-----------------|---|--|---|
| <i>dbspace</i>  | Dbpace that stores system generated fragments | Must exist when you execute the statement.   | <a href="#">Identifier on page 1456</a> |
| <i>fragment</i> | Name of the fragment                          | Must exist when you execute the statement. For list or range interval fragments, the PARTITION keyword must precede this name. | <a href="#">Identifier on page 1456</a> |

If the table is fragmented by expression, you cannot drop a fragment containing data that cannot be moved to another fragment. If the distribution scheme has a REMAINDER option, or if the expressions overlap, you can drop a fragment that contains data. You cannot, however, drop a fragment if the table has only two fragments.

When you want to make a fragmented table nonfragmented, you can use either the INIT clause or the DETACH clause of the ALTER FRAGMENT statement, rather than the DROP clause.

If the *fragment* was not given a name by the user who created the table or index or added the fragment, then the name of the dbspace is also the name of the fragment. If the fragment is a system-generated range interval fragment of a table or of an index, its name is **sys\_***pevalpos*, where *evalpos* is the **sysfragments.evalpos** entry for the fragment in the system catalog. If a

23. Range interval fragmentation only

table and its index use the same range interval fragmentation strategy, each system-generated index fragment has the same identifier as a system-generated fragment of the table.

When you drop a fragment, the database server attempts to move all records in the dropped fragment to another fragment. In this case, the destination fragment might not have enough space for the additional records. If this happens, follow one of the procedures that [ALTER FRAGMENT and Transaction Logging on page 25](#) describes to increase your available space, and retry the ALTER FRAGMENT operation.

When the DROP clause specifies one or more dbspaces to remove from a range interval fragmentation strategy, those dbspaces are not affected, but the database server moves the data in any fragments of the table or index that are stored in those dbspaces to other available dbspaces. (The range interval fragmentation strategy is also affected, because it no longer includes the specified dbspaces among its storage locations for new system-generated fragments.)

You cannot use the DROP clause to drop a range interval fragment that contains data.

You can use this clause to drop a list fragment that contains data only if a remainder fragment exists to receive the data.

If the fragmented table has fragment level statistics, the ALTER FRAGMENT DROP operation also drops any fragment-level statistic distribution for the fragment been dropped. Table-level statistics, however, are not recalculated. The next explicit or automatic UPDATE STATISTICS operation on the table will rebuild stale fragment-level distributions and merge them to form table level distributions and store the results in the system catalog.

### Examples of the DROP clause of the ALTER FRAGMENT statement

The following examples show how to drop a fragment from a round-robin fragmentation list. The first line shows how to drop an index fragment, and the second line shows how to drop a table fragment.

```
ALTER FRAGMENT ON INDEX cust_indx DROP dbsp2;
ALTER FRAGMENT ON TABLE customer DROP dbsp1;
```

The following examples each drop a fragment that was defined by list fragmentation strategies. The first line shows how to drop a table fragment, and the second line shows how to drop an index fragment.

```
ALTER FRAGMENT ON TABLE T2 DROP PARTITION part4;
ALTER FRAGMENT ON INDEX idx2 DROP PARTITION part4;
```

In both examples above, the PARTITION keyword is required, and the name of the dropped fragment is **part4**. If the index **idx2** is defined on table **T2** and thus the same storage distribution strategy as table **T2**, the second statement is not necessary, because the database server automatically modifies the fragmentation strategy of an attached index when the table fragmentation list is modified. If these fragments are not empty, the database server moves their data to the remainder fragments (or returns an error, if no remainder fragment exists).

The following examples each drop two dbspaces that store system-defined interval range fragments, as defined by range interval fragmentation strategies. The first statement drops dbspaces **db7** and **db8** from the storage spaces for table fragments, and the second statement drops the same storage spaces for index fragments:

```
ALTER FRAGMENT ON TABLE T1 DROP INTERVAL STORE IN (db7, db8);
ALTER FRAGMENT ON INDEX idx1 DROP INTERVAL STORE IN (db7, db8);
```

The PARTITION keyword is again required, and if **idx1** is an attached index on table **T1**, the second statement is not necessary: When the table fragmentation list is modified, the database server automatically modifies the fragmentation

strategy of any attached index to match the modified strategy of its table. If these fragments are not empty, the database server moves any fragments from the specified **db7** and **db8** dbspaces to other available dbspaces.

## MODIFY Clause

Use the MODIFY clause to change the fragmentation list or the fragment key of a table or of an index that is fragmented by list or by expression, or to define, modify, or disable a range-interval or rolling window fragmentation scheme.

Use the MODIFY clause to change the existing fragmentation list of a table or of an index. You can use this clause to accomplish one or more of the following tasks:

- Move an existing fragment from one dbspace to a different dbspace
- Change the expression associated with an existing list-based or expression-based fragment
- Change the expression that defines the transition fragment in a range-interval fragmentation list
- Rename one or more existing fragments
- Enable or disable the automatic creation of interval fragments
- Replace the list of dbspaces or the function specifying where to store new interval fragments
- Change a rolling window table to a table fragmented by interval (with no purge policy)
- Change a table that is fragmented by range interval to a rolling window table
- Change the purge policy of a rolling window table by one or more of these actions:
  - Resetting the limit on the number of interval fragments,
  - Changing the allocated storage size limit for the table,
  - Replacing the `ATTACH` or `DISCARD` keyword option,
  - Replacing the `ANY` or `INTERVAL FIRST` or `INTERVAL ONLY` keyword option.

The MODIFY clause of the ALTER FRAGMENT statement has the following syntax:

MODIFY Clause

## Usage

Here *dbspace* and *old* (or *old* and *new*) can be identical, if you are not changing the storage location. For tables or indexes that are fragmented by range interval, the specified list of dbspaces that follows the STORE IN keywords replaces the list of dbspaces that was in effect before you issued the ALTER FRAGMENT . . . MODIFY statement. Fragments in the former list of dbspaces are not relocated by this option.

Instead of a list of literal dbspace identifiers, the STORE IN clause can optionally specify a user-defined function that returns the name of an existing dbspace. The identifier that you declare for this UDF is arbitrary. For more information about this UDF and an example of how to create it, see the discussion of the STORE IN clause in the CREATE TABLE topic .

To use the MODIFY clause both to change the *expression* and to move its corresponding fragment to a new storage location, you must change the *expression* and you must also specify the name of a different *dbspace* or partition.

You must declare a *new* fragment name if more than one fragment of the same table or index has the same identifier as the *dbspace*. The PARTITION keyword is required immediately before the *new* fragment name for range interval fragments and for list fragments, but it is optional for round-robin fragments and expression-based fragments.

The *expression* must evaluate to a Boolean value (true or false).

No subqueries or aggregates are allowed in the *expression*. In addition, the built-in **CURRENT**, **DATE**, **DBINFO**, **SYSDATE**, and **TODAY** expressions are not valid.

When you use the MODIFY clause to change an expression without changing the storage location for the expression, you must use the same name for the *old* and the *new* fragment. If the dbspace consists of only a single partition, however, you can specify the same name for *old* and for *dbspace*, as in the following example:

```
ALTER FRAGMENT ON TABLE cust_acct
  MODIFY dbsp1 TO acct_num < 65 IN dbsp1;
```

For list fragmentation strategies, the ALTER FRAGMENT MODIFY statement fails with an error if a new list expression overlaps any existing list expressions for another fragment of the same table or index.

When you use the MODIFY clause to move a fragment from one dbspace to another, *old* is the name of the dbspace where the fragment was previously located, and *dbspace* is the new location for the fragment, as in the following example:

```
ALTER FRAGMENT ON TABLE cust_acct
  MODIFY PARTITION part1 TO PARTITION part2 (acct_num < 35) IN dbsp2;
```

The ALTER FRAGMENT statement above modifies the distribution scheme for the **cust\_acct** table, so that the rows with values in column **acct\_num** that are less than 35 (and that had previously been assigned to fragment **part1** that was stored in the dbspace **dbsp1**) will now be assigned to the fragment **part2** that is stored in the dbspace **dbsp2**.

When you use the MODIFY clause, the underlying dbspaces are not affected. Only the data values within the fragments or dbspaces are affected.

Unless the fragmentation strategy is by range interval, if no remainder fragment already exists, you can redefine a nonremainder fragment as a remainder fragment for rows that do not match the fragment key values for any other fragment. You cannot change a REMAINDER fragment into a nonremainder fragment, however, if any rows already stored in the REMAINDER fragment do not satisfy the new *expression*.

An *attached* index has the same storage distribution as its table. If all the indexes on a table are attached indexes, and you use the MODIFY clause to modify the table fragments, the database server automatically modifies the storage distribution strategy for the index to match the new table fragmentation strategy.

The *old* specification cannot reference the transition fragment (the last range fragment) of any table that is fragmented by a range-interval storage distribution scheme. The only modification that is valid for that fragment is to use the TRANSITION TO *const\_expr* clause to increase the transition value. For any other syntax that attempts to redefine the range expression of the transition fragment directly, the database server returns an error. For more information, see the topic [Using the MODIFY INTERVAL TRANSITION option on page 63](#).

## Restrictions on the MODIFY clause for range interval fragments

The MODIFY clause of the ALTER FRAGMENT statement cannot change the interval value, nor the fragment key. To change either of these elements of the range interval storage distribution scheme, you must use the INIT option of the ALTER FRAGMENT statement.

The MODIFY clause cannot change the value of the range expression of a fragment if any of the following are true:

- The fragment is the last fragment, and the new value is smaller than the current value.
- The new value overlaps the boundary of an existing fragment.
- The fragment is a system-generated interval fragment.

You can modify the value of a user-defined range fragment, but the new value cannot cross adjacent fragment boundaries, and the database server must be able to accomplish any data movement that the new range expression implies.

The MODIFY clause can change the list of storage spaces where an existing fragment is stored, and it can also change the list of storage spaces where new system-generated interval fragments will be stored, but the same MODIFY clause cannot accomplish both tasks. To change both lists, you must issue two separate ALTER FRAGMENT . . . MODIFY statements.

Similarly, a MODIFY clause that enables or disables the current range interval distribution scheme cannot also move an existing range interval fragment to a different dbspace, or create a new user-defined fragment. Separate ALTER FRAGMENT . . . MODIFY statements are required for each of these tasks.

For range fragments of tables and indexes fragmented by interval, you can modify the fragment expression for the first and for intermediate range fragments. Any overlaps are resolved by moving data, so that fragment key values of the rows stored in the redefined range fragments are non-overlapping. For the last range fragment, however, you can modify the transition value in its fragment expression only if the new range expression satisfies all of the following conditions:

- It does not partially or completely match any existing interval fragment expression.
- It will not partially match any future interval fragment expressions that the system can generate automatically.
- Any gap that the new transition value leaves between fragments must be an integer multiple of the *intvl\_expr* interval value.

You cannot define a remainder fragment for a table that is fragmented by range interval.

If you use the MODIFY clause to rename an existing fragment, the new name cannot begin with the characters `sys_p`.

### Range, interval, and transition fragments

For objects that use a range interval storage distribution strategy, it is useful to distinguish among three types of fragments:

- A *range* fragment is a fragment whose name, fragment-key expression, and storage location are defined explicitly in the Interval Fragment clause within the table or index definition. Range interval fragmentation requires that at least one range fragment be defined.
- An *interval* fragment is a fragment whose name, fragment-key expression, and storage location are defined automatically by the database server when an insert or load operation attempts to store a row whose fragment-key value is false for the fragment-key expression of every existing fragment.
- The range fragment whose upper limit in its VALUES clause is larger than for the fragment-key expression for any other range fragment is called the *transition* fragment. The upper limit specified in the VALUES clause of the transition fragment is called the *transition value* for the table. If no interval fragments have been created for the object, inserting a row whose fragment-key value exceeds that transition value requires the database server to create a new interval fragment.

Operations that the MODIFY clause of the ALTER FRAGMENT statement can perform on transition fragments are more restricted than MODIFY operations on other range and interval fragments.

The ALTER FRAGMENT MODIFY statement cannot change the range expression that defines a transition fragment unless you also include the MODIFY TRANSITION keywords.

The database server cannot create interval fragments unless the Interval Fragment clause within the table or index definition defined a range interval fragment key, and the fragmentation scheme is not currently disabled by the ALTER FRAGMENT . . . MODIFY INTERVAL DISABLE statement.

### Restrictions on modifying rolling window tables

The Rolling Window clause of the ALTER FRAGMENT MODIFY INTERVAL statement cannot define a purging policy on a table that has any of the following attributes:

- The table has a ROWID shadow column.
- Another table has a foreign key constraint that references a PRIMARY KEY in the table.

## Rolling Window clause

Use the Rolling Window clause of the ALTER FRAGMENT MODIFY INTERVAL statement to add a purge policy to a table that uses range-interval distributed storage, or to modify or drop the purge policy of a rolling window table.

For tables with range-interval distributed storage, the Rolling Window clause supports the following syntax to drop all purge policy limits on interval fragments, or to set new purge policy limits on interval fragments:

Figure 1. Rolling Window clause of ALTER FRAGMENT

**ALTER FRAGMENT FOR TABLE *table* MODIFY INTERVAL Rolling Window clause**

Case 1: Destroy all Purge Policies for a table

**DROP ALL ROLLING**

Case 2: Limit the maximum allocated storage size

**ROLLING(*quantity* FRAGMENTS)**

**LIMIT TO *size* *units***

**DETACH DISCARD**

**INTERVAL FIRST**

**ANY INTERVAL ONLY**

Case 3: Limit only the quantity of interval fragments

**ROLLING(*quantity* FRAGMENTS)**

**DETACH DISCARD**

| Element         | Description   | Restrictions  | Syntax  |
|-----------------|---|---|---|
| <i>quantity</i> | Upper limit in purge policy on the number of interval fragments                                     | Must be an integer greater than zero.<br>User-defined range fragments are not included in this limit.   | Literal integer   |
| <i>size</i>     | Upper limit on the total allocated storage for the table and its indexes                            | Must be greater than zero   | Literal integer   |
| <i>table</i>    | Name of an existing table with range-interval fragmentation   | Must not have a ROWID column or a primary-key constraint that a foreign-key constraint references. Any index must have the same storage distribution.   | <a href="#">Identifier on page 1456</a>   |
| <i>units</i>    | Abbreviated unit of total mass storage for the table. Any trailing characters cause a syntax error. | Must be <code>K</code> , <code>KB</code> , <code>KiB</code> , <code>M</code> , <code>MB</code> , <code>MiB</code> , <code>G</code> , <code>GB</code> , <code>GiB</code> , <code>T</code> , <code>TB</code> , <code>TiB</code> (case insensitive). | Unquoted character string, beginning with the letter <code>K</code> , <code>M</code> , <code>G</code> , or <code>T</code> |

### Usage

The syntax of the Rolling Window clause in ALTER FRAGMENT MODIFY INTERVAL statement supports a superset of the syntax of the Rolling Window clause in CREATE TABLE FRAGMENT BY INTERVAL statements.

## Modifying rolling window tables

The Rolling Window clause of the ALTER FRAGMENT MODIFY INTERVAL statement resembles in its syntax, but is not identical to, the Rolling Window clause of the CREATE TABLE statement. The Rolling Window clause of ALTER FRAGMENT supports the following functionality:

- You can define a purge policy for a table that uses range-interval fragmentation.
- You can modify an existing purge policy by any of the following changes:
  - Changing the `ROLLING FRAGMENTS` value for *quantity*
  - Changing the `LIMIT TO` value for *size*
  - Replacing the `DETACH` or `DISCARD` keyword with the `DETACH` or `DISCARD` keyword.
  - Replacing the `ANY` or `INTERVAL FIRST` or `INTERVAL ONLY` keyword option.

If you delete the `ANY` or `INTERVAL FIRST` or `INTERVAL ONLY` keyword specification without replacement, the default purge policy action is `INTERVAL FIRST`. (For more information about the effects of these keywords on which qualifying fragments will be purged, see the topic .)

- You can specify the `INTERVAL DISABLED` keywords to disable interval fragmentation for a rolling window table, thereby suspending its purge policy.
- You can specify the `INTERVAL ENABLED` keywords to restore interval fragmentation (and re-enable the purge policy) for a table for which interval fragmentation and the creation and archiving or destruction of rolling fragments had been disabled.
- You can specify the `DROP ALL ROLLING` keywords to remove an existing purge policy. The effect is to change the rolling window table to a table fragmented by interval.

If you intend to suspend the current purge policy temporarily, and subsequently to restore the same purge policy, you should use the `INTERVAL DISABLED` keywords, rather than the `DROP ALL ROLLING` keywords.

## Enforcing a purge policy

A rolling window table's purge policy is not immediately enforced when the total allocated storage size or the total number of interval fragments exceeds the limit that the Rolling Window clause specifies.

Purge policies are designed to be enforced daily as a Scheduler task at a time when the required `DETACH` and `ATTACH` operations on fragments of the rolling window table are unlikely to conflict with access attempts by concurrent users. By default, purge policies are enforced daily, at 00:45 local time. For more information, see the description of the built-in `purge_tables` task of the Scheduler in your *Informix® Administrator's Guide*.

Purge policies also can be manually enforced by running the `syspurge()` system function. After the DBA invokes the `syspurge()` function, the database server inspects the system catalog, and identifies any rolling window tables whose purging policy has been exceeded. The database server then either discards or detaches, as specified by the purge policy, qualifying rolling fragments until the purging policy is satisfied, or until no more rolling fragments can be removed. The `syspurge()` function requires no arguments, but accepts an optional argument that enables online log diagnostics.

Only users with DBA access privileges can call routines that implement the `DETACH` or `DISCARD` options for detached rolling fragments. Users with `RESOURCE` access privileges can execute the `syspurge()` function, but this can only enforce purging policies on tables that they own.

The database server silently ignores any invocation of the `syspurge()` function on secondary servers in High Availability Data Replication (HDR) cluster environments. Similarly, in grid environments, purge policies on replicated tables are not enforced. This is because grid environments and cluster environments do not replicate `ALTER FRAGMENT` changes that the `DETACH` and `DISCARD` options trigger, which are at the core of rolling window purge policies.

The Rolling Window clause provides two keyword options for processing detached rolling interval fragments:

- Use `DETACH` to attach the fragments into independent tables that the database server automatically creates, and whose table identifiers are of this form:

```
< original_table_name >_< lower value >_< higher value >
```

Here *lower\_value* and *higher\_value* are the minimum and maximum values of the interval range for that fragment, before it was detached.

If a table of that name already exists, a numeric counter is appended after the higher value, beginning with `_1` for the first additional table:

```
< original_table_name >_< lower value >_< higher value >_1
```

and so forth, with `_2` appended to the next table name (or a larger integer is appended, if appending `_2` does not produce a unique table name).

- Use `DISCARD` to destroy the detached fragments.

The `DISCARD` keyword specifies that successfully detached fragments be dropped, so that when the purge policy is enforced, unneeded data records are removed in a timely manner. In this way, the number of rolling fragments or the total amount of storage space for the rolling window table is constrained to the stipulated value

## Examples of modifying an existing rolling window table

The examples of `ALTER FRAGMENT ON TABLE . . . MODIFY INTERVAL` statements that follow all change the current rolling-window options of a table called `window_orders` that the following `CREATE TABLE` statement defined:

```
CREATE TABLE window_orders
  (order_id INT, cust_id INT,
   order_date DATE, order_desc CHAR (1024))
FRAGMENT BY RANGE (order_date)
INTERVAL (NUMTOYMINTERVAL (1,'MONTH'))
ROLLING (4 FRAGMENTS) DETACH
STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < DATE ('01/01/2015') IN dbs1,
PARTITION p4 VALUES IS NULL in dbs3;
```

Here the `window_orders` table uses a range-interval distributed storage strategy

- a range fragment `p0` for fragment-key values earlier than the year 2015,
- and three rolling-window interval fragments,
- and fragment `p4` as a NULL fragment to store rows with no value in the `order_date` fragment-key column.

Because the interval within the range of this fragment key is defined as one month, and the interval transition value is the first day of the year 2015, the first interval fragment will be generated when a record is inserted with an `order_date` value in a year later than 2014. Successive interval fragments will be stored in the dbspaces `dbs1`, `dbs2`, and `dbs3` in round-robin fashion.

In the CREATE TABLE statement example above, the Rolling Window clause sets at 3 the maximum number of rolling interval fragments. If rows are added in each of the first three months of 2015, three rolling fragments will be generated by March of that year, because each new interval fragment stores data from only a single month. If a 5th interval fragment is created in May, this will exceed the purge policy limit on rolling fragments. Because no limit on storage size is specified, the default `INTERVAL FIRST` criterion will detach the interval fragment whose **evalpos** value is smallest among the four rolling fragments. That fragment will be attached to another table, rather than destroyed, because the purge policy specifies `DETACH`, rather than `DISCARD`.

ALTER FRAGMENT ON TABLE **window\_orders** MODIFY INTERVAL statements that follow illustrate various changes to the original Rolling Window distribution scheme, as defined above for the **window\_orders** table.

- Set a maximum size limit on the data stored in the table:

```
ALTER FRAGMENT ON TABLE window_orders MODIFY INTERVAL
LIMIT TO 30 MiB DETACH INTERVAL ONLY;
```

This sets a 30 megabyte limit on the total storage size of the **window\_orders** table, and stipulates that range fragments like **p0** cannot be detached to reduce the current size below that limit. The maximum number of interval fragments (4) and the disposal mode of the purge policy (`DETACH`) are unchanged. Note that the actual storage size could exceed the new limit until the Scheduler enforces the purge policy. At that point, however, at least one interval fragment would be detached, in an effort to comply with the `LIMIT TO` setting.

The `ANY`, or `INTERVAL FIRST`, or `INTERVAL ONLY` option for the fragments to purge cannot be reset unless you also include a `LIMIT TO` specification in the Rolling Window clause of the ALTER FRAGMENT MODIFY statement.

- Changing the disposal option:

```
ALTER FRAGMENT ON TABLE window_orders MODIFY INTERVAL
ROLLING (4 FRAGMENTS) DISCARD;
```

This maintains the current number of interval fragments, but changes the disposal option to `DISCARD`, so that the detached will be dropped from the database, in accordance with this change to the original purge policy for the **window\_orders** table.

- Changing the number of interval fragments:

```
ALTER FRAGMENT ON TABLE window_orders MODIFY INTERVAL
ROLLING (6 FRAGMENTS);
```

This increases the number of interval fragments to six, so that no new fragment is added (and no existing fragment is detached) until a new row is inserted whose fragment-key value is a DATE whose month is seven months later than the month values in the oldest fragment.

- Rolling back both previous changes to the quantity and disposal of interval fragments:

```
ALTER FRAGMENT ON TABLE window_orders MODIFY INTERVAL
ROLLING (4 FRAGMENTS) DETACH;
```

This restores the original **window\_orders** storage options, and illustrates that a single ALTER FRAGMENT ON TABLE . . . MODIFY INTERVAL statement can change more than one option of a Rolling Window strategy.

- Drop the rolling-window distributed-storage behavior of the table:

```
ALTER FRAGMENT ON TABLE window_orders MODIFY INTERVAL
DROP ALL ROLLING;
```

This drops the automatic purge policy, changing **window\_orders** from a rolling-window table to an ordinary range-interval table. If a `LIMIT TO` maximum size, or if `ANY` or other keyword option priorities for dropping fragments had been part of the purge policy, those would have also been dropped. No existing data is destroyed, but the future distributed-storage behavior of the **window\_orders** table will match what the following CREATE TABLE statement (with no Rolling Window clause) implies:

```
CREATE TABLE window_orders
  (order_id INT, cust_id INT,
   order_date DATE, order_desc CHAR (1024))
  FRAGMENT BY RANGE (order_date)
  INTERVAL (NUMTOYMINTERVAL (1,'MONTH'))
  STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES < DATE ('01/01/2015') IN dbs1,
  PARTITION p4 VALUES IS NULL in dbs3;
```

### Restrictions on rolling window tables

The ALTER FRAGMENT MODIFY statement cannot use the Rolling Window clause to change a table that has any of the following attributes into a rolling window table:

- a ROWID column
- a column or columns defined as the primary key of a referential constraint.
- a detached index (that is, an index whose storage distribution scheme is not identical to the fragmentation strategy of the table).

Similarly, the ALTER TABLE statement cannot add a ROWID column or a primary-key constraint to a rolling window table.

- The purging strategy that the Rolling Window clause defines for rolling fragments requires the database server to perform ALTER FRAGMENT DETACH operations on fragments that satisfy the `DETACH` or `DISCARD` criteria. The ALTER FRAGMENT DETACH statement is disallowed, however, on tables with primary keys that are referenced by an enabled foreign key constraint, or on tables with ROWIDs. For this reason, the CREATE TABLE and ALTER FRAGMENT ON TABLE . . . MODIFY INTERVAL statements cannot define or modify a purging policy on tables that have primary key constraints or ROWID shadow columns.
- Any index defined on a rolling window table must have the same range-interval storage distribution as the rolling window table.

### Using the MODIFY INTERVAL TRANSITION option

You can use this option to increase the transition value of the last range fragment of a table that has a range-interval fragmentation scheme. The transition value cannot be decreased by using this MODIFY INTERVAL TRANSITION option to the ALTER FRAGMENT statement.

You cannot use the PARTITION *partition* VALUES syntax of the MODIFY option to modify the range expression for the last range fragment (also called the *transition fragment*) of a table that uses a range-interval storage distribution scheme. The

transition value, however, which is the upper limit in the range expression, can be increased by using the `MODIFY INTERVAL TRANSITION TO` keywords to specify the new upper limit. There is no data movement when the transition value is changed. To decrease the transition value (by resetting the upper limit on the range of the transition fragment), you must perform an `ALTER FRAGMENT INIT` operation to redefine the range-interval distributed storage scheme for the table.

### Automatic fragment renaming when the transition value increases

`ALTER FRAGMENT` statements that specify the `MODIFY INTERVAL TRANSITION` option can cause existing fragments to be renamed:

- If there are no interval fragments between the new and old transition values, but interval fragments already exist above the new transition value, the digit that terminates the system-generated interval fragment name is reduced by the number of interval fragment boundaries occupied by the difference between the new and old transition values. For example, if the interval value expression defining an interval size evaluates to 20, and the difference between the old transition value and the new transition value is 60, then an interval fragment whose name is `sys_p7` is renamed to `sys_p4`, because the quotient is  $(60/20) = 3$ .
- If interval fragments exist between the new and old transition values, the characters `rg` are appended to their names to indicate that they have become range fragments, because the upper limit of their fragment expression is no longer greater than the transition value for the table.

For example, if the transition value of a table were increased to match the upper `VALUES` limit of its interval fragment `sys_p5`, that fragment would be changed to a range fragment, and renamed `sys_p5rg`. (It would also become the transition fragment.) If another interval fragment called `sys_p4` also had a smaller `VALUES` upper limit in its fragment expression, that fragment would also become a range fragment, and would be renamed `sys_p4rg`.

During a fragment renaming operation, an exclusive lock is placed on the fragment while the `sysfragments` system catalog table is being updated

- with new fragment-identifier values in the `partition` column,
- and with new integer values in the `evalpos` column for any interval fragments or rolling interval fragments whose ordinal positions in the fragment list changed during the current `ALTER FRAGMENT MODIFY` operation.

In the cases listed above, some fragments are renamed to ensure that every fragment name in the fragment list is unique, and to maintain the correlation between system-generated names for interval fragments and the corresponding `sysfragments.evalpos` value for those fragments in the system catalog. (See also the section [Automatic renaming of interval fragment identifiers on page 26.](#))

Several of the `ALTER FRAGMENT` examples that follow illustrate this fragment-renaming behavior.

### Example of ALTER FRAGMENT MODIFY INTERVAL TRANSITION

The following statements define a fragmented `tabtrans` table that uses a range-interval storage distribution scheme, with the integer column `i` the fragment key, and an interval value of 100. The transition fragment `p2` has a transition value of 300, meaning that the database server will define a new interval fragment during any operation on the table to store a new row with a fragment key value of 300 or greater.

```
CREATE TABLE tabtrans (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1,
PARTITION p2 VALUES < 300 IN dbs0; -- last range fragment (also
-- called transition fragment)
```

Examples that follow are based on this **tabtrans** table.

The following ALTER FRAGMENT statement attempts to increase the transition fragment value from 300 to 250:

```
ALTER FRAGMENT ON TABLE tabtrans
MODIFY INTERVAL TRANSITION TO 250;
```

This statement fails, because it attempts to reduce the transition value. If the design goal is to keep the current interval value of 100, but for the new transition value to become 250, an ALTER FRAGMENT INIT operation is required to redefine the range fragments. To keep the range-fragment boundaries aligned, the new upper limit for the range fragment immediately preceding the transition fragment must be 150. In the new distributes storage scheme, if a row with a fragment-key value greater than 250 is inserted into the table, the database server generates a new interval fragment with a range of 100, and with an integer value of the form 50 (modulo 100) as the upper limit.

If there are no interval fragments between the new and old transition values, the database server updates the expression for the last range fragment to `VALUES < new`, where `new` is the new transition value:

```
INSERT INTO tabtrans VALUES (601, "BB"); -- creates interval fragment sys_p6
-- with fragment expression >= 600 AND < 700
```

The fragment list and the fragment expressions for the **tabtrans** table become as follows

|        |                                |                                       |
|--------|--------------------------------|---------------------------------------|
| p0     | VALUES < 100                   | - range fragment                      |
| p1     | VALUES < 200                   | - range fragment                      |
| p2     | VALUES < 300                   | - last range (or transition) fragment |
| sys_p6 | VALUES >= 600 AND VALUES < 700 | - interval fragment                   |

Here the system-generated name of the new interval fragment is **sys\_p6** because 6 is the **sysfragments.evalpos** value for the new fragment in the system catalog. The **evalpos** values 7 and 5 are reserved for (not yet created) interval fragments to store rows whose fragment key values match the fragment expressions `VALUES >= 300 AND VALUES < 400` and `VALUES >= 400 AND VALUES < 500`, based on the current transition value of the table and on the `INTERVAL (100)` specification in the FRAGMENT BY clause that defined the fragmentation scheme of the table.

During a change of transition value, the fragments are modified to not cause any data movement. The following statement successfully modifies the transition value to 500.

```
ALTER FRAGMENT ON TABLE tabtrans
MODIFY INTERVAL TRANSITION TO 500;
```

The old transition value is 300 and the new transition value is 500, with no interval fragments in between. The first interval fragments starts at 600. This also means that there is no data between 300 and 500. So the expression of the last range fragment (the transition fragment) can be updated to `VALUES < 500` without data movement. Because there are interval fragments after the new transition value, the new transition value must align at an interval fragment boundary. In the above case, the new transition value 500 aligns at an interval fragment boundary (whether or not the fragment currently exists). As

result of modification, the **evalpos** value in the system catalog for interval fragments changes, and the interval fragments are renamed to adhere to the **sys\_pevalpos** naming format.

The resulting modified table has the following fragments:

```
p0    VALUES < 100  -- range fragment
p1    VALUES < 200  -- range fragment
p2    VALUES < 500  -- last range fragment (= transition fragment
                    -- with its expression modified)
sys_p4 VALUES >= 600 AND VALUES < 700 - interval fragment (renamed
                    -- to sys_p4 as evalpos changes from 6 to 4
                    -- after the transition fragment change)
```

The following modification fails with an error, because there are interval fragments beyond the new transition value, and the new transition value does not align at an interval fragment boundary:

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL TRANSITION TO 550;
```

The possible interval fragments are 300 to 400, 400 to 500, 500 to 600, 600 to 700 and so on. The new transition value of 550 is not at an interval fragment boundary, and therefore the error is issued.

If there are interval fragments between the new and old transition value, the new transition value must align to the boundary of an interval fragment (and the interval fragment need not exist), unless the new transition value is beyond the range of the last interval fragment. All interval fragments between the new and the old transition values are converted to range fragments, and their expressions are modified to match the expression format of range fragments. The expression for the last interval fragment that was converted to a range fragment is updated to `VALUES < new`, where *new* is the new transition value.

Here is another example of INSERT operations that result in new interval fragments:

```
CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES < 100 IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0; -- last range fragment
                                       -- or transition fragment

INSERT INTO tab
  VALUES (301, "AA"); -- creates interval fragment sys_p3 with
                       -- fragment expression >= 300 AND < 400

INSERT INTO tab
  VALUES (601, "BB"); -- creates interval fragment sys_p6
                       -- with fragment expression >= 600 AND < 700
```

The fragment list for the table now consists of these fragments:

```
p0    VALUES < 100    -- range fragment
p1    VALUES < 200    -- range fragment
p2    VALUES < 300    -- range fragment
sys_p3 VALUES >= 300 AND VALUES < 400 -- interval fragment
sys_p6 VALUES >= 600 AND VALUES < 700 -- interval fragment
```

The ALTER FRAGMENT examples that follow are based on the above statements.

The following statement increases the transition value from 300 to 500:

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL TRANSITION TO 500;
```

Because there is an interval fragment (**sys\_p3**) between the old and new transition values, that fragment is converted to a range fragment (expression becomes `< 400`). Because there is also an interval fragment (**sys\_p6**) beyond the new transition value, the new transition value must align at an interval fragment boundary, which as an integer multiple of the `INTERVAL(100)` specification, it does. Here the possible interval fragments are `300 to 400`, `400 to 500`, `500 to 600`, `600 to 700` and so on. And the new transition value of `500` is at an interval fragment boundary (whose fragment need not exist). We also do not want to move data during the transition fragment modification or create any fragments. This can be accomplished by converting fragment **sys\_p3** to the new transition fragment, updating its expression to `< 500` (because it is now a range fragment), and renaming it.

The resulting fragment list for the table consists of these fragments:

```
p0      VALUES < 100 -- range fragment
p1      VALUES < 200 -- range fragment
p2      VALUES < 300 -- range fragment (was the old transition fragment)
sys_p3rg  VALUES < 500 -- range fragment (was previously interval
                        -- fragment sys_p3. Its expression was modified to a
                        -- range expression. Its name was changed to a
                        -- system-generated name in format sys_p<evalpos>rg )
                        -- becomes the new transition fragment
sys_p5   VALUES >= 600 AND VALUES < 700
                        -- interval fragment (renamed to sys_5 because the
                        -- evalpos value changes from 6 to 5 after the
                        -- transition fragment change.)
```

The following attempted modification of the transition value returns an error:

```
ALTER FRAGMENT ON TABLE tab
  MODIFY INTERVAL TRANSITION TO 550;
```

The statement above fails because there is an interval fragment **sys\_p6** beyond the new transition value, and because the new transition value is not aligned at an interval fragment boundary.

The next example increases the transition value from `500` to `700`:

```
ALTER FRAGMENT ON TABLE tab
  MODIFY INTERVAL TRANSITION TO 700;
```

The resulting fragment list for the table includes the following fragments:

```
p0      VALUES < 100 -- range fragment
p1      VALUES < 200 -- range fragment
p2      VALUES < 300 -- range fragment (was the old transition fragment)
sys_p3rg  VALUES < 400 -- range fragment (was previously interval fragment
                        -- sys_p3, and its expression changed to a range
                        -- expression.
                        -- The fragment has been renamed to system-generated name
                        -- in the format sys_p<evalpos>rg ).
sys_p6rg  VALUES < 700 -- range fragment (was previously the interval
                        -- fragment sys_p6. Its expression was modified to a
                        -- range expression and its name replaced by a system-
                        -- generated name in the format sys_p<evalpos>rg )
                        -- becomes the new transition fragment.
```

The following example increases the transition value from `700` to `750`:

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL TRANSITION TO 750;
```

Because there are no interval fragments beyond the new transition value, it need not align to an interval fragment boundary.

The resulting table includes the following fragments:

```
p0      VALUES < 100 -- range fragment
p1      VALUES < 200 -- range fragment
p2      VALUES < 300 -- range fragment (was the old transition fragment)
sys_p3rg  VALUES < 400 -- range fragment (was previously interval
                        -- fragment sys_p3. expression modified to a
                        -- range expression. Fragment was renamed to a system
                        -- generated name in the format sys_p<evalpos>rg)
sys_p6rg  VALUES < 750 -- range fragment (was previously the interval
                        -- fragment sys_p6. Its expression was modified to a
                        -- range expression, and the fragment was renamed to a
                        -- system-generated name in format sys_p<evalpos>rg)
                        -- becomes the new transition fragment
```

If you wish to avoid having existing fragments automatically renamed during ALTER FRAGMENT MODIFY INTERVAL TRANSITION operations, you can first use the ALTER FRAGMENT MODIFY statement to rename with user-defined names the interval fragments whose system-generated names might otherwise be changed by the ALTER FRAGMENT MODIFY INTERVAL TRANSITION statement. The database server renames only system-generated interval fragment names (to avoid non-unique fragment names resulting when new interval fragments are created).

## Using the ONLINE keyword in MODIFY operations

The ONLINE keyword instructs the database server to commit the ALTER FRAGMENT . . . MODIFY work internally, if there are no errors, and to apply an intent exclusive lock to the table, rather than an exclusive lock.

### Requirements for ONLINE MODIFY operations

You can use the MODIFY option to the ALTER FRAGMENT ONLINE ON TABLE statement only for a table that is fragmented by a range interval fragmentation scheme.

Only the transition value (the starting value for interval fragments) can be modified ONLINE. All other restrictions that apply to the MODIFY option also apply to ONLINE MODIFY operations. For those restrictions, see [General Restrictions for the ATTACH Clause on page 29](#) and [Restrictions on the MODIFY clause for range interval fragments on page 57](#).

### Example of ALTER FRAGMENT ONLINE . . . MODIFY

The following SQL statements define a fragmented **employee** table that uses a range-interval storage distribution scheme, with a unique index **employee\_id\_idx** on the column **emp\_id** (that is also the fragmentation key) and another index **employee\_dept\_idx** on the column **dept\_id**.

```
CREATE TABLE employee
  (emp_id INTEGER, name CHAR(32),
   dept_id CHAR(2), mgr_id INTEGER, ssn CHAR(12))
FRAGMENT BY RANGE (emp_id)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3, dbs4)
  PARTITION p0 VALUES < 200 IN dbs1,
  PARTITION p1 VALUES < 400 IN dbs2;
CREATE UNIQUE INDEX employee_id_idx ON employee(emp_id);
CREATE INDEX employee_dept_idx ON employee(dept_id);

INSERT INTO employee VALUES (401, "Susan", "DV", 101, "123-45-6789");
```

```
INSERT INTO employee VALUES (601, "David", "QA", 104, "987-65-4321");
```

The last two statements insert rows with fragment key values above the upper limit of the transition fragment, causing the database server to generate two new interval fragments, so that the fragment list consists of four fragments:

```
Fragments in surviving table before ALTER FRAGMENT ONLINE:
p0      VALUES < 200          - range fragment
p1      VALUES < 400          - range fragment (transition fragment)
sys_p2  VALUES >= 400 AND VALUES < 500 - interval fragment
sys_p4  VALUES >= 600 AND VALUES < 700 - interval fragment
```

The following statement returns an error because a transition value can only be increased. This is also a restriction for offline ALTER FRAGMENT . . . MODIFY operations.

```
ALTER FRAGMENT ONLINE ON TABLE employee
  MODIFY INTERVAL TRANSITION TO 300;
```

The following statement runs successfully:

```
ALTER FRAGMENT ONLINE ON TABLE employee MODIFY INTERVAL TRANSITION TO 600;

Fragments in surviving table after ALTER FRAGMENT ONLINE:
p0      VALUES < 200          - range fragment
p1      VALUES < 400          - range fragment
sys_p2rg VALUES < 600        - range fragment (new transition fragment)
sys_p3  VALUES >= 600 AND VALUES < 700 - interval fragment
```

The following examples are also valid:

```
ALTER FRAGMENT ONLINE ON TABLE employee MODIFY INTERVAL TRANSITION TO 700;
ALTER FRAGMENT ONLINE ON TABLE employee MODIFY INTERVAL TRANSITION TO 900;
```

## Examples of the MODIFY clause with interval fragments

Sections that follow illustrate syntax features of the MODIFY clause of the ALTER FRAGMENT statement, and restrictions on what the MODIFY clause can change, for tables that use range and interval fragments as their distribution strategy.

For similar examples of using the MODIFY clause with tables that are fragmented by list, see [Examples of the MODIFY clause for list fragments on page 79](#).

### Enabling or disabling range interval fragmentation

This statement disables range interval fragment creation:

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL DISABLED;
```

The following statement restores range interval fragment creation, undoing the effects of the previous example:

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL ENABLED;
```

The following statement disables range interval fragment creation, and also modifies the list of dbspaces in the STORE IN clause where new fragments will be stored (if a subsequent ALTER FRAGMENT MODIFY statement enables range interval fragment creation for table **tab**).

```
ALTER FRAGMENT ON TABLE tab MODIFY INTERVAL DISABLED
  STORE IN (dbs4, dbs5);
```

## Renaming fragments in range interval fragmentation

This statement renames two range interval fragments. No IN clause specifies new storage locations, so the new names replace the existing names for the two fragments:

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p1 TO PARTITION newp1,
  PARTITION sys_p6 TO PARTITION newsys_p6;
```

The PARTITION keywords are required for range interval fragments. If you use the MODIFY clause to rename an existing fragment, the new name that you declare in the MODIFY clause cannot begin with the character string `sys`, which is reserved for system-defined fragments, but the example above successfully renames the system-defined fragment `sys_p6`.

## Relocating a range or interval fragment

Suppose that the following table was created with range interval fragmentation and received two rows from insert operations:

```
CREATE TABLE tab2 (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES < 100 IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1;

INSERT INTO tab2 VALUES (201, "AA");
  -- creates a system-generated interval fragment sys_p2
  -- with fragment expression >= 200 AND < 300
  -- assume that this fragment is created in dbs1

INSERT INTO tab2 VALUES (601, "BB");
  -- creates a system-generated interval fragment sys_p6
  -- with fragment expression >= 600 AND < 700
  ---assume that this fragment is created in dbs2
```

The following statement instructs the database server to move range fragment `p1` from `dbs1` to `dbs2`:

```
ALTER FRAGMENT ON TABLE tab2 MODIFY
  PARTITION p1 TO PARTITION p1 IN dbs2;
```

The next example moves range fragment `p1` from `dbs1` to `dbs2` and moves interval fragment `sys_p6` from `dbs2` to `dbs3`:

```
ALTER FRAGMENT ON TABLE tab2 MODIFY
  PARTITION p1 TO PARTITION p1 IN dbs2,
  PARTITION sys_p6 TO PARTITION sys_p6 IN dbs3;
```

## Replacing the list of dbspaces that store new interval fragments

The following CREATE TABLE statement defines a range interval fragmentation strategy, in which

- column `i` is the fragmentation key,
- 100 is the range interval size,
- new fragments will be stored in dbspaces `dbs1`, `dbs2`, and `dbs3`,
- the initial fragments `p0` (in dbspace `dbs0`) and `p1` (in dbspace `dbs1`) have transition values of 100 and 200 respectively.

```
CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
```

```
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1;
```

The following ALTER FRAGMENT statement replaces the STORE IN list (`dbs1`, `dbs2`, `dbs3`) with a new list (`dbs4`, `dbs5`).

```
ALTER FRAGMENT ON TABLE tab
MODIFY INTERVAL STORE IN (dbs4, dbs5);
```

In the example above, the MODIFY clause specifies that new fragments will be created alternately in `dbs4` and `dbs5`. Any system-defined fragments (and the fragment **p1**) that were created in dbspaces of the original STORE IN list (`dbs1`, `dbs2`, `dbs3`) remain in those dbspaces. Existing and subsequently inserted rows whose fragmentation-key values are within the range intervals of those fragments continue to be stored in those fragments, but new interval fragments will be created, alternating in round-robin fashion, in the `dbs4` and `dbs5` dbspaces.

Consider that the following fragmented table:

```
CREATE TABLE mytab (col1 int)
FRAGMENT BY RANGE (c1) INTERVAL (100)
STORE IN (dbs1, dbs2, dbs3, dbs4, dbs5)
PARTITION p1 VALUES < 300 in dbs0;
```

This ALTER FRAGMENT statement replaces the list of dbspaces where new interval fragments will be stored:

```
ALTER FRAGMENT ON TABLE mytab MODIFY
STORE IN (dbs1, dbs6, dbs3, dbs4, dbs8);
```

The new list replaces `dbs2` with `dbs6` and replaces `dbs5` with `dbs8`. If you want any of the dbspaces from the current STORE IN list to be available for new fragments, the MODIFY clause must also include them in the new list, which replaces the old list in the modified fragmentation scheme. In the example above, new range interval fragments will be created in the five dbspaces listed after the STORE IN keywords, but any existing fragments that were created in **dbs2** and **dbs5** continue to store rows whose data values match the fragmentation key ranges for those fragments.

You can modify the list of dbspaces in the STORE IN clause. The old list is replaced by the new list that you specify. Existing fragments in the old dbspace are not moved. Consider the following table:

You can move an existing fragment to another dbspace by changing the IN *dbspace* specification for the fragment:

```
CREATE TABLE tab (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1;

INSERT INTO tab VALUES (201, "AA");
-- creates interval fragment sys_p2
-- with fragment expression >= 200 AND < 300
-- (assume that this fragment is created in dbs1)
INSERT INTO tab VALUES (601, "BB");
-- creates interval fragment sys_p6
-- with fragment expression >= 600 AND < 700
-- (assume that this fragment is created in dbs2)
```

The next statement instructs the database server to moves fragment **p1** from **dbs1** to **dbs2**:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p1 TO PARTITION p1 IN dbs2;
```

The next example moves range fragment **p1** from **dbs1** to **dbs2**, and moves interval fragment **sys\_p6** from **dbs2** to **dbs3**;

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p1 TO PARTITION p1 IN dbs2,
PARTITION sys_p6 TO PARTITION sys_p6 IN dbs3;
```

You cannot, however, modify an expression for an interval fragment after the system has generated the fragment. Consider this table:

```
CREATE TABLE tab (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1;

INSERT INTO tab VALUES (201, "AA");
-- creates interval fragment sys_p2
-- with fragment expression >= 200 AND < 300
INSERT INTO tab VALUES (601, "BB");
-- creates interval fragment sys_p6
-- with fragment expression >= 600 AND < 700
```

Now you cannot modify the fragment expression for **sys\_p2** or **sys\_p6**. An error is returned if you try to do so.

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION sys_p6 TO PARTITION sys_p6
VALUES < 900 IN dbs2;
```

The above statement fails with an error.

### Modifying the expression that defines a range fragment

Under some circumstances, you can use the MODIFY clause to change the expression that defines a range fragment; examples that follow illustrate various restrictions on changes that you can make to the expressions that define to range fragments. You cannot, however, modify an expression for an interval fragment after the system has generated that fragment. Consider this table:

```
CREATE TABLE tab (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1;

INSERT INTO tab VALUES (201, "AA");
-- creates interval fragment sys_p2
-- with fragment expression >= 200 AND < 300
INSERT INTO tab VALUES (601, "BB");
-- creates interval fragment sys_p6
-- with fragment expression >= 600 AND < 700
```

Now you cannot modify the expressions for interval fragments **sys\_p2** or **sys\_p6**. The database server returns an error if you try to do so.

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION sys_p6 TO PARTITION sys_p6
VALUES < 900 IN dbs2;
```

The above statement fails with an error.

You can modify an expression for the first intermediate range fragment, but the replacement expression cannot cross adjacent fragment boundaries. This operation can result in data movement. Here is an example;

```

CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES < 100 IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0;

INSERT INTO tab VALUES (301, "AA");
  -- creates interval fragment sys_p3
  -- with fragment expression >= 300 AND < 400
INSERT INTO tab VALUES (601, "BB");
  -- creates interval fragment sys_p6
  -- with fragment expression >= 600 AND < 700

```

All of the ALTER examples below are based on fragments of the table defined in the CREATE statement above. The following ALTER FRAGMENT statement modifies the expression for range fragment **p0**

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < -50 IN dbs0;

```

The following modifies expression for fragment **p0** and also moves the fragment from `dbs0` to `dbs5`

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < -50 IN dbs5;

```

The following statement successfully makes three changes to fragment **p0**:

- modifies the fragment expression for **p0**,
- modifies the fragment name to **newp0**,
- and also moves the renamed fragment from `dbs0` to `dbs5`.

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION newp0
  VALUES < -50 IN dbs5;

```

The next example fails with an error, however, because the new expression for fragment **p0** crosses the boundary of the range of the next adjacent fragment **p1**

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < 250 IN dbs0;

```

The following ALTER FRAGMENT example successfully modifies the expression for range fragment **p1**:

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p1 TO PARTITION p1
  VALUES < 150 IN dbs1;

```

The following modification fails with an error, because the new expression for fragment **p1** crosses the boundary of the previous adjacent fragment **p0**:

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < 50 IN dbs0;

```

If for any reason, as result of the ALTER FRAGMENT MODIFY operation, the rows cannot be moved to the new fragments, an error is returned. This is an example:

```
CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES IS NULL IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0;

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < 100 IN dbs0;
```

As a result of the modification, the resultant table will have the following fragments

```
PARTITION p0 VALUES < 100 IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0
```

If the previous NULL fragment stored any rows (meaning rows in the table that have NULL value for column i), then those rows would not fit in any of the fragments in the new fragmentation scheme. The above ALTER FRAGMENT operation would therefore fail while moving rows.

Also note that the NULL fragment is always the first fragment in the table. Even if the user specifies the NULL fragment as the last fragment during CREATE TABLE or ALTER TABLE operations, it is rearranged as the first fragment in the table, with the smallest **evalpos** value in the fragment list. While modifying first and intermediate range fragments, the database server imposes the restriction that the new expression cannot cross adjacent fragment boundaries. So while modifying the NULL fragment, whatever new expression you specify cannot cross the boundary of the next range or interval fragment. Here is an example:

```
CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES IS NULL IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0;
```

Suppose that the table does not have any rows in fragment **p0**. In this case, **p0** can be modified to a non-NULL fragment.

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0
  VALUES < 250 IN dbs0;
```

Because the new expression for **p0** (**VALUES < 250**) crosses the boundary for **p1** (**VALUES < 200**), however, the example above returns an error.

The following ALTER FRAGMENT statement is possible:

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p0 TO PARTITION p0 VALUES < 150 IN dbs0;
```

You can modify expression for last range fragment (transition fragment) but you can only increase the transition value. There is no data movement in this operation.

```
CREATE TABLE tab (i INT, c CHAR(2))
  FRAGMENT BY RANGE (i)
  INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
```

```

PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1,
PARTITION p2 VALUES < 300 IN dbs0;
-- last range fragment or transition fragment

```

The following modification returns an error, because it attempts to decrease the transition value (from 300 to 250):

```

ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2
VALUES < 250 IN dbs0;

```

The following statement modifies the fragment expression for **p2** (the transition fragment). Because there are not yet any system-generated interval fragments, the new transition value need not align at the interval fragment boundary.

```

ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2
VALUES < 350 IN dbs0;

```

If there are no interval fragments between new and the old transition value, you can update the expression for the last range fragment to `VALUES < new transition value`. Here is an example:

```

CREATE TABLE tab (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
PARTITION p0 VALUES < 100 IN dbs0,
PARTITION p1 VALUES < 200 IN dbs1,
PARTITION p2 VALUES < 300 IN dbs0;
-- last range fragment is the "transition fragment"

INSERT INTO tab VALUES (601, "BB");
-- creates interval fragment sys_p6
-- with fragment expression >= 600 AND < 700
-- (assume that this fragment is created in dbs3)

```

The modified table now has these fragments:

### Fragment

#### Expression and Fragment Type

#### p0

```
VALUES < 100 - range fragment
```

#### p1

```
VALUES < 200 - range fragment
```

#### p2

```
VALUES < 300 - last range fragment (or transition fragment)
```

#### sys\_p6

```
VALUES >= 600 AND VALUES < 700 - interval fragment
```

During the change of transition value, the fragments are modified in a manner that does not cause any data movement.

The following statement modifies the fragment expression for **p2**, the transition fragment (or last range fragment).

```

ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2 VALUES < 500 IN dbs0;

```

The old transition value was 300 and the new transition value is 500. There are no system-generated interval fragments between these range fragments, and the first interval fragments starts at 600. This also means that there is no data rows between 300 and 500, so the expression of the transition fragment (the last range fragment) can be updated to `VALUES < 500` without data movement. Because there are now interval fragments after the new transition value, the new transition value must align at an interval fragment boundary. In this case, the new transition value of 500 aligns with an interval fragment boundary. (The interval fragment need not exist.)

As a result of this modification, the **evalpos** value for subsequent interval fragments changes, and interval fragments are renamed to adhere to the format for system-generated fragment names. After this ALTER TABLE MODIFY operation, the resulting table has these fragments:

### Fragment

#### Expression and Fragment Type

#### p0

`VALUES < 100` - range fragment

#### p1

`VALUES < 200` - range fragment

#### p2

`VALUES < 500` - modified expression for transition fragment

#### sys\_p4

`VALUES >= 600 AND VALUES <700` - interval fragment

Here the modified expression is for fragment **p2**, which is the last range fragment. (This is also called the *transition fragment*, because any fragments to store larger values in the range of the fragment key will be system-generated interval fragments.)

The system-generated interval fragment is renamed to **sys\_p4** because the **evalpos** value changes from 6 to 4 after the expression for the transition fragment changed.

The following modification fails with an error because there are interval fragments beyond the new transition value, and the new transition value does not align at an interval fragment boundary:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2 VALUES YY 550 IN dbs0;
```

The ranges of the possible interval fragments are 300 to 400, 400 to 500, 500 to 600, 600 to 700, and so on, but the new transition value of 550 is not at an interval fragment boundary, and so the database server issues an error.

If there are interval fragments between the new and old transition value, then the new transition value must align to the boundary of an interval fragment (but that interval fragment need not exist), unless the new transition value is beyond the last interval fragment. All interval fragments between the new and old transition values are converted to range fragments, and their expressions are modified to match the range fragment expressions. The expression for the last interval fragment that was converted to a range fragment is updated to `VALUES < new transition value`.

This behavior is illustrated by the following example

```
CREATE TABLE tab (i INT, c CHAR(2))
FRAGMENT BY RANGE (i)
```

```

INTERVAL (100) STORE IN (dbs1, dbs2, dbs3)
  PARTITION p0 VALUES < 100 IN dbs0,
  PARTITION p1 VALUES < 200 IN dbs1,
  PARTITION p2 VALUES < 300 IN dbs0;
  -- last range fragment or transition fragment

INSERT INTO tab VALUES (301, "AA");
  -- creates interval fragment sys_p3
  -- with fragment expression >= 300 AND < 400
  -- (assume this fragment is created in dbs1)
INSERT INTO tab VALUES (601, "BB");
  -- creates interval fragment sys_p6
  -- with fragment expression >= 600 AND < 700
  -- (assume this fragment is created in dbs3)

```

After the two INSERT operations, the table would have these range and interval fragments:

### Fragment

#### Expression and Fragment Type

#### p0

VALUES < 100 - range fragment

#### p1

VALUES < 200 - range fragment

#### p2

VALUES < 300 - range fragment

#### sys\_p3

VALUES >= 300 AND VALUES <400 - interval fragment

#### sys\_p4

VALUES >= 600 AND VALUES <700 - interval fragment

The ALTER FRAGMENT examples that follow are based on this table.

The following example modifies the expression for fragment **p2** (the transition fragment).

```

ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p2 TO PARTITION p2 VALUES < 500 IN dbs0;

```

Because there is an interval fragment (**sys\_p3**) between the old and new transition value, that fragment is converted to range fragment (whose expression becomes VALUES < 400).

And because there are interval fragments beyond the new transition value (for fragment **sys\_p6**), the new transition value must align at an interval fragment boundary, which it does. The possible interval fragments must be an integer multiple of the range interval size (including 400 to 500, 500 to 600, 700 to 800, and so on. The new transition value is 500, which is at an interval fragment boundary. It is also efficient to avoid move data during the transition fragment modification, and to avoid creating any fragments. This can be made possible by converting fragment **sys\_p3** to the new transition fragment, updating its expression to < 500, and renaming it to the name of the old transition fragment.

The resulting table has the following fragments:

**Fragment****Expression and Fragment Type****p0**

VALUES &lt; 100 - range fragment

**p1**

VALUES &lt; 200 - range fragment

**sys\_p2rg**VALUES < 300 - range fragment (This was the old transition fragment, now renamed **sys\_p2rg** in the system generated format **sys\_pevalposrg**.)**p2**VALUES <500 - range fragment (This was previously interval fragment **sys\_p3**. Its expression, modified to a range expression. now defines the new transition fragment)**sys\_p5**VALUES >= 600 AND VALUES <700 - interval fragment (renamed to **sys\_5** as its **evalpos** value changes from 6 to 5 after the transition fragment change)

The following modification of transition fragment **p2** returns an error:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2 VALUES < 550 IN dbs0;
```

The error is issued because there is an interval fragment **sys\_p6** beyond the new transition value, and the new transition value is not aligned at an interval fragment boundary.

The next example modifies the expression for fragment **p2**, which is a transition fragment:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2 VALUES < 750 IN dbs0;
```

Because there are no interval fragments beyond the new transition value, it need not align to an interval fragment boundary.

The resulting table has the following fragments:

**Fragment****Expression and Fragment Type****p0**

VALUES &lt; 100 - range fragment

**p1**

VALUES &lt; 200 - range fragment

**sys\_p2rg**VALUES < 300 - range fragment (This was the old transition fragment, now renamed **sys\_p2rg** in the system generated format **sys\_pevalposrg**.)

**sys\_p3rg**

< 400 - range fragment (This was previously interval fragment **sys\_p3** before its expression was modified to a range expression.)

**p2**

VALUES <750 - range fragment (Previously interval fragment **sys\_p6** before its expression was modified to a range expression. This becomes the new transition fragment.)

## Examples of the MODIFY clause for list fragments

You can use the MODIFY clause to change fragments of a table or index that is fragmented by list, including these modifications:

- Change the names of existing list fragments
- Move the storage location of an existing list fragment to another dbspace
- Modify the expression list for one or more list fragments.

The following ALTER FRAGMENT ON TABLE statement modifies the name, the list of fragment expressions, and the storage location for a fragment of a table that is partitioned by list:

```
ALTER FRAGMENT ON TABLE T2 MODIFY
PARTITION part1 TO PARTITION part11
VALUES ('CA', 'OR', 'TX') IN dbs1;
```

This changes the partition name from **part1** to **part11**, adds the value **'TX'** to the list of expressions for that fragment, and moves the renamed partition into the dbspace **dbs1**.

Examples that follow illustrate these and other uses of the MODIFY clause with list fragmentation schemes, and also illustrate MODIFY operations that fail because of logical restrictions on list fragmentation.

Suppose that this CREATE TABLE statement has defined table **myTable** with the following schema and with a list fragmentation strategy:

```
CREATE TABLE myTable (i int, c char(2))
FRAGMENT BY LIST (c)
PARTITION p1 VALUES ("AB", "CD") IN dbs1,
PARTITION p2 VALUES ("PQ", "RS") IN dbs2,
PARTITION p3 REMAINDER IN dbs3;
```

The next ALTER FRAGMENT statement modifies the storage distribution strategy for the **p2** fragment:

```
ALTER FRAGMENT ON TABLE myTable MODIFY
PARTITION p2 TO PARTITION newp2
VALUES (NULL) IN dbs5;
```

The statement above has these effects on the definition of the fragment and its storage distribution:

- redefines the fragment expression for fragment **p2** to make it a NULL fragment,
- changes the fragment name to **newp2**,

- moves the storage location of that fragment from `dbs2` to `dbs5`,
- and moves any existing data rows that had been stored in fragment **p2** to the remainder fragment **p3**, because the fragment key values ("`PQ`" and "`RS`") in column `c` of those rows do not match the new NULL expression.

If the automatic mode for updating distribution statistics is enabled, an `ALTER FRAGMENT . . . MODIFY` statement that results in data redistribution causes the fragment-level statistics for the affected fragments to be dropped. Table-level statistics, however, are not dropped. Because no fragment-level statistics exist for the affected fragments, the next explicit or automatic `UPDATE STATISTICS` operation on the table will rebuild the fragment-level distributions, and store the results in the system catalog.

The `ALTER FRAGMENT` examples that follow specify modifications to fragments of the **tab** table that this `CREATE TABLE` statement defines with a list fragmentation scheme:

```
CREATE TABLE tab (i int, c char(2))
  FRAGMENT BY LIST (c)
  PARTITION p1 VALUES ("AB", "CD") IN dbs1,
  PARTITION p2 VALUES ("PQ", "RS") IN dbs2,
  PARTITION p3 VALUES (NULL) IN dbs3,
  PARTITION p4 REMAINDER IN dbs4;
```

The following modifies fragment expression for fragment **p1**

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p1 TO PARTITION p1
  VALUES ("AB", "CD", "EF") IN dbs1;
```

The following statement modifies the fragment expression for fragment **p3**:

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p3 TO PARTITION p3
  VALUES ("XX", "YY", "ZZ") IN dbs3;
```

If for any reason, as result of the `ALTER FRAGMENT ON TABLE MODIFY` operation, any rows cannot be moved to the new fragments, an error is returned, as in the following example:

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p3 TO PARTITION p3
  VALUES ("XX", "YY", "ZZ") IN dbs3;
```

As a result of the modification, the resulting storage distribution scheme for the **tab** table will have the following fragments:

```
PARTITION p1 VALUES ("AB", "CD")      IN dbs1,
PARTITION p2 VALUES ("PQ", "RS")      IN dbs2,
PARTITION p3 VALUES ("XX", "YY", "ZZ") IN dbs2
```

If the previous remainder fragment **p3** had a row with value "`AA`" in column `c`, then that row does not fit in any of the fragments in the new fragmentation scheme. The `ALTER FRAGMENT` statement above would therefore fail with an error while attempting to move rows from the remainder fragment.

The next three examples illustrate modifications to the same table fragmentation scheme that will fail because of overlaps.

```
ALTER FRAGMENT ON TABLE tab MODIFY
  PARTITION p2 TO PARTITION p2 VALUES (NULL) IN dbs2;
```

Because the ALTER FRAGMENT statement above attempts to change fragment **p2** into a duplicate NULL fragment, the statement fails with an error, because the NULL fragment **p3** already exists.

The following modification of the same table attempts to modify fragment **p2** into a duplicate remainder fragment:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p2 TO PARTITION p2 REMAINDER IN dbs2;
```

The statement above fails with an error, because the existing fragment **p4** is already defined as a remainder fragment.

The following modification creates a duplicate expression-list value "RS" in two of the fragments:

```
ALTER FRAGMENT ON TABLE tab MODIFY
PARTITION p1 TO PARTITION p1
VALUES ("AB", "CD", "RS") IN dbs1;
```

Because list value "RS" is already defined in the expression list for fragment **p2**, the statement above fails with an error.

For an example of using the MODIFY option to the ALTER FRAGMENT ON INDEX statement, see [Examples of ALTER FRAGMENT ON INDEX statements on page 81](#).

## Examples of ALTER FRAGMENT ON INDEX statements

The following series of examples illustrate the use of ALTER FRAGMENT ON INDEX with the INIT, ADD, DROP, and MODIFY options.

This first example creates an index stored in **dbsp1**:

```
CREATE INDEX item_idx ON items (stock_num) IN dbsp1;
```

The following statement modifies the index to add fragmentation by expression. Values up to 50 are stored in **dbsp1**, values between 51 and 80 in **dbsp2**, and the remainder in **dbsp3**:

```
ALTER FRAGMENT ON INDEX item_idx INIT
FRAGMENT BY EXPRESSION
stock_num <= 50 IN dbsp1,
stock_num > 50 AND stock_num <= 80 IN dbsp2,
REMAINDER IN dbsp3;
```

The following statement adds a new fragment to the index:

```
ALTER FRAGMENT ON INDEX item_idx
ADD stock_num > 80 AND stock_num <= 120 IN dbsp4;
```

The following statement changes the first fragment of the index:

```
ALTER FRAGMENT ON INDEX item_idx
MODIFY dbsp1 TO stock_num <= 40 IN dbsp1;
```

The following statement drops the fragment in **dbsp4** from the index:

```
ALTER FRAGMENT ON INDEX item_idx
DROP dbsp4;
```

The following statement defines an index that is fragmented by expression, with the fragments stored in named partitions of the dbspaces **dbsp1** and **dbsp2**:

```
ALTER FRAGMENT ON INDEX item_idx INIT
PARTITION BY EXPRESSION
PARTITION part1 stock_num <= 10 IN dbsp1,
PARTITION part2 stock_num > 20 AND stock_num <= 30 IN dbsp1,
```

```
PARTITION part3 REMAINDER IN dbsp2;
```

The following statement adds a new named fragment:

```
ALTER FRAGMENT ON INDEX item_idx ADD
PARTITION part4 stock_num > 30 AND stock_num <= 40 IN dbsp2
BEFORE part3;
```

The following statement defines a range interval storage distribution scheme on the index **idx1**:

```
ALTER FRAGMENT ON INDEX idx2 INIT
FRAGMENT BY RANGE(c2)
INTERVAL (NUMTOYMINTERVAL(1, 'MONTH')
PARTITION part0 VALUES < DATE('01/01/2007') IN dbs0,
PARTITION part1 VALUES < DATE('07/01/2007') IN dbs1,
PARTITION part2 VALUES < DATE('01/01/2008') IN dbs2
```

In the example above,

- the fragmentation key is the value of column **c2**,
- the interval value is one month,
- because no STORE IN clause is included, new system-generated interval partitions will be stored in `dbs0`, `dbs1`, and `dbs2` in round-robin fashion;
- the interval partition transition value is 01/01/2008. (This is the smallest value beyond the range of the last user-defined fragment.)

The following statement defines a list storage distribution scheme on the index **idx2**:

```
ALTER FRAGMENT ON INDEX idx2 INIT
FRAGMENT BY LIST(state)
PARTITION part0 VALUES ('KS','IL') IN dbs0,
PARTITION part1 VALUES ('CA','OR') IN dbs0,
PARTITION part2 VALUES (NULL) IN dbs1,
PARTITION part3 REMAINDER IN dbs2;
```

In the list fragmentation example above,

- the fragmentation key is the value of column **state**,
- the expression lists for the first two fragments are each the strings for postal abbreviations of two states,
- and both a NULL fragment (**part2**) and a remainder fragment (**part3**) are defined for rows with fragmentation key values that do not match the first two fragment expression lists.

## ALTER FUNCTION statement

Use the ALTER FUNCTION statement to change the routine modifiers or pathname of a user-defined function. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****ALTER**

```
FUNCTION function(
, parameter_type
)
```

**SPECIFIC FUNCTION**

```
Specific Name29
```

**WITH(****ADD MODIFY DROP**

```
Routine Modifier30
31
```

**MODIFY EXTERNAL NAME =**

```
Shared-Object Filename32
)
```

| Element               | Description                          | Restrictions   | Syntax                                  |
|-----------------------|--------------------------------------|--|---|
| <i>function</i>       | User-defined function to be modified | Must be registered in the database. If the name does not uniquely identify a function, you must enter one or more appropriate values for <i>parameter_type</i> . | <a href="#">Identifier on page 1456</a> |
| <i>parameter_type</i> | Data type of a parameter             | Must be the same data types (and specified in the same order) as in the definition of <i>function</i> .  | <a href="#">Data Type on page 1163</a>  |

**Usage**

The ALTER FUNCTION statement can modify a user-defined function to tune its performance by modifying characteristics that control how the function executes. You can also add or replace related user-defined routines (UDRs) that provide alternatives for the query optimizer, which can improve performance.

All modifications take effect on the next invocation of the function.

Only the UDR owner or the DBA can use the ALTER FUNCTION statement.

## Keywords That Introduce Modifications

Use the following keywords to introduce what you modify in the UDR.

| Keyword  | Effect on Specified Routine Modifier   |
|--|--|
| ADD  | Add a new routine modifier to the UDR  |
| MODIFY   | Change an attribute of the routine modifier  |
| DROP   | Delete the routine modifier from the UDR   |
| MODIFY EXTERNAL NAME (for external functions only) | Replace the file specification of the executable file. When the IFX_EXTEND_ROLE configuration parameter = ON, this option is valid only for users to whom the DBSA has granted the EXTEND role. With IFX_EXTEND_ROLE = OFF (or not set), the UDR owner or the DBA can use this option. |
| WITH   | Introduces all modifications   |

If the routine modifier is a BOOLEAN value, MODIFY sets the value to be `1` (equivalent of using the keyword ADD to add the routine modifier). For example, both of the following statements alter the **func1** function so that it can be executed in parallel in the context of a parallelizable data query:

```
ALTER FUNCTION func1 WITH (MODIFY PARALLELIZABLE);
ALTER FUNCTION func1 WITH (ADD PARALLELIZABLE);
```

See also [Example of Altering Routine Modifiers on page 91](#).

## ALTER INDEX statement

Use the ALTER INDEX statement to change the clustering attribute of an existing index. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****ALTER INDEX***index***TO****NOT**<sup>34</sup>**CLUSTER**

33

| Element      | Description                     | Restrictions | Syntax                                  |
|--------------|---------------------------------|--------------|---|
| <i>index</i> | Name of the index to be altered | Must exist   | <a href="#">Identifier on page 1456</a> |

**Usage**

ALTER INDEX is valid only for indexes that the CREATE INDEX statement created explicitly. ALTER INDEX cannot modify an index on a temporary table, nor an index that the database server created implicitly to support a constraint.

You cannot change the collating order of an existing index. If you use ALTER INDEX to modify an index after the SET COLLATION statement of SQL has specified a non-default collating order, the SET COLLATION statement has no effect on the index.

The ALTER INDEX statement cannot reference a forest of trees index. For information on forest of trees indexes, see [HASH ON clause on page 268](#).

**Related reference**

[RENAME INDEX statement on page 713](#)

[CREATE INDEX statement on page 253](#)

**TO CLUSTER Option**

The TO CLUSTER option causes the database server to reorder the rows of the physical table according to the order of index-key values.

Clustering an index rebuilds the table in a different location within the same dbspace. When you run the ALTER INDEX statement with the `TO CLUSTER` keywords, all of the extents associated with the previous version of the table are released. The resulting newly-built version of the table has no empty extents.

For an ascending index, `TO CLUSTER` puts rows in lowest-to-highest order. For a descending index, the rows are reordered in highest-to-lowest order.

When you reorder, the entire file is rewritten. This process can take a long time, and it requires sufficient disk space to maintain two copies of the table.

33. See [TO CLUSTER Option on page 85](#)

34. See [TO NOT CLUSTER Option on page 86](#)

While a table is clustering, it is locked `IN EXCLUSIVE MODE`. When another process is using the table to which the index name belongs, the database server cannot execute the `ALTER INDEX` statement with the `TO CLUSTER` keywords; it returns an error unless lock mode is set to `WAIT`. (When lock mode is set to `WAIT`, the database server retries the `ALTER INDEX` statement.)

Over time, if you modify the table, you can expect the benefit of an earlier cluster to disappear because rows are added in space-available order, not sequentially. You can recluster the table to regain performance by issuing another `ALTER INDEX TO CLUSTER` statement on the clustered index. You do not need to drop a clustered index before you issue another `ALTER INDEX TO CLUSTER` statement on a currently clustered index.

### Example of clustering an index

The following example shows how you can use the `ALTER INDEX TO CLUSTER` statement to physically order the rows in the **orders** table. The `CREATE INDEX` statement creates an index on the **customer\_num** column of the table. Then the `ALTER INDEX` statement causes the physical reordering of the existing rows within the **orders** table: following

```
CREATE INDEX ix_cust ON orders (customer_num);
ALTER INDEX ix_cust TO CLUSTER;
```

### TO NOT CLUSTER Option

The `TO NOT CLUSTER` option drops the cluster attribute on the specified index without affecting the physical order of rows in the table.

Because no more than one clustered index can exist on a given table, you must use the `TO NOT CLUSTER` option to release the cluster attribute from one index before you assign it to another index on the same table.

### Example of dropping the clustering attribute

The following statements illustrate how to remove clustering from one index and how a second index physically reclusters the table:

```
CREATE UNIQUE INDEX ix_ord ON orders (order_num);

CREATE CLUSTER INDEX ix_cust ON orders (customer_num);
. . .
ALTER INDEX ix_cust TO NOT CLUSTER;

ALTER INDEX ix_ord TO CLUSTER;
```

The first two statements create indexes for the **orders** table and cluster the physical table in ascending order on the **customer\_num** column. The last two statements recluster the physical table in ascending order on the **order\_num** column.

### ALTER PROCEDURE statement

Use the `ALTER PROCEDURE` statement to change the routine modifiers or pathname of a previously defined external procedure. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****ALTER**

```
PROCEDURE procedure(
, parameter_type
)
```

**SPECIFIC PROCEDURE**

```
Specific Name35
```

**WITH(**

```
,
ADD MODIFY DROP
```

```
Routine Modifier36
37
```

**MODIFY EXTERNAL NAME =**

```
Shared-Object Filename38
)
```

| Element               | Description                      | Restrictions   | Syntax                                  |
|-----------------------|----------------------------------|--|---|
| <i>procedure</i>      | User-defined procedure to modify | Must be registered in the database. If the name does not uniquely identify a function, you must enter one or more appropriate values for <i>parameter_type</i> . | <a href="#">Identifier on page 1456</a> |
| <i>parameter_type</i> | Data type of a parameter         | Must be the same data types (and specified in the same order) as in the definition of <i>procedure</i> .   | <a href="#">Data Type on page 1163</a>  |

**Usage**

The ALTER PROCEDURE statement enables you to modify an external procedure to tune its performance by modifying characteristics that control how it executes. You can also add or replace related UDRs that provide alternatives for the optimizer, which can improve performance. All modifications take effect on the next invocation of the procedure.

Only the UDR owner or the DBA can use the ALTER PROCEDURE statement.

If the procedure name is not unique among routines registered in the database, you must enter one or more appropriate values for *parameter\_type*.

The following keywords introduce what you want to modify in *procedure*.

| Keyword | Effect                                    |
|---------|---|
| ADD     | Add a new routine modifier to the UDR     |
| MODIFY  | Change an attribute of a routine modifier |

35. See [Specific Name on page 1521](#)

36. See [Routine modifier on page 1506](#)

37. External routines only

38. See [Shared-Object Filename on page 1518](#)

| Keyword   | Effect   |
|---|--|
| DROP  | Delete a routine modifier from the UDR   |
| MODIFY EXTERNAL NAME (for external procedures only) | Replace the file specification of the executable file. When the IFX_EXTEND_ROLE configuration parameter = ON, this option is valid only for users to whom the DBSA has granted the EXTEND role. With IFX_EXTEND_ROLE = OFF (or not set), the UDR owner or the DBA can use this option. |
| MODIFY EXTERNAL NAME (for external procedures only) | Replace the file specification of the executable file. (Valid only for users who have the EXTEND role)   |
| WITH  | Introduces all modifications   |

If the routine modifier is a BOOLEAN value, MODIFY sets the value to be `T` (equivalent to using the keyword ADD to add the routine modifier). For example, both of the following statements alter the **proc1** procedure so that it can be executed in parallel in the context of a parallelizable data query:

```
ALTER PROCEDURE proc1 WITH (MODIFY PARALLELIZABLE);
ALTER PROCEDURE proc1 WITH (ADD PARALLELIZABLE);
```

See also [Example of Altering Routine Modifiers on page 91](#).

[DROP ROUTINE statement on page 522](#)

## ALTER ROUTINE statement

Use the ALTER ROUTINE statement to change the routine modifiers or pathname of a previously defined user-defined routine (UDR). This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****ALTER**

```
ROUTINE routine(
, parameter_type
)
```

**SPECIFIC ROUTINE**

```
Specific Name39
```

**WITH(****ADD MODIFY DROP**

```
Routine Modifier40
41
```

**MODIFY EXTERNAL NAME =**

```
Shared-Object Filename42
)
```

| Element               | Description                    | Restrictions  | Syntax                                  |
|-----------------------|--------------------------------|---|---|
| <i>routine</i>        | User-defined routine to modify | Must be registered in the database. If the name does not uniquely identify a routine, you must enter one or more appropriate values for <i>parameter_type</i> . | <a href="#">Identifier on page 1456</a> |
| <i>parameter_type</i> | Data type of a parameter       | Must be the same data types (and specified in the same order) as in the definition of <i>routine</i> .  | <a href="#">Data Type on page 1163</a>  |

**Usage**

The ALTER ROUTINE statement allows you to modify a previously defined UDR to tune its performance by modifying characteristics that control how the UDR executes. You can also add or replace related UDRs that provide alternatives for the optimizer, which can improve performance.

This statement is useful when you do not know whether a UDR is a user-defined function or a user-defined procedure. When you use this statement, the database server alters the appropriate user-defined procedure or user-defined function.

All modifications take effect on the next invocation of the UDR.

Only the UDR owner or the DBA can use the ALTER ROUTINE statement.

[DROP ROUTINE statement on page 522](#)

[Arguments on page 1433](#)

#### Related information

[Overloading the Name of a Function on page 247](#)

## Restrictions

If the name does not uniquely identify a UDR, you must enter one or more appropriate values for *parameter\_type*.

When you use this statement, the type of UDR cannot be ambiguous. The UDR that you specify must refer to either a user-defined function or a user-defined procedure. If either of the following conditions exist, the database server returns an error:

- The name (and parameters) that you specify applies to both a user-defined procedure and a user-defined function.
- The specific name that you specify applies to both a user-defined function and a user-defined procedure.

## Keywords That Introduce Modifications

Use these keywords to introduce the items in the UDR that you want to modify:

| Keyword   | Effect   |
|---|--|
| ADD   | Add a routine modifier to the UDR  |
| DROP  | Delete a routine modifier from the UDR   |
| MODIFY  | Change an attribute of the routine modifier  |
| MODIFY EXTERNAL NAME (for external routines only) | Replace the file specification of the executable file. When the IFX_EXTEND_ROLE configuration parameter = ON, this option is valid only for users to whom the DBSA has granted the EXTEND role. With IFX_EXTEND_ROLE = OFF (or not set), the UDR owner or the DBA can use this option. |
| WITH  | Introduces all modifications   |

If the routine modifier is a BOOLEAN value, MODIFY sets the value to be **T** (equivalent to using the keyword ADD to add the routine modifier).

For example, both of the following statements alter the **func1** UDR so that it can be executed in parallel in the context of a parallelizable data query statement:

```
ALTER ROUTINE func1 WITH (MODIFY PARALLELIZABLE);
ALTER ROUTINE func1 WITH (ADD PARALLELIZABLE);
```

## Example of Altering Routine Modifiers

Suppose you have an external function **func1** that is set to handle NULL values and has a cost per invocation set to 40. The following ALTER ROUTINE statement adjusts the settings of the function by dropping the ability to handle NULL values, tunes the **func1** by changing the cost per invocation to 20, and indicates that the function can execute in parallel:

```
ALTER ROUTINE func1(CHAR, INT, BOOLEAN)
  WITH (
    DROP HANDLESNULLS,
    MODIFY PERCALL_COST = 20,
    ADD PARALLELIZABLE
  );
```

Because the name **func1** is not unique to the database, the data type parameters are specified so that the routine signature is unique. If this function had a Specific Name, for example, **raise\_sal**, specified when it was created, you could identify the function with the following first line:

```
ALTER SPECIFIC ROUTINE raise_sal;
```

## ALTER SECURITY LABEL COMPONENT statement

Use the ALTER SECURITY LABEL COMPONENT statement to add one or more new elements to an existing security label component in the current database. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**ALTER SECURITY LABEL COMPONENT** *component* **ADD**

**ARRAY**[

,

*element*

**BEFORE AFTER**

*old\_element*

]

**SET**{

*element*

}

**TREE**(

*element***UNDER***old\_element*

)

| Element            | Description                                | Restrictions   | Syntax                                     |
|--------------------|--|--|--|
| <i>component</i>   | Component to which <i>element</i> is added | Must already exist in the database.  | <a href="#">Identifier on page 1456</a>    |
| <i>element</i>     | New element of <i>component</i>            | Must be unique among elements of this <i>component</i> , and no longer than 32 bytes. The left ( ( ) ) and right ( ) ) parentheses, comma ( , ), and colon ( : ) symbols are not valid characters. | <a href="#">Quoted String on page 1424</a> |
| <i>old_element</i> | Existing element of <i>component</i>       | Must be an element of <i>component</i> .   | <a href="#">Quoted String on page 1424</a> |

## Usage

Only DBSECADM can issue the ALTER SECURITY LABEL COMPONENT statement, which defines new elements of an existing security label component. The new elements become part of any security policy defined in a CREATE SECURITY POLICY statement that references the specified component.

A security label component consists of a set of no more than 64 *elements* that the CREATE SECURITY LABEL COMPONENT statement defines as string constants. Each string constant can have no more than 32 bytes, and each must be unique among elements of this component. The declaration of each element, which is a valid value that the component can have, defines a category of data sensitivity. By adding new elements to an existing component, the ALTER SECURITY LABEL COMPONENT statement expands the set of values that a component can have within a security policy that includes the component, or within a security label that supports the security policy.

When the ALTER SECURITY LABEL COMPONENT statement executes successfully, Informix® updates the following tables of the system catalog of the current database:

- The **sysseclabelcomponentelements** table, to add new rows for each new elements of the component,
- The **sysseclabelcomponents** table, to show the new cardinality of the security elements that comprise the modified security component.

This statement can define new elements of a security label component, but it cannot modify or drop an existing element. If the security design changes so that different elements are required, DBSECADM can add the new elements, if the total number of elements remains within the size and cardinality limits, and not use any obsolete elements in defining labels that include the component.

Alternatively, DBSECADM can use the DROP SECURITY LABEL COMPONENT statement to drop the component, and then use the CREATE SECURITY LABEL COMPONENT statement to redefine a new component that has only the required elements. You cannot, however, drop a security component if it is part of an existing security policy. See [DROP SECURITY statement on page 526](#) for information about restrictions on dropping security label components and other security objects of Informix®.

The security label component to which new elements are added must be one of three component types. The ARRAY, SET, or TREE keyword that immediately follows the *component* name must specify the same component type that the CREATE SECURITY LABEL COMPONENT statement specified when the component was originally defined. The syntax for specifying

the new list of elements depends on whether the specified component is of type ARRAY, SET, or TREE, which are the three types of security component that Informix® supports.

## The ADD ARRAY Clause

A security label component of type ARRAY is an ordered set of no more than 64 elements. The order in which array elements are declared is significant, because it defines a descending order of data sensitivity, with each successive element ranking lower in data sensitivity than the preceding element. The set of label elements of the array and their comma (,) separators must be enclosed between a pair of bracket ( [ ... ] ) symbols. The same new *element* cannot be declared more than once in the same ADD ARRAY clause.

In the ADD ARRAY clause, the BEFORE or AFTER keyword must follow the new element (or a comma-separated list of new elements) to specify the position of the new element within the descending order of data sensitivity. Within restrictions on the size and the number of elements, this syntax enables DBSECADM to insert a new element anywhere in the array, including the highest or the lowest position, or between consecutive existing elements. The ALTER SECURITY LABEL COMPONENT statement fails with an error, however, if the BEFORE or AFTER keyword of the ADD ARRAY clause specifies an array element that was not previously defined, either when the array component was created, or else in a previous ALTER SECURITY LABEL COMPONENT statement that modified the same array component.

If multiple ALTER SECURITY LABEL COMPONENT operations are performed to add elements to the same component of type ARRAY, DBSECADM might not be able to reach the maximum of 64 array elements because of how array elements are encoded. For information on how security elements are encoded, see the Informix® Security Guide.

The following example defines a security label component of type ARRAY called **aquilae** that is an ordered set of five elements, with **imperator** highest in data sensitivity and **asinus** lowest. The subsequent ALTER SECURITY LABEL COMPONENT statement adds two new elements:

- a new element called **legatus** that ranks between **imperator** and **tribunus**
- a new element called **cunctator** that ranks below **asinus** as the new low in data sensitivity.

```
CREATE SECURITY LABEL COMPONENT aquilae
  ARRAY [ "imperator", "tribunus", "centurio", "miles", "asinus" ];

ALTER SECURITY LABEL COMPONENT aquilae
  ADD ARRAY [ "legatus" BEFORE "tribunus","cunctator" AFTER "asinus" ];
```

Successful execution of this ALTER SECURITY LABEL COMPONENT ... ADD ARRAY statement modifies the **aquilae** security label component array, so that the new descending order of component elements becomes this: **imperator, legatus, tribunus, centurio, miles, asinus, cunctator**.

## The ADD SET Clause

A security label component of type SET is an unordered set of no more than 64 elements. The order in which the elements of a SET component are declared is not significant. The set of elements of the array and their comma separators must be enclosed between a pair of braces ( { ... } ) symbols. The same new *element* cannot be declared more than once in the same ADD SET clause.

The following example defines a type SET security label component called **departments** that is an unordered set of three elements, called **Marketing, HR, and Finance**, which the ALTER SECURITY LABEL COMPONENT statement modifies by adding three new elements called **Training, QA, and Security**:

```
CREATE SECURITY LABEL COMPONENT departments
  SET { 'Marketing', 'HR', 'Finance' };

ALTER SECURITY LABEL COMPONENT departments
  ADD SET { 'Training', 'QA', 'Security' };
```

Unlike ADD ARRAY or ADD TREE specifications, ADD SET operations of ALTER SECURITY LABEL COMPONENT do not create "greater than" or "less than" data-sensitivity relationships among the new and existing elements of the redefined component, because the elements of a type SET component have no implicit order of data sensitivity.

## The ADD TREE Clause

A security label component of type TREE has the logical topology of a simple graph with no loops. Each TREE component has a single root node and no more than 63 additional nodes. Any new elements that the ALTER SECURITY LABEL COMPONENT statement adds to this hierarchy must be inserted below the root node. The string constant for each new node must be followed by the keyword UNDER and by the string constant for some previously declared node. The set of elements of the TREE component, including their UNDER keywords and comma separators, must be enclosed between a pair of parenthesis ( ( ... ) ) symbols.

The component element specified after the UNDER keyword is called the *parent* of the new element that precedes the same UNDER keyword. The new element is called the *child* of that parent element. The ALTER SECURITY LABEL COMPONENT statement fails with an error, however, if the ADD TREE clause specifies a parent element that is not already defined in the database for this component. The UNDER keyword cannot be followed by an element that is added to the component in the same ADD TREE clause.

The string constant that designates the root node of a TREE component has the highest data sensitivity of all the nodes within the TREE hierarchy. In any subset of successive parent nodes and child nodes in the tree, each non-root element has lower data sensitivity than its parent element or than any ancestor of its parent element, but has higher data sensitivity than any of its child elements or than the descendants of its child elements.

When a user who holds no exemptions attempts to access a data row that is protected by a label that includes a TREE component, a read operation fails if the security label of the user does not include an element that matches one of the TREE elements for the same component of the data row label, or that matches an ancestor of one of those elements. Unless the security policy of the label includes the OVERRIDE clause, a write operation also fails in the same circumstances. If the data row label has multiple TREE components, the user security label must include a matching (or an ancestral) element value for every TREE component of the data row security label.

In the following example, the ALTER SECURITY LABEL COMPONENT statement modifies a tree component called **Oakland** by adding two new nodes to its tree structure that was defined with six nodes by this CREATE SECURITY LABEL COMPONENT statement:

```
CREATE SECURITY LABEL COMPONENT Oakland
TREE ( 'Port' ROOT,
      'Downtown' UNDER 'Port',
      'Airport' UNDER 'Port',
      'Estuary' UNDER 'Airport',
      'Avenues' UNDER 'Downtown',
      'Hills' UNDER 'Avenues');

ALTER SECURITY LABEL COMPONENT Oakland
ADD TREE ( 'Uptown' UNDER 'Port',
          'Bay' UNDER 'Estuary');
```

Here new **Uptown** node is a child of **Port**, which has the highest data sensitivity because it is the root node. The new **Bay** node is the child of **Estuary**, which is the child of **Airport**, which is the child of **Port**, implying that **Bay** has a lower data sensitivity than these three nodes of the hierarchy. In practice, it is unlikely that any data would be labeled with **Port**, rather than classified at a lower level. The **Port** value might be used for a label granted to a user who is allowed to access all of the data about the **Port**.

If the ALTER SECURITY LABEL COMPONENT statement in this example succeeds, and a subsequently defined data row label specifies **Bay** as its value for the **Oakland** component, a user with no exemption for the security policy who attempts to read the protected row in a query would need either **Port**, **Airport**, **Estuary**, or **Bay** as a user label value to satisfy this component of the data row label. Values of **Uptown** or **Downtown** for this component in the user label are insufficient, because they do not match **Bay** and are not ancestors of **Bay**. For a query to read the protected row, the security label of the user must also include values that satisfy any other components of the row security label, and the user must also hold Select access privilege on the table and at least Connect access privilege on the database that contains the protected row.

The ADD TREE clause cannot interpose a new node between an existing child node and its parent.

## ALTER SEQUENCE statement

Use the ALTER SEQUENCE statement to modify the definition of a sequence object. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****ALTER SEQUENCE***owner.**sequence*

43

**NOCYCLE CYCLE**

43

**CACHE** *size***NOCACHE**

43

**NOORDER** **ORDER**<sup>43</sup>**INCREMENT** **BY***step*<sup>43</sup>**RESTART****WITH***restart*

43

**MAXVALUE***max***NOMAXVALUE**

43

**MINVALUE***min***NOMINVALUE**

| Element         | Description                                   | Restrictions   | Syntax                                      |
|-----------------|---|--|---|
| <i>max</i>      | New upper limit on values                     | Must be integer > <b>CURRVAL</b> and <i>restart</i>  | <a href="#">Literal Number on page 1419</a> |
| <i>min</i>      | New lower limit on values                     | Must be integer < <b>CURRVAL</b> and <i>restart</i>  | <a href="#">Literal Number on page 1419</a> |
| <i>owner</i>    | Owner of <i>sequence</i>                      | Cannot be changed by this statement  | <a href="#">Owner name on page 1488</a>     |
| <i>restart</i>  | New first value in sequence                   | Must be integer in the INT8 range  | <a href="#">Literal Number on page 1419</a> |
| <i>sequence</i> | Name of existing sequence                     | Must exist. Cannot be a synonym.   | <a href="#">Identifier on page 1456</a>     |
| <i>size</i>     | New number of values to preallocate in memory | Integer > 2 but < cardinality of values in one cycle (= $\lfloor (max - min) / step \rfloor$ ) | <a href="#">Literal Number on page 1419</a> |
| <i>step</i>     | New interval between successive values        | Must be a nonzero integer  | <a href="#">Literal Number on page 1419</a> |

**Usage**

The ALTER SEQUENCE statement can update the definition of a specified sequence object in the **syssequences** system catalog table.

43. Use path no more than once

44. Default specification

ALTER SEQUENCE redefines an existing sequence object. It only affects subsequently generated values (and any unused values in the sequence cache). You cannot use the ALTER SEQUENCE statement to rename a sequence nor to change the owner of a sequence.

You must be the owner, or the DBA, or else have the Alter privilege on the sequence to modify its definition. Only elements of the sequence definition that you specify explicitly in the ALTER SEQUENCE statement are modified. An error occurs if you make contradictory changes, such as specifying both MAXVALUE and NOMAXVALUE, or both the CYCLE and NOCYCLE options.

## Examples

The examples below are based on the following sequence object and table:

```
CREATE SEQUENCE seq_2
  INCREMENT BY 1 START WITH 1
  MAXVALUE 30 MINVALUE 0
  NOCYCLE CACHE 10 ORDER;

CREATE TABLE tab1 (col1 int, col2 int);
INSERT INTO tab1 VALUES (0, 0);

INSERT INTO tab1 (col1, col2) VALUES (seq_2.NEXTVAL, seq_2.NEXTVAL)

SELECT * FROM tab1;

      col1      col2
       0         0
       1         1

ALTER SEQUENCE seq_2
  RESTART WITH 5
  INCREMENT by 2
  MAXVALUE 300;

INSERT INTO tab1 (col1, col2) VALUES (seq_2.NEXTVAL, seq_2.NEXTVAL)
INSERT INTO tab1 (col1, col2) VALUES (seq_2.NEXTVAL, seq_2.NEXTVAL)
SELECT * FROM tab1;

      col1      col2
       0         0
       1         1
       5         5
       7         7
```

---

[NEXTVAL and CURRVAL Operators on page 1243](#)

## INCREMENT BY Option

Use the INCREMENT BY option to specify a new interval between successive numbers in a sequence. The interval, or *step* value, can be a positive whole number (for ascending sequences) or a negative whole number (for descending sequences) in the INT8 range. The BY keyword is optional.

## RESTART WITH Option

Use the RESTART WITH option to specify a new first number of the sequence. The *restart* value must be an integer within the INT8 range that is greater than or equal to the *min* value (for an ascending sequence) or that is less than or equal to the *max* value (for a descending sequence), if *min* or *max* is specified in the ALTER SEQUENCE statement. The WITH keyword is optional.

When you modify a sequence using the RESTART option, the *restart* value is stored in the **syssequences** system catalog table only until the first use of the sequence object in a **NEXTVAL** expression. After that, the value is reset in the system catalog. Use of the **dbschema** utility can increment sequence objects in the database, creating gaps in the generated numbers that might not be expected in applications that require serialized integers.

## MAXVALUE or NOMAXVALUE Option

Use the MAXVALUE option to specify a new upper limit of values in the sequence. The maximum value, or *max*, must be an integer in the INT8 range that is greater than *sequence.CURRVAL* and *restart* (or greater than the *origin* in the original CREATE SEQUENCE statement, if *restart* is not specified).

Use the NOMAXVALUE option to replace the current limit with a new default maximum of  $2^{64}$  for ascending sequences or  $-1$  for descending sequences.

## MINVALUE or NOMINVALUE Option

Use the MINVALUE option to specify a new lower limit of values in the sequence. The minimum value, or *min*, must be an integer in the INT8 range that is less than *sequence.CURRVAL* and *restart* (or less than the *origin* in the original CREATE SEQUENCE statement, if *restart* is not specified).

Use the NOMINVALUE option to replace the current lower limit with a default of 1 for ascending sequences or `-(2e64)` for descending sequences.

## CYCLE or NOCYCLE Option

Use the CYCLE option to continue generating sequence values after the sequence reaches the maximum (ascending) or minimum (descending) limit, to replace the NOCYCLE attribute. After an ascending sequence reaches *max*, it generates the *min* value for the next value. After a descending sequence reaches *min*, it generates the *max* value for the next sequence value.

Use the NOCYCLE option to prevent the sequence from generating more values after reaching the declared limit. Once the sequence reaches the limit, the next reference to *sequence.NEXTVAL* returns an error message.

## CACHE or NOCACHE Option

Use the CACHE option to specify a new number of sequence values that are preallocated in memory for rapid access. The cache size must be a whole number in the INT range that is less than the number of values in a cycle (or less than  $(max - min)/step$ ). The minimum size is 2 preallocated values.

Use NOCACHE to have no values preallocated in memory. (See also the description of SEQ\_CACHE\_SIZE in [CREATE SEQUENCE statement on page 326](#).)

## ORDER or NOORDER Option

These keywords have no effect on the behavior of the sequence. The sequence always issues values to users in the order of their requests, as if the ORDER keyword were always specified. The ORDER and NOORDER keywords are accepted by the ALTER SEQUENCE statement, however, for compatibility with implementations of sequence objects in other dialects of SQL.

## ALTER TABLE statement

Use the ALTER TABLE statement to modify the schema of an existing table.

|----------------|-------------------------------------|---|---|
| <i>synonym</i> | Synonym for the table to be altered | Synonym and its table must exist; <b>USETABLENAME</b> must not be set | <a href="#">Identifier on page 1456</a> |
| <i>table</i>   | Name of table to be altered         | Must exist in the current database                                    | <a href="#">Identifier on page 1456</a> |

## Usage

You can use the Basic Table Options segment to modify the schema of a table by adding, modifying, or dropping columns and constraints, or changing the extent size or locking granularity of a table. The database server performs alterations in the order that you specify. If any of the actions fails, the entire operation is canceled. You can associate an existing table with a named ROW type, or specify a new storage space to store large-object data. You can add or drop shadow columns to support secondary-server update operations of the USELASTCOMMITTED feature, or add or drop a **rowid** column. However, a single ALTER TABLE statement cannot specify these options with most other alterations to the schema of the table.

To use ALTER TABLE, your discretionary access privileges must meet at least one of the following conditions:

- You must have DBA privilege on the database that contains the table.
- You must own the table.
- You must have the Alter privilege on the specified table and the Resource privilege on the database where the table resides.
- To add a referential constraint, you must have the DBA or References privilege on either the referenced columns or the referenced table.
- To drop a constraint, you must have the DBA privilege or be the owner of the constraint. If you are the owner of the constraint but not the owner of the table, you must have Alter privilege on the specified table. You do not need the References privilege to drop a constraint.

If you run a slow alter on a table that contains a compressed partition, then the corresponding new partition is compressed. The number of compressed rows in the new partition might differ from the number of compressed rows in the original partition. The difference is caused by the timing of operations to rewrite the rows in the partition and to build the compression dictionary. If the resulting new partition has fewer compressed rows, you can recompress the partition, and optionally repack and shrink it.

The ALTER TABLE statement cannot add a fragmentation strategy to a nonfragmented table, nor modify the storage distribution strategy of a fragmented table. To modify the distributed storage strategy of a table, you must use the ALTER FRAGMENT statement, rather than the ALTER TABLE statement. For information on adding, modifying, or dropping the storage distribution strategy of a table, see the [ALTER FRAGMENT statement on page 22](#).

Altering a table on which a view depends might invalidate the view.

**Warning:** The clauses available with this statement have varying performance implications. Before you undertake alter operations, check information in the [Altering a table definition on page](#) section in your *Informix® Performance Guide* to review effects and strategies.

The table whose name or synonym follows the ALTER TABLE keywords must be a permanent table in the current database. It is subject to the following restrictions:

- It cannot be a temporary table.
- It cannot be a table in a database that is not the current database.
- It cannot be a table object that the CREATE EXTERNAL TABLE statement defined.
- It cannot be a violations table or a diagnostics table.
- If the **USETABLENAME** environment variable is set, you cannot specify a *synonym* for the table in the ALTER TABLE statement.

In addition, you cannot use the ALTER TABLE statement for the following operations:

- Add, drop, or modify a column in a table that has an associated violation table or diagnostics table.
- Define a referential constraint or a unique constraint on a RAW table.
- Define an index on a column or on a set of columns that would conflict with the [Restrictions on columns as index keys on page 261](#).

## Add or drop specialized columns

You can add or drop specialized columns when you alter a table. Most specialized columns are shadow columns that support Enterprise Replication or high availability.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

Adding or dropping specialized columns

### ADD DROP

### CRCOLS ERKEY REPLCHECK ROWIDS VERCOLS

## Usage

The following keywords control one or more specialized columns.

### CRCOLS

The ADD CRCOLS keywords create shadow columns, **cdrserver** and **cdrtime**, that Enterprise Replication uses for conflict resolution. If Enterprise Replication is active while you are altering the table with the ADD CRCOLS clause, you must first put the table in alter mode with the `cdr alter` command. Altering a table to add the CRCOLS shadow columns can be a slow alter operation, if any of the table columns have data types that require a slow alter. Slow alter operations require disk space at least twice the size of the original table plus log space. For information on the performance implications of ALTER TABLE statements, see [Altering a table definition on page](#) .

Use the DROP CRCOLS keywords to drop the **cdrserver** and **cdrtime** shadow columns. You must stop replication before you drop the **cdrserver** and **cdrtime** shadow columns.

For more information, refer to [Using the WITH CRCOLS Option on page 372](#).

### ERKEY

The ADD ERKEY keywords create shadow columns, **ifx\_erkey\_1**, **ifx\_erkey\_2**, and **ifx\_erkey\_3**, that Enterprise Replication uses in place of a primary key. If Enterprise Replication is active while you are altering the table with the ADD ERKEY clause, you must first put the table in alter mode with the `cdr alter` command. Altering a table to add the ERKEY shadow columns is a slow alter operation.

Use the DROP ERKEY keywords to drop the **ifx\_erkey\_1**, **ifx\_erkey\_2**, and **ifx\_erkey\_3** shadow columns.

For more information, see [Using the WITH ERKEY Keywords on page 373](#).

### REPLCHECK

The ADD REPLCHECK keywords create the shadow column, **ifx\_replcheck**, that you can create an index on, along with your primary key, to speed the processing of consistency checking with Enterprise Replication. If Enterprise Replication is active while you are altering the table with the ADD REPLCHECK clause, you must first put the table in alter mode with the `cdr alter` command. Altering a table to add the **ifx\_replcheck** shadow column is a slow alter operation, which requires disk space at least twice the size of the original table plus log space.

Use the DROP REPLCHECK keywords to drop the **ifx\_replcheck** shadow column.

For more information, see [Using the WITH REPLCHECK Keywords on page 374](#).

## ROWIDS

**!** **Important:** This is a deprecated feature. The query optimizer might not use an index scan when explicit **rowid** shadow columns are defined on fragmented tables. When you create new applications, use primary keys as a method of row identification instead of using **rowid** values.

Use the ADD ROWIDS keywords to add a column called **rowid** to a fragmented table. (Fragmented tables do not contain the hidden **rowid** column by default.) When you add a **rowid** column, the database server assigns a unique number to each row that remains stable for the life of the row. The database server creates an index that it uses to find the physical location of the row. After you add the **rowid** column, each row of the table contains an additional 4 bytes to store the **rowid** value. Use the ADD ROWIDS clause only on fragmented tables. In nonfragmented tables, the **rowid** column remains unchanged.

The DROP ROWIDS keywords can drop a **rowid** column that you added (with either the ALTER TABLE or ALTER FRAGMENT statement) to a fragmented table.

## VERCOLS

The ADD VERCOLS keywords create shadow columns, **ifx\_insert\_checksum** and **ifx\_row\_version**, that are used to support secondary server updates. Altering a table to add row versioning columns is a fast alter operation.

Use the DROP VERCOLS keywords to drop the **ifx\_insert\_checksum** and **ifx\_row\_version** shadow columns.

For more information, see [Using the WITH VERCOLS Option on page 374](#) and [Row versioning on page 374](#).

### Example

#### Example: ADD CRCOLS

In the following example, the **cdserver** and **cdtime** shadow columns are added to the **customer** table:

```
ALTER TABLE customer ADD CRCOLS;
```

### Example

#### Example: ADD ERKEY

The following example adds the **ifx\_erkey\_1**, **ifx\_erkey\_2**, and **ifx\_erkey\_3** columns to the **customer** table:

```
ALTER TABLE customer ADD ERKEY;
```

### Example

#### Example: ADD REPLCHECK and DROP REPLCHECK

In the following example, the **ifx\_replcheck** shadow column is added to the **customer** table:

```
ALTER TABLE customer ADD REPLCHECK;
```

The following example drops the **ifx\_replcheck** column from the **customer** table:

```
ALTER TABLE customer DROP REPLCHECK;
```

### Example

**Example: DROP ROWIDS**

The following example drops the **rowid** column from the **frag1** table:

```
ALTER TABLE frag1 DROP ROWIDS;
```

**Example****Example: ADD VERCOLS**

In the following example, the **ifx\_insert\_checksum** and **ifx\_row\_version**, shadow columns are added to the **customer** table:

```
ALTER TABLE customer ADD VERCOLS;
```

## ADD Column Clause

Use the ADD Column clause to add a column to a table, and to define constraints on the new column. This clause can also associate a security policy with a table that has no security policy, or can specify a security label for the new column, if the table already has a security policy.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

ADD Column Clause

**ADD**

```
(  
, New Column  
)
```

New Column

New Column

*new\_column*

Data Type <sup>62</sup>

<sup>66</sup> DEFAULT Clause <sup>63</sup>

<sup>66</sup> Single-Column Constraint Format <sup>64</sup>

**BEFORE** *column* <sup>67</sup>

Add Column SECURED WITH label clause <sup>65</sup>

| Element       | Description   | Restrictions                    | Syntax                                  |
|---------------|---|---------------------------------|---|
| <i>column</i> | Name of column before which <i>new_column</i> is to be placed | Must already exist in the table | <a href="#">Identifier on page 1456</a> |

62. See [Data Type on page 1163](#)

63. See [DEFAULT clause of ALTER TABLE on page 107](#)

64. See [Single-Column Constraint Format on page 111](#)

65. See [Add column SECURED WITH label clause on page 117](#)

66. Use this path no more than once

67. See [BEFORE Clause on page 107](#)

| Element           | Description                        | Restrictions  | Syntax                                  |
|-------------------|------------------------------------|---|---|
| <i>new_column</i> | Name of column that you are adding | You cannot add a serial column if the table contains data | <a href="#">Identifier on page 1456</a> |

The following restrictions apply to the ADD clause:

- You cannot add a serial column to a table that contains data.
- You cannot add columns beyond the maximum row size of 32,767 bytes.

### Restrictions on adding columns of type `IDSSECURITYLABEL`

The following restrictions affect the use of the ADD Column clause to add a column of the `IDSSECURITYLABEL` data type to support a label-based access control (LBAC) security policy:

- If the table has no security policy, a user who holds the `DBSECADM` role must also include the `ADD SECURITY POLICY` keywords to specify an LBAC security policy, as in this example:

```
CREATE TABLE tA
  (Col_1 BIGINT
   Col_2 INTERVAL(YEAR TO MONTH);
   Col_3 VARCHAR (255));
. . .
ALTER TABLE tA
  ADD (Col_4 IDSSECURITYLABEL DEFAULT 'label4'), --to add this column
  ADD SECURITY POLICY Watchdog; --a security policy is also required
                                -- and 'label4' must be a Watchdog label
```

- Only a user who holds the `DBSECADM` role can add a column of type `IDSSECURITYLABEL`.
- A table can have at most one column of type `IDSSECURITYLABEL`.
- The `IDSSECURITYLABEL` column cannot have `SECURED WITH` column protection.
- The `IDSSECURITYLABEL` column has an implicit NOT NULL constraint by default. If no *label* name for the default security label is specified in the DEFAULT clause, the default value for this column is the security label for write access that is held by the current user.
- The `IDSSECURITYLABEL` column cannot have any explicit single-column constraints, and it cannot be part of multiple-column referential or check constraints.

For the ALTER TABLE syntax to add or drop row-level LBAC protection for the table, see [SECURITY POLICY Clause on page 160](#).

For the ALTER TABLE syntax to add column-level protection for a new column in a table already protected by an LBAC security policy, see [Add column SECURED WITH label clause on page 117](#).

For the ALTER TABLE syntax to add or drop column-level LBAC protection for an existing column, see [Modify Column Security clause on page 148](#).

## Logical Character Support in Character Columns

For new columns that you declare as built-in character data types, explicit or default size specifications are interpreted in units of bytes, unless the `SQL_LOGICAL_CHAR` configuration parameter has enabled logical character semantics for the current database. This feature is designed to reduce the risk of truncating data strings in locales that support a multibyte code set, such as **UTF-8**. Enabling this feature causes the SQL parser to interpret the declared column size as units of logical characters, rather than as bytes, and multiplies the declared storage size allocated for the new character column by a positive integer value, based on the `SQL_LOGICAL_CHAR` setting.

- If the value of this setting is `OFF` or `1`, the `SQL_LOGICAL_CHAR` configuration parameter has no effect.
- If the value of this setting is `ON`, rather than a digit, the expansion factor is the number of bytes that are required to store the largest logical character in the code set of the database. (The `ON` setting is equivalent to `4`, which is the largest valid digit.)

The value of this expansion factor is an attribute of the database, and is based on the `SQL_LOGICAL_CHAR` setting when the database was created, rather than when the `ALTER TABLE` statement is issued, if the two settings are not identical.

For columns that you declare as `VARCHAR` or `NCHAR` data types when this feature is enabled, only the maximum size specification is expanded by this feature. The reserved size is the number of bytes specified by the explicit or default *reserved* value in the data type declaration, because the minimum size of a logical character is 1 byte.

Size specifications for character columns of user-defined types (UDTs) are always interpreted as bytes, and are not affected by this feature. Columns that store strings as large objects, such as `CLOB` and `TEXT`, are similarly unaffected.

For more information about the `SQL_LOGICAL_CHAR` configuration parameter, see your . For additional information about multibyte locales and logical characters, see the *Informix® GLS User's Guide*.

## BEFORE Clause

The optional `BEFORE` clause determines the ordinal positions of the new columns within the schema of the table by specifying the name of an existing column before which the `ALTER TABLE ADD` statement inserts the new columns.

### About this task

In the following example, the `BEFORE` option directs the database server to add the `item_weight` column before the `total_price` column:

```
ALTER TABLE items
  ADD (item_weight DECIMAL(6,2) NOT NULL BEFORE total_price);
```

By default, if you do not include the `BEFORE` clause, the database server appends the new columns after the last column in the current schema of the table, in their lexical order within the `ADD` clause.

## DEFAULT clause of ALTER TABLE

Use the DEFAULT clause of the ALTER TABLE statement to specify value that the database server should insert in a column in DML operations that specify no explicit value for the column.

This syntax fragment is part of the [ADD Column Clause on page 105](#) and the [MODIFY Clause on page 143](#).

DEFAULT Clause

**DEFAULT**

*label literal*

**NULL**

**USER CURRENT\_USER**

68

**CURRENT SYSDATE**

DATETIME Field Qualifier <sup>69</sup>

**TODAY**

**SITENAME DBSERVERNAME**

| Element        | Description                          | Restrictions  | Syntax                                  |
|----------------|--------------------------------------|---|---|
| <i>label</i>   | Name of a security label             | Must exist and must belong to the security policy that protects the table. The column must be of type IDSSECURITYLABEL.   | <a href="#">Identifier on page 1456</a> |
| <i>literal</i> | Literal default value for the column | Must be appropriate for the data type of the column. See <a href="#">Using a Literal as a Default Value on page 351</a> . | <a href="#">Expression on page 1193</a> |

### Usage

If the table that you are altering already has rows in it when you use the ALTER TABLE ADD statement to add a column that contains a default value, the default values are applied to all existing rows and rows inserted after the ALTER TABLE ADD statement that added the new column.

Similarly, when the ALTER TABLE MODIFY statement uses the DEFAULT clause to define a new default value for a column that had no default or that had a different default, the rows that existed before the column was modified are unchanged, unless you update those rows to insert some NULL or non-NULL value. New rows that you insert will have the default value that the DEFAULT clause of the ALTER TABLE MODIFY statement specified, unless you insert some other value into the new column.

You cannot specify a default value for columns of type SERIAL, SERIAL8, or BIGSERIAL. For information about using the ALTER TABLE MODIFY statement to set the next value of a serial column to an arbitrary value higher than the current maximum, see [Altering the Next Serial Value on page 146](#).

For columns of DISTINCT or OPAQUE data types, you cannot specify as the default value a constant expression (such as CURRENT, SYSDATE DBSERVERNAME, SITENAME, TODAY, USER, or CURRENT\_USER) that behaves like a variant function.

68. Informix® extension

69. See [DATETIME Field Qualifier on page 1191](#)

## The DEFAULT NULL keywords

If you use the ALTER TABLE ADD statement to add a new column with an explicit default value, or if you use the ALTER TABLE MODIFY statement to change the data type or the default value of an existing column, the following restrictions apply to `NULL` as a default value:

- For columns of large-object data types like BYTE, TEXT, BLOB, or CLOB, or for columns of key-value pair (KVP) data types like BSON or JSON, the only valid default value is `NULL`.
- If you specify `NULL` as the default value for a column, you cannot specify a NOT NULL constraint as part of the column definition. (For details of NOT NULL constraints, see [Using the NOT NULL Constraint on page 354.](#))
- `NULL` is not a valid default value for a column that is part of a primary key.
- Serial columns cannot have a default value, including `DEFAULT NULL`.
- If a column was created or altered with no DEFAULT clause, and with no implicit or explicit NOT NULL constraint, its implicit default value is `NULL`.

## Examples of default column values

The following statement adds column `item_velocity` to the `items` table, with `NULL` as its implicit default value:

```
ALTER TABLE items
  ADD (item_velocity DECIMAL(6,3) BEFORE total_price);
```

The following statement modifies the default value of column `item_velocity` by replacing `NULL` with an explicit default value:

```
ALTER TABLE items
  MODIFY (item_velocity DECIMAL(6,3) DEFAULT 299792.458);
```

Each existing row in the `items` table has the default value of `NULL` for the `item_velocity` column. Any new rows have the default value of `299792.458`.

The next example adds a new column of data type `CHAR(12)` to the `items` table, where the new `item_color` column has an explicit default value of `translucent`:

```
ALTER TABLE items
  ADD (item_color CHAR(12) DEFAULT "translucent"
  BEFORE item_velocity);
```

Suppose that table `tabB` has the following schema:

```
CREATE TABLE tabB
(
  id VARCHAR(128) NOT NULL,
  data DATE DEFAULT TODAY,
  modcount BIGINT,
  flags INTEGER DEFAULT 12,
);
```

The following statement modifies `tabB` by changing the data type and the default value of the `data` column from type `DATE` with a default of `TODAY` to a `BSON` type with a default of `NULL`:

```
ALTER TABLE tabB
  MODIFY ( data "informix".BSON DEFAULT NULL);
```

The original default value of `TODAY` for the `data` column is not valid for a key-value pair data type like `BSON`.

For more information about the options of the `DEFAULT` clause, refer to the [DEFAULT clause of CREATE TABLE on page 350](#) topic of the `CREATE TABLE` statement.

## DEFAULT security labels

When `DBSECADM` adds a `IDSSECURITYLABEL` column to a table that is protected by a security policy, the `DEFAULT label` specification is required unless the table is empty. If the table is not empty, the specified `label` is inserted into the existing rows of the table

If the `DEFAULT` value is the name of a security label, an error is issued in the following cases:

- if the `label` is the default value for a column whose data type is not `IDSSECURITYLABEL`,
- or if the table has no security policy,
- or if the security policy of the `label` is not the security policy of the table.

The same `ALTER TABLE` statement that adds the `IDSSECURITYLABEL` column can add a security policy.

To define a specific `label` as the default value of an `IDSSECURITYLABEL` column, specify the `label` name without the `policy` qualifier, rather than as `policy.label`. The current security policy of the table is the only valid policy for any security label that protects data in the table.

### Examples of security labels as default values

The `ALTER TABLE` statement in the following example adds security policy **MegaCorp** to table **T1** and specifies column-level protection for the table by declaring a new column **D** of type `IDSSECURITYLABEL`, whose default value is a security label called **mylabel**:

```
ALTER TABLE T1
  ADD (D IDSSECURITYLABEL DEFAULT myLabel1)
  ADD SECURITY POLICY MegaCorp;
```

Because no `BEFORE` clause is included, column **D** is last among the columns in the schema of table **T1**. This statement fails if any of the database objects that it references (except new column **D**) does not already exist in the database, or if the table already has a different security policy.

To replace the security policy of a table, you must hold the `DBSECADM` role. You must first use the `ALTER TABLE DROP SECURITY POLICY` statement to drop the current security policy and any of its labels from the table. Then you must add the new security policy, and at least one of its labels, as in the following example:

```
ALTER TABLE T1
  DROP SECURITY POLICY MegaCorp;
ALTER TABLE T1
  ADD (D IDSSECURITYLABEL DEFAULT myNewLabel1)
  ADD SECURITY POLICY Watchdog;
```

In these `ALTER TABLE` statements that reference table **T1**,

- The DROP SECURITY POLICY clause of the first statement removes table **T1** from the protection of the **MegaCorp** security policy,
- and automatically drops from the schema of table **T1** any IDSSECURITYLABEL column that stores a label of the **MegaCorp** security policy. This has no effect, however, on other tables in the database that are protected by the **MegaCorp** security policy.
- The `ADD (D IDSSECURITYLABEL DEFAULT myNewLabel1)` clause protects table **T1** with the **myNewLabel1** security label,
- and the `ADD SECURITY POLICY Watchdog` clause replaces **MegaCorp** with **Watchdog** as the new security policy of table **T1**.

The second ALTER TABLE example fails unless the **myNewLabel1** security label is a label of the **Watchdog** security policy.

For more information about using the ALTER TABLE statement to add, modify, or drop an association between a table and a label-based security policy, see [Modify Column Security clause on page 148](#) and [SECURITY POLICY Clause on page 160](#). See also the DDL statements for creating label-based security objects, including [CREATE SECURITY POLICY statement on page 322](#), [CREATE SECURITY LABEL statement on page 316](#), and [CREATE SECURITY LABEL COMPONENT statement on page 318](#).

## Single-Column Constraint Format

Use the Single-Column Constraint Format to associate one or more constraints with a single column when you alter a table.

This syntax fragment is part of the [ADD Column Clause on page 105](#) and the [MODIFY Clause on page 143](#).

Single-Column Constraint Format

**NULL NOT NULL**

**UNIQUE**

<sup>70</sup>**DISTINCT**

**PRIMARY KEY**

REFERENCES Clause<sup>72</sup>

CHECK Clause<sup>73</sup>

<sup>70</sup>

Constraint Definition<sup>71</sup>

You cannot specify a primary-key or unique constraint on a new column if the table contains data. In the case of a unique constraint, however, the table can contain a *single* row of data. When you want to add a column with a primary-key constraint, the table must be empty when you issue the ALTER TABLE statement.

The following rules apply when you place primary-key or unique constraints on existing columns:

70. Informix® extension

71. See [Constraint Definition on page 112](#)

72. See [REFERENCES Clause on page 114](#)

73. See [CHECK Clause on page 117](#)

- When you place a primary-key or unique constraint on a column or on a set of columns, the database server creates an internal B-tree index on the constrained column or set of columns, and automatically calculates column statistics, equivalent to distributions created by the UPDATE STATISTICS statement in HIGH mode, unless a user-created index was already defined on the same column or set of columns.
- When you place a primary-key or unique constraint on a column or set of columns, and a unique index already exists on that column or set of columns, the constraint shares that index. If the existing index allows duplicates, however, the database server returns an error. You must then drop the existing index before you can add the constraint.
- When you place a primary-key constraint or a unique constraint on a column or on a set of columns on which a referential constraint already exists, the existing index that enforces the constraint is upgraded to UNIQUE (if possible), and the index is shared.

You cannot place a unique constraint on a BYTE or TEXT column, nor can you place referential constraints on columns of these data types. A check constraint on a BYTE or TEXT column can check only for IS NULL, IS NOT NULL, or LENGTH.

The statement fails with an error if you specify both a NOT NULL constraint and a NULL constraint on the same column. You cannot define a NULL constraint on a column whose data type is LIST, MULTISSET, SET, or IDSSECURITYLABEL.

The IDSSECURITYLABEL column has an implicit NOT NULL constraint, but it cannot have explicit single-column constraints nor be part of multiple-column referential constraints or check constraints. If the constraint is on a column that stores encrypted data, Informix® cannot enforce the constraint.

#### Important:

You cannot use the Single-Column Constraint Format to add a new column with a foreign-key constraint in ENABLED NOVALIDATE or FILTERING WITH ERROR NOVALIDATE or FILTERING WITHOUT ERROR NOVALIDATE constraint mode. For the ALTER TABLE statement to create a new foreign-key constraint with the NOVALIDATE keyword bypassing violations-checking during the ALTER TABLE operation, you must use the ALTER TABLE ADD CONSTRAINT syntax with the Multiple-Column Constraint Format.

---

#### Related reference

[Choosing a Constraint-Mode Option on page 363](#)

## Using NOT NULL Constraints with ADD COLUMN

If a table contains data, when you add a column with a NOT NULL constraint you must also include a DEFAULT clause.

If the table is empty, however, you can add a column and apply only the NOT NULL constraint. The following statement is valid whether or not the table contains data:

```
ALTER TABLE items
  ADD (item_weight DECIMAL(6,2)
  DEFAULT 2.0 NOT NULL
  BEFORE total_price);
```

## Usage

If the ALTER TABLE statement includes the Single-Column Constraint format or the Multiple-Column Constraint format, but the Constraint Definition is empty, the database server creates and enables whatever type of constraint the Single-Column Constraint or Multiple-Column Constraint format specified, assigns to the constraint a system-generated identifier and a default object state, and registers these attributes in the **sysconstraints** and **sysobjstate** system catalog tables.

If you specify no mode for the constraint, the constraint is enabled by default.

The optional `ON DELETE CASCADE` keywords can precede or follow the declaration of the constraint name. For referential constraints, the `ON DELETE CASCADE` keywords instructs the database server to delete foreign-key rows from the child tables when it deletes rows with the corresponding primary key from the parent table. For more information on the effects of these keywords on DELETE operations, see [Using the ON DELETE CASCADE Option on page 116](#).

While creating and enabling foreign-key or check constraints that the ALTER TABLE ADD CONSTRAINT statement defines, the `NOVALIDATE` keyword prevents the database server from checking every row of the table for compliance with the constraint while the ALTER TABLE statement is running. For more information on the restrictions and effects of this keyword for foreign-key constraints, see [Creating foreign-key constraints in NOVALIDATE modes on page 128](#).

Just as in the CREATE TABLE statement, you cannot define unique constraints, primary-key constraints, or referential constraints on a BYTE or TEXT column. In addition, the table cannot be a RAW table.

For more information about constraint-mode options, see [Choosing a Constraint-Mode Option on page 363](#).

## REFERENCES Clause

This syntax fragment is part of the [Single-Column Constraint Format on page 111](#).

REFERENCES Clause

**REFERENCES** *table*

```
(
, column
)
74 ON DELETE CASCADE
```

| Element       | Description                               | Restrictions   | Syntax                                  |
|---------------|---|--|---|
| <i>column</i> | Referenced column in the referenced table | See <a href="#">Restrictions on Referential Constraints on page 115</a> .  | <a href="#">Identifier on page 1456</a> |
| <i>table</i>  | The referenced table                      | The referenced and the referencing tables must reside in the same database | <a href="#">Identifier on page 1456</a> |

The REFERENCES clause allows you to place a foreign-key constraint on one or more columns. The referenced column can be in the same table as the referencing column, or in a different table in the same database.

For example, the following example declares a disabled foreign-key constraint called **detail\_fork1** on the **detail** table.

74. Informix® extension

```
CREATE TABLE master (col_one INT, col_two CHAR);
CREATE TABLE detail (col_one INT, col_twain CHAR);
. . .
ALTER TABLE detail ADD CONSTRAINT (FOREIGN KEY ( col_one )
REFERENCES master( col_one ) CONSTRAINT detail_fork1 DISABLED);
```

In DISABLED mode, **detail\_fork1** has no effect, but if it were subsequently enabled, it would restrict INSERT and UPDATE operations on the **detail** table to rows whose column **col\_one** values matched existing values in column **col\_one** of the referenced **master** table. In the ALTER TABLE statement above, the parentheses (FOREIGN KEY . . . DISABLED) that delimit the new referential constraint definition are optional.

If the referenced table is different from the referencing table, the default *column* is the primary-key column. If the referenced table is the same as the referencing table, there is no default.

The optional ON DELETE CASCADE keywords can either be specified the last keywords in the REFERENCES clause, or they can follow the declaration of the constraint name in the Constraint definition.

For more information on the effects of these keywords in DELETE operations, see [Using the ON DELETE CASCADE Option on page 116](#).

## Restrictions on Referential Constraints

You must have the REFERENCES privilege to create a referential constraint.

The following restrictions apply to the *column* that is specified (the referenced column) in the REFERENCES clause:

- The referenced and referencing tables must be in the same database.
- The referenced column (or set of columns) must have a unique or primary-key constraint.
- The referencing and referenced columns must be the same data type.
 

The only exceptions are that a referencing column must be an integer data type if the referenced column is a serial data type:

  - For BIGSERIAL referenced columns, use BIGINT referencing columns.
  - For SERIAL referenced columns, use INT referencing columns.
  - For SERIAL8 referenced columns, use INT8 referencing columns.
- You cannot place a referential constraint on a BYTE or TEXT column.
- You cannot place a constraint on any column of a RAW table.
- Constraints uses the collation in effect at their time of creation.
- A column-level REFERENCES clause can include only a single column name.
- Maximum number of columns in a table-level REFERENCES clause is 16.
- The total length of the columns in a table-level REFERENCES clause cannot exceed 390 bytes.

## Default Column for the References Clause

If the referenced table is different from the referencing table, you do not need to specify the referenced column; the default column is the primary-key column (or columns) of the referenced table. If the referenced table is the same as the referencing table, you must specify the referenced column.

The following example creates a new column in the **cust\_calls** table, **ref\_order**. The **ref\_order** column is a foreign key that references the **order\_num** column in the **orders** table.

```
ALTER TABLE cust_calls
  ADD ref_order INTEGER
  REFERENCES orders (order_num)
  BEFORE user_id;
```

When you place a referential constraint on a column or set of columns, and a duplicate or unique index already exists on that column or set of columns, the index is shared.

## Using the ON DELETE CASCADE Option

Use the ON DELETE CASCADE option if you want rows deleted from the child table when the DELETE or MERGE statement removes corresponding rows from the parent table.

Here the *parent table* is the table specified in the REFERENCING clause of the definition of an enabled foreign key constraint, and the *child table* is the table on which the enabled foreign key constraint is defined. If you do not specify cascading deletes, the default behavior of the database server prevents DELETE and MERGE statements from deleting data in a table that another table references within a primary-key foreign-key relationship.

If you specify this option, when you delete a row in the parent table, the database server also deletes any rows associated with that row (foreign keys) in a child table. The advantage of the ON DELETE CASCADE option is that it allows you to reduce the quantity of SQL statements needed to perform delete actions.

For example, in the **stores\_demo** database, the **stock** table contains the **stock\_num** column as a primary key. The **catalog** table refers to the **stock\_num** column as a foreign key. The following ALTER TABLE statements drop an existing foreign-key constraint (without cascading delete) and add a new constraint that specifies cascading deletes:

```
ALTER TABLE catalog DROP CONSTRAINT aa;

ALTER TABLE catalog ADD CONSTRAINT
  (FOREIGN KEY (stock_num, manu_code) REFERENCES stock
  ON DELETE CASCADE CONSTRAINT ab);
```

With cascading deletes specified on the child table, in addition to deleting a stock item from the **stock** table, the delete cascades to the catalog table that is associated with the **stock\_num** foreign key. This cascading delete works only if the **stock\_num** that you are deleting was not ordered; otherwise, the constraint from the **items** table would disallow the cascading delete. For more information, see [Restrictions on DELETE When Tables Have Cascading Deletes on page 490](#).

If a table has a trigger with a DELETE trigger event, you cannot define a cascading-delete referential constraint on that table. You receive an error when you attempt to add a referential constraint that specifies ON DELETE CASCADE to a table that has a delete trigger.

The TRUNCATE statement cannot result in cascading deletes from a child table. The target table of the TRUNCATE statement cannot be referenced in the definition of an enabled foreign-key constraint on another table (unless that child table has no rows).

For information about syntax restrictions and locking implications when you delete rows from tables that have cascading deletes, see [Considerations When Tables Have Cascading Deletes on page 490](#).

## Locks Held During Creation of a Referential Constraint

When you create a referential constraint, the database server places an exclusive lock on the referenced table. The lock is released after you finish with the ALTER TABLE statement or at the end of a transaction (if you are altering the table in a database that uses transaction logging).

## CHECK Clause

A check constraint designates a condition that must be met before data can be inserted into a column.

This syntax fragment is part of the [Single-Column Constraint Format on page 111](#).

CHECK Clause

### CHECK

```
(
Condition75
)
```

During an insert or update, if a row returns *false* for any check constraint defined on a table, the database server returns an error. No error is returned, however, if a row returns NULL for a check constraint. In some cases, you might want to use both a check constraint and a NOT NULL constraint.

Check constraints are defined using *search conditions*. The search condition cannot contain user-defined routines, subqueries, aggregates, host variables, or rowids. In addition, the condition cannot contain the variant built-in functions CURRENT, SYSDATE, USER, CURRENT\_USER, SITENAME, DBSERVERNAME, or TODAY.

The check constraint cannot include columns in different tables. When you are using the ADD or MODIFY clause, the check constraint cannot depend upon values in other columns of the same table.

The next example adds a new **unit\_price** column to the **items** table and includes a check constraint to ensure that the entered value is greater than 0:

```
ALTER TABLE items
  ADD (unit_price MONEY (6,2) CHECK (unit_price > 0));
```

To create a constraint that checks values in more than one column, use the ADD CONSTRAINT clause. The following example builds a constraint on the column that was added in the previous example. The check constraint now spans two columns in the table.

```
ALTER TABLE items ADD CONSTRAINT CHECK (unit_price < total_price);
```

When you create or enable a check constraint, you can speed up the statement by including the NOVALIDATE keyword to skip the checking of existing rows for violations. The check constraint is enabled when the statement completes.

75. See [Condition on page 1144](#)

## Add column SECURED WITH label clause

The SECURED WITH Label clause associates the new column that the ALTER TABLE ADD statement defines with a label-based access control (LBAC) security label. This clause is valid only for a table that is protected by an LBAC security policy, and for a security label of the same policy.

This syntax fragment is part of the [ADD Column Clause on page 105](#).

COLUMN SECURED WITH Label clause

### COLUMN

#### SECURED WITH *label*

| Element      | Description                    | Restrictions   | Syntax                                  |
|--------------|--------------------------------|--|---|
| <i>label</i> | Name of an LBAC security label | Must exist and must belong to the same LBAC security policy that protects the table. | <a href="#">Identifier on page 1456</a> |

### Usage

In a database that supports label-based access control, only tables that have a column of type IDSSECURITYLABEL can be protected by an LBAC security policy. When the ALTER TABLE ADD statement adds a new column to a protected table, the COLUMN SECURED WITH Label clause can associate the column with a security label of the same security policy.

- In a protected table, any data in a column that the SECURED WITH label clause associates with an LBAC security label is protected with *column-level granularity* for those columns. Only users whose security credentials satisfy the label of the column can access data in the column.
- In the same table, the data in other columns not referenced by any SECURED WITH label clause are protected with *row-level granularity* by the LBAC label in the column of type IDSSECURITYLABEL. Only users whose security credentials satisfy that label can access data in any row.

Only users who hold the DBSECADM role can include this clause in the ALTER TABLE statement.

The COLUMN SECURED WITH Label clause is an extension to the ISO/ANSI standard for the SQL language.

The COLUMN keyword is optional, and has no effect on the result of the ALTER TABLE SECURED WITH operation, but it might make your code easier for human readers to understand.

The ALTER TABLE statement cannot add a security label to table objects in any of the following categories:

- virtual-table interface (VTI) tables or virtual-index interface (VII) tables
- user-defined or system-defined temporary (TEMP) tables
- tables of named or unnamed ROW types
- parent tables or child tables within a typed-table hierarchy
- a table with no label-based security policy.

You must specify the *label* name without the *policy* qualifier, rather than as *policy.label*, because the current security policy of the table is the only valid policy for any security label that protects data in the table.

The *column* cannot be of type IDSSECURITYLABEL.

When a user who holds appropriate label-based access privileges attempts to access a value in the protected column, the database server compares this label with the security credentials of the user, and allows or withholds access on the basis of this comparison.

You can use similar syntax in the ALTER TABLE MODIFY statement to associate an existing column of a protected table with an LBAC security label, or to drop the association between a protected column and its label. For more information, see [Modify Column Security clause on page 148](#).

For the ALTER TABLE syntax to add an LBAC security policy to protect a table that has no security policy, or to drop the association of the current security policy with the table, see [SECURITY POLICY Clause on page 160](#).

### Example of adding a column protected by a security label

Suppose that protected table **SecuriTab** was created with the following schema:

```
CREATE TABLE SecuriTab
  (Col1 CHAR (18),
   Col2 INT,
   Col4 IDSSecurityLabel DEFAULT LabelRW)
SECURITY POLICY company;
```

The table **SecuriTab** is protected with row-level granularity by the LBAC security policy **company**, **Col4** of type IDSSecurityLabel stores security label **LabelRW**. The security label **LabelRW** in the IDSSecurityLabel column

In the following statement, a user who holds the DBSECADM role adds a new CHAR(20) column **Col3** and provides row-level protection for its data by protecting that column with security label **Label23**:

```
ALTER TABLE SecuriTab
  ADD (Col3 CHAR (20) BEFORE Col4 COLUMN SECURED WITH Label23);
```

Like the security label **Label23** in column **Col4**, the security label **Label23** must be a label of the current security policy, in this case the **company** policy.

### ADD AUDIT Clause

Use the ADD AUDIT clause with the ALTER TABLE command to include a table in selective row-level auditing.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

```
-----+>
|           |
+-- Add AUDIT --+
```

When you alter a table with the ADD AUDIT clause, row-level audit events in that table are recorded when selective row-level auditing is turned on. Applying the ADD AUDIT attribute to a table by itself does not enable selective row-level auditing. This type of auditing is enabled when the ADTROWS parameter of the `adt.cfg` file is set to 1 or 2 by using the `onaudit -R` command.

If selective row-level auditing is not enabled, the ADD AUDIT attribute on a table has no effect.

You must have RESOURCE or DBA privileges to run ALTER TABLE command with the ADD AUDIT clause.

## ADD CONSTRAINT Clause

Use the ADD CONSTRAINT clause to specify a primary key, foreign key, referential, unique, or check constraint on a new or existing column or on a set of columns.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

ADD CONSTRAINT Clause

**ADD CONSTRAINT** <sup>76</sup>

```
(
, Multiple-Column Constraint Format 77
)
```

For example, to add a unique constraint to the **fname** and **lname** columns of the **customer** table, use the following statement:

```
ALTER TABLE customer ADD CONSTRAINT UNIQUE (lname, fname);
```

To declare a name for the constraint, change the preceding statement by adding the CONSTRAINT keyword and an identifier for the constraint:

```
ALTER TABLE customer
  ADD CONSTRAINT UNIQUE (lname, fname) CONSTRAINT u_cust;
```

The name must be unique among the identifiers of constraints that are defined on the same table. If you define no name for the constraint, the database server assigns to the constraint a system-defined identifier, and stores this in the **sysconstraints.constrid** column of the system catalog.

The new constraint is enabled by default. To add a constraint that is not enabled, you can include the DISABLED keyword after the name of the constraint:

```
ALTER TABLE customer
  ADD CONSTRAINT UNIQUE (lname, fname) CONSTRAINT u_cust DISABLED;
```

Before you perform subsequent DML operations in which you want the constraint to be enforced. You can use the SET Database Object Mode statement to enable the disabled constraint.

When you do not specify a name for a new constraint, the database server provides one. You can find the name of the constraint in the **sysconstraints** system catalog table. For more information about the **sysconstraints** system catalog table, see the *Informix® Guide to SQL: Reference*.

### Restrictions on constraints defined by ALTER TABLE

The following restrictions on the ADD CONSTRAINT clause (and on the MODIFY clause) affect constraints that the ALTER TABLE statement defines:

- When you add a constraint, the collating order must be the same as when the table was created.
- The ADD CONSTRAINT clause cannot define NULL or a NOT NULL constraints on columns of any data type. Only the MODIFY clause can define a NULL or a NOT NULL constraint on columns in existing tables.

76. For NULL and NOT NULL constraints, use instead the [MODIFY Clause on page 143](#)

77. See [Multiple-Column Constraint Format on page 121](#)

- You cannot define primary key constraints, foreign key constraints, or unique constraints on RAW tables. You can, however, use the MODIFY clause of the ALTER TABLE statement to define a NOT NULL constraint or a NULL constraint (but not both) on a column in a RAW table. For the syntax to add a NULL or NOT NULL constraint on a column in an existing table, see [MODIFY Clause on page 143](#).
  - You cannot place a unique constraint nor referential constraints on a BYTE or TEXT column.
  - A check constraint on a BYTE or TEXT column can check only for IS NULL, IS NOT NULL, or LENGTH.
  - By default, every IDSECURITYLABEL column has an implicit NOT NULL constraint. You cannot, however, use the ADD CONSTRAINT clause to reference an IDSECURITYLABEL column in the definition of a single-column constraint, nor as part of a multiple-column referential constraint or check constraint.
- 

## Multiple-Column Constraint Format

Use this option to assign one or more constraints to a column or to a set of columns in an existing table.

This closely resembles the syntax of the Multiple Column Constraint Format of the CREATE TABLE statement, but the optional INDEX DISABLED keywords are not valid (and return an error) in foreign key constraints that the CREATE TABLE statement defines. This syntax fragment is part of the [ADD CONSTRAINT Clause on page 119](#).

| Element           | Description                                   | Restrictions  | Syntax                                  |
|-------------------|---|---|---|
| <i>column</i>     | A column on which the constraint is placed    | No more than 16 columns   | <a href="#">Identifier on page 1456</a> |
| <i>constraint</i> | The name of a disabled foreign-key constraint | Must be unique among the names of indexes and constraints in the database | <a href="#">Identifier on page 1456</a> |

As in the CREATE TABLE statement, the Multiple-Column Constraint format for ALTER TABLE differs from the Single-Column Constraint format by requiring the FOREIGN KEY keywords before the REFERENCES clause when you specify a foreign key constraint. In addition, as its name implies, the Multiple-Column format can specify a list of columns as the scope of the new constraint, but this syntax is also valid with a single column.

78. See [Using the INDEX DISABLED keywords in a foreign key definition on page 125](#)

79. Informix® extension

80. Use path no more than 16 times

81. See [CHECK Clause on page 117](#)

82. See [REFERENCES Clause on page 114](#)

83. See [Constraint Definition on page 112](#)

84. Not valid in ALTER TABLE ADD CONSTRAINT statements. See [MODIFY Clause on page 143](#).

For information about the INDEX DISABLED keyword option, see [Using the INDEX DISABLED keywords in a foreign key definition on page 125](#).

A multiple-column constraint has these cardinality and size restrictions:

- It can specify no more than 16 column names.
- The maximum total length of the list of columns depends on the page size, according to this formula:

$$\text{MAXLength} = (((\text{PageSize} - 93) / 5) - 1)$$

- For a page size of 2K, the total length cannot exceed 390 bytes.
- For a page size of 16K, the total length cannot exceed 3257 bytes.

Here the slash ( / ) symbol represents integer division.

The statement fails with an error if you specify both a NOT NULL constraint and a NULL constraint on the same column, or if you define a NOT NULL constraint on a column whose default value is NULL.

You cannot define a NULL constraint on a column whose data type is LIST, MULTISSET, SET, or IDSSECURITYLABEL.

If the constraint is on a set of columns that includes a column that stores encrypted data, Informix® cannot enforce the constraint. You can declare a name for the constraint and set its mode with [Constraint Definition on page 112](#).

If the ALTER TABLE ADD CONSTRAINT statement defines more than one referential constraints on the same table, each constraint requires its own REFERENCES clause, so that options like ON DELETE CASCADE can be specified (or omitted) for each individual constraint, rather than applied to all of the constraints.

If the database server implicitly creates an index on the same non-opaque column or set of columns as the referential constraint, distribution statistics are automatically calculated on the specified column, or on the lead column of a multiple-column constraint.

These distribution statistics are equivalent to distributions created by the UPDATE STATISTICS statement in HIGH mode, and are available to the query optimizer when it designs query plans for the table on which the new constraint was created. See also the section [Automatic Calculation of Distribution Statistics on page 280](#) in the description of the CREATE INDEX statement for additional information about statistical distributions that are calculated when an index or constraint is created on an existing table.

### Example of adding a multiple-column referential constraint

In the **stores\_demo** database, the **stock** table contains the **stock\_num** column as its primary key. An enabled referential constraint **aa** on the **catalog** table has columns **catalog.stock\_num** and **catalog.manu\_code** as its multiple-column foreign-key, referencing the **stock** table. The following example drops that existing foreign-key constraint, and add a new constraint called **ai**, in DISABLED object mode, that disables the associated system-generated index on those columns:

```
ALTER TABLE catalog DROP CONSTRAINT aa;

ALTER TABLE catalog ADD CONSTRAINT
  (FOREIGN KEY (stock_num, manu_code) REFERENCES stock
  CONSTRAINT ai DISABLED INDEX DISABLED);
```

The parentheses that delimit the definition of the new constraint are optional, the following ALTER TABLE statement is equivalent:

```
ALTER TABLE catalog ADD CONSTRAINT
  FOREIGN KEY (stock_num, manu_code) REFERENCES stock
  CONSTRAINT ai DISABLED INDEX DISABLED;
```

The first DISABLED sets the object mode of the constraint. The last DISABLED sets the object mode of the index.

## Creating foreign-key constraints when an index exists on the referenced table

By default, the database server automatically validates enabled referential constraints when the ADD CONSTRAINT or MODIFY option to the ALTER TABLE statement includes the REFERENCES keyword to define a foreign-key constraint. You might be able to save time during validation of the new foreign-key constraint, if the referenced table already has a unique index or a primary-key constraint on the column (or on the set of columns) corresponding to the key of the referential constraint.

The database server makes a cost-based decision on how to validate the foreign-key constraint. The index-key algorithm might be faster in many contexts, because it validates the new constraint by scanning only the index values, rather than by scanning all the rows in the table.

The database server can consider using the index-key algorithm to validate the foreign-key constraint that it creates, but only if all of the following conditions are satisfied:

- The ALTER TABLE statement is creating only one foreign-key constraint.

If this is the case, the database server needs to check individual values for only the column on which the foreign-key constraint is being created. Validating two foreign-key constraints at the same time would require two indices to be used on the same scan, which is not supported.

- The statement is not also creating or enabling a CHECK constraint.

If the ALTER TABLE statement is creating more than one constraint, validating CHECK constraints requires that every row be checked, rather than individual values. In that case, the index-key algorithm cannot be used for validating the foreign-key constraint.

- The statement that creates the foreign-key constraint does not also change the data type of any existing column in the same table.

If the ALTER TABLE statement that creates the foreign-key constraint includes a MODIFY clause that changes the data type of any column, the database server does not consider an index-scan execution path for validating the constraint.

- The foreign-key columns do not include user-defined data types (UDTs) or built-in opaque data types.

To make the fast index-key algorithm as efficient as possible, it eliminates all the inefficiencies of executing routines associated with user-defined or opaque data types, such as the BOOLEAN and LVARCHAR built-in opaque types.

- The mode of the new foreign-key constraint is not DISABLED.

If it is disabled, then no constraint-checking algorithm is needed, because no checking for referential integrity violations occurs.

- The table is not associated with an active violation table.

Violations tables require that at the time of checking, every row that does not satisfy the new constraint must be inserted into the violation table. Scanning every row for violations prevents the database server from using the faster index-key algorithm that skips duplicate rows.

Except in the case of one or more violating rows, the ALTER TABLE ADD CONSTRAINT or ALTER TABLE MODIFY statement can create and validate a foreign-key constraint when some of these requirements are not satisfied, but the database server will not consider using the index-key algorithm to validate the foreign-key constraint. The additional validation costs for scanning the entire table are generally proportional to the size of the table. These costs can be substantial for very large tables.

When you create a self-referencing foreign-key constraint, whose REFERENCING clause specifies the same table on which the constraint is defined, the database server can consider an index-key algorithm for validating referential-integrity, if all of the conditions listed above are satisfied.

## Using the INDEX DISABLED keywords in a foreign key definition

By including the optional INDEX DISABLED keywords when you define a foreign key constraint, you prevent DML operations on the table from using the index that the database server associates with the foreign key. If you include the INDEX DISABLED keywords, they must be the last specification in the ALTER TABLE statement.

### Defining foreign key constraints in the ALTER TABLE statement

To add a foreign key constraint, you must have the References privilege on either the referenced columns or the child table. If you own the parent table or have the Alter privilege on the parent table, you can create a foreign key constraint on that table and specify yourself as the owner of the constraint. When you hold the DBA privilege, you can create foreign key constraints for other users.

When the ALTER TABLE ADD CONSTRAINT statement places a foreign key constraint on a column or on a set of columns that reference a child table, and no referential constraint or user-defined index already exists on that column or on that set of columns, the database server creates an internal B-tree index on the specified column or set of columns. If a user-created index already exists on that column or set of columns, the constraint shares the existing index.

If the ALTER TABLE ADD CONSTRAINT statement defines more than one foreign key constraint on the same table, each constraint requires its own REFERENCES clause, and the INDEX DISABLED keywords can be specified (or omitted) for each constraint.

This INDEX DISABLED option is valid in ALTER TABLE ADD CONSTRAINT statements issued from updatable secondary servers in cluster environments.

## Circumstances where a foreign key index can reduce performance

Although referential constraints protect data integrity, in some contexts the user-defined or system-generated B-tree index that the database server associates with a foreign key constraint can reduce the efficiency of data manipulation operations on tables that are very large. If there are no deletes from the parent table, the index is not used to look up rows in the child table for cascading deletes. If no queries use this index on the child table. In this scenario, the index is simply not needed, but it imposes unnecessary overhead in operations that update, delete, or insert rows into the child table. A data warehousing application on a child table with millions of rows could require fewer resources if the index that corresponds to the foreign key constraint were disabled.

In these cases, the `INDEX DISABLED` keyword option to the `ALTER TABLE ADD CONSTRAINT` statement offers a mechanism for defining a foreign key constraint but avoiding the overhead of the large associated b-tree index.

When you include the `INDEX DISABLED` keywords at the end of the constraint definition, the database server disables the system-generated index, if no appropriate user-defined index already exists. If a user-defined index on the foreign key column (or set of columns) of the child table already exists, the database server disables that index. Subsequent DML operations on the child table are accomplished without an index, and minimal system resources are needed for maintenance and storage of the disabled index.

## Effects of the `INDEX DISABLED` keywords

When you include the `INDEX DISABLED` keywords at the end of the constraint definition, the database server disables the system-generated index, if no appropriate user-defined index already exists. If a user-defined index on the foreign key column (or set of columns) of the child table already exists, the database server disables that index. Subsequent foreign key enforcement during DML operations on the child or parent table are accomplished without this disabled index, and minimal system resources are needed for maintenance and storage of the disabled index.

These are the actions of the database server when you successfully add a foreign key constraint with the `INDEX DISABLED` option:

- The index associated with the foreign key constraint is identified.
- That index is disabled, and marked as disabled in the **sysobjstate** table of the system catalog.
- The physical index is dropped from the database.
- The **sysfragments** system catalog table is updated to show no storage allocation for that index.

The `INDEX DISABLED` keywords have no effect on foreign key constraint that you define. The database server enforces that constraint, and issues an error if any subsequent operation on the child table or on the parent table violates the specified foreign key constraint.

The following restrictions apply to the `INDEX DISABLED` keywords in constraint definitions:

- The `INDEX DISABLED` option is valid only in foreign key definitions.
- Only the `ALTER TABLE ADD CONSTRAINT` statement supports this syntax. The `CREATE TABLE` or `ALTER TABLE MODIFY COLUMN` statements return an exception if a foreign key constraint definition includes the `INDEX DISABLED` keywords.

- If the index used by the foreign key is in use by another constraint, the database server returns an error.
- If you include the `DISABLED` keyword in the constraint definition to disable the foreign key constraint, the database server returns an error if you also specify the `INDEX DISABLED` keywords, as in the following example.

```
ALTER TABLE child ADD
  CONSTRAINT(FOREIGN KEY(x1) REFERENCES parent(c1)
  CONSTRAINT cons_child_x1 DISABLED INDEX DISABLED);
```

To correct the error in `ALTER TABLE ADD CONSTRAINT` example above, you must either drop the first `DISABLED` keyword, or else drop the `INDEX DISABLED` keywords.

### Example of creating a foreign key constraint with `INDEX DISABLED`

Suppose that the **parent** table and the **child** table in the following example have a primary key and foreign key dependency, and that the data stored in these tables satisfies the following conditions:

- The **parent** table has only a few rows.
- The **child** table has millions of rows.
- The foreign key columns in the **child** table have only few distinct possible values, based on the primary key of the **parent** table.

This example shows how to use the `INDEX DISABLED` keyword option of the `ALTER TABLE ADD CONSTRAINT` statement.

```
CREATE TABLE parent(c1 INT, c2 INT, c3 INT);
CREATE UNIQUE INDEX idx_parent_c1 ON parent(c1);
ALTER TABLE parent ADD
  CONSTRAINT PRIMARY KEY(c1)
  CONSTRAINT cons_parent_c1;
CREATE TABLE child(x1 INT, x2 INT, x3 VARCHAR(32));
CREATE INDEX idx_child_x1 ON child(x1);

ALTER TABLE child ADD
  CONSTRAINT(FOREIGN KEY(x1) REFERENCES parent(c1)
  CONSTRAINT cons_child_x1 INDEX DISABLED);
```

In the example above,

- **cons\_parent\_c1** is a primary key constraint on the **parent** table,
- **cons\_child\_x1** is a foreign key constraint on the **child** table,
- **idx\_parent\_c1** is a unique index shared by the **cons\_parent\_c1** constraint,
- and **idx\_child\_x1** is an index shared by the **cons\_child\_x1** constraint.

Data manipulation language operations like `UPDATE`, `DELETE`, `INSERT`, and `MERGE` on the **child** table cannot use the **idx\_child\_x1** index that is shared by with the foreign key constraint, because that index is now disabled.

For some tables that have a primary key and foreign key dependencies, however, the query optimizer might choose other indexes on the **child** table, based on `WHERE` clause predicates, in execution plans.

As indicated above, use of the `INDEX DISABLED` option in the foreign key definition can improve performance only when the **child** table is very large, typically in the context of data warehouse applications. This syntax option is not recommended for DML operations on small tables.

## Creating foreign-key constraints in NOVALIDATE modes

The ALTER TABLE ADD CONSTRAINT statement can create an enabled or filtering foreign-key constraint in a NOVALIDATE mode. The NOVALIDATE constraint modes prevent the database server from verifying that the foreign-key value in every row matches a primary-key value in the referenced table while the referential constraint is being created.

Use this syntax to create an enabled or filtering foreign-key constraint in NOVALIDATE mode:

|----------------------------------|--|------------------------------------|---|
| <i>table</i> ,<br><i>synonym</i> | Table on which <i>constraint</i> is placed | Must exist in the current database | <a href="#">Identifier on page 1456</a> |

## Usage

This diagram omits the `DISABLED` keyword. Because disabled constraints are not checked for violations, the `NOVALIDATE` keyword is unnecessary in that case.

If no column or list of columns immediately follows the `REFERENCES` keyword, the default column (or columns) is the primary key of the *pk\_tab* table. If *pk\_tab* and the *table* or *synonym* specify the same table, then the constraint is self-referencing, and there is no default primary-key column.

If you declare no constraint name, the database server generates an identifier for the new constraint that it registers in the `sysconstraints` and `sysobjstate` system catalog tables.

The ALTER TABLE ADD CONSTRAINT statement supports the NOVALIDATE mode for referential constraints as a mechanism for bypassing the data-integrity check when creating an enabled or filtering referential constraint.

## Circumstances where NOVALIDATE modes can improve performance

Although referential constraints protect data integrity, in some contexts a database table that you are moving to a new database server instance is known to be free of referential integrity violations. For foreign-key constraints on large tables, the time required to validate the constraint can be substantial. If a table with a million rows is moving from an OLTP environment to a data warehousing environment, validating the foreign key in the target environment might increase the time required for migration by orders of magnitude.

For example, you can drop the foreign-key constraints on the large table, and then re-create those constraints in an ENABLED NOVALIDATE mode or in a FILTERING NOVALIDATE mode immediately before you migrate the large table to the target database environment. The cost of the ALTER TABLE ADD CONSTRAINT operation that re-creates the foreign-key constraint will be relatively small, because it bypasses validation of every row for each referential constraint. Because the NOVALIDATE mode does not persist beyond the ALTER TABLE operation that created the constraints, the table arrives in the warehousing environment with those constraints in an ENABLED or FILTERING mode, protecting the referential integrity of the data in subsequent DML operations.

## Restrictions on using the NOVALIDATE keyword

The ALTER TABLE ADD CONSTRAINT statement is the only DDL context where the `NOVALIDATE` keyword is valid when a foreign-key constraint is being created. You cannot, for example, create a foreign-key constraint in a NOVALIDATE mode in any of the following SQL statements:

- CREATE TABLE statements
- CREATE TEMP TABLE statements
- SELECT INTO TABLE statements.

You can use the ALTER TABLE ADD CONSTRAINT statement to create an enabled constraint on an existing table in NOVALIDATE mode only if all of the following conditions are satisfied:

- The constraint that you are adding is a foreign-key constraint. If you create multiple constraints in an ALTER TABLE statement that includes the `NOVALIDATE` keyword, all must be foreign-key constraints.
- In ALTER TABLE statements, the `NOVALIDATE` keyword is valid only in the ADD CONSTRAINT FOREIGN KEY option.
- The `NOVALIDATE` keyword is not valid for constraints that ALTER TABLE creates in DISABLED mode.

The ALTER TABLE statement fails with an error if the constraint definition includes the `NOVALIDATE` keyword in any of the following syntax contexts:

- ALTER TABLE ADD *column* statements.
- ALTER TABLE INIT statements
- ALTER TABLE MODIFY statements.

The only other DDL statement where the `NOVALIDATE` keyword is valid is the SET CONSTRAINTS option to the SET Database Object Mode statement. While the SET CONSTRAINTS statement is running, it can change the mode of an existing foreign-key constraint to any of these NOVALIDATE constraint modes:

- ENABLED NOVALIDATE mode
- FILTERING WITH ERROR NOVALIDATE mode
- FILTERING WITHOUT ERROR NOVALIDATE mode.

For more information, see the [SET CONSTRAINTS statement on page 869](#).

### Establishing NOVALIDATE modes as the default

Both the SET ENVIRONMENT NOVALIDATE ON statement of SQL and the `dbimport -nv` command for loading databases can override any foreign-key constraint mode (except `DISABLED`) that ALTER TABLE ADD CONSTRAINT or SET CONSTRAINTS statement specifies, if that constraint mode specification omits the `NOVALIDATE` keyword.

- The scope of the SET ENVIRONMENT NOVALIDATE ON statement is subsequent ALTER TABLE ADD CONSTRAINT and SET CONSTRAINTS statements in the same user session.
- The scope of the `dbimport -nv` command is the ALTER TABLE ADD CONSTRAINT and SET CONSTRAINTS statements in the `.sql` file of the exported database, whose path name is specified in the same `dbimport` command.

Just as when `NOVALIDATE` is specified explicitly in ALTER TABLE ADD CONSTRAINT and SET CONSTRAINTS statements, during the session that issued the SET ENVIRONMENT NOVALIDATE ON statement the default NOVALIDATE mode for foreign-key constraints persists

- only while the foreign-key constraint is being created,
- or only while an existing constraint is being reset to ENABLED or to FILTERING mode.

When the ADD CONSTRAINT or SET CONSTRAINTS statement completes execution without validating the foreign-key constraint, no record of the transient NOVALIDATE mode is created in the `sysobjstate` system catalog table. Instead, the database server registers the mode of the new or updated foreign-key constraint as ENABLED or as FILTERING in the `sysobjstate.state` column of its row in the system catalog.

### Example of a constraint created in NOVALIDATE mode

The following DDL statements create a table called **parent** and define a unique index and a primary-key constraint on column **c1** of that table:

```
CREATE TABLE parent(c1 INT, c2 INT, c3 INT);
CREATE UNIQUE INDEX idx_parent_c1 ON parent(c1);
ALTER TABLE parent ADD CONSTRAINT
    PRIMARY KEY(c1) CONSTRAINT cons_parent_c1;
```

The next statements create another table, called **child**, whose first column is of the same data type as the primary-key column of the **parent** table, and define an enabled foreign-key constraint, called **cons\_child\_x**, on the **child** table:

```
CREATE TABLE child(x1 INT, x2 INT, x3 VARCHAR(32));
ALTER TABLE child
    ADD CONSTRAINT (FOREIGN KEY(x1)
        REFERENCES parent(c1) CONSTRAINT cons_child_x1);
```

Suppose that subsequent DML operations (not shown) populate the **parent** table and the **child** table with rows of data. At some point, the workflow requires the data to be moved from its OLTP production environment to another database for processing by business-analytics applications.

If at this point the data set in the **child** table contains a large number of rows, a significant cost of importing the **child** table to its new database will be validating the **cons\_child\_x1** referential constraint. To avoid this cost, the following statement drops that constraint:

```
ALTER TABLE child DROP CONSTRAINT cons_child_x1;
```

After the **child** table has been exported to its new environment, the following statement can re-create a new constraint of the same name on the **child** table without checking every row for referential-integrity violations:

```
ALTER TABLE child
    ADD CONSTRAINT (FOREIGN KEY(x1)
        REFERENCES parent(c1)
        CONSTRAINT cons_child_x1 NOVALIDATE);
```

By default, the new **cons\_child\_x1** referential constraint is in ENABLED mode after the ALTER TABLE statement completes execution.

Like the optional parentheses that can enclose various ALTER TABLE ADD CONSTRAINT syntax options, the parentheses enclosing the "Foreign key constraint in NOVALIDATE mode" syntax segment are optional. The next statement has the same effect as the previous `NOVALIDATE` example:

```
ALTER TABLE child
    ADD CONSTRAINT FOREIGN KEY(x1)
        REFERENCES parent(c1)
        CONSTRAINT cons_child_x1 NOVALIDATE;
```

Including the parentheses might make the logical structure clearer to human readers, but those delimiters have no effect on how the database server processes this ALTER TABLE ADD CONSTRAINT NOVALIDATE statement without validating each record.

## Adding a Primary-Key or Unique Constraint

When you place a primary-key or unique constraint on a column or set of columns, those columns must contain unique values. The database server checks for existing constraints and indexes:

- If a user-created unique index already exists on that column or set of columns, the constraint shares the index.
- If a user-created index that allows duplicates already exists on that column or set of columns, the database server returns an error.

In this case, you must drop the existing index before adding the primary-key or unique constraint.

- If a referential constraint already exists on that column or set of columns, the duplicate index is upgraded to unique (if possible) and the index is shared.
- If no referential constraint or user-created index exists on that column or set of columns, the database server creates an internal B-tree index on the specified columns.

When you place a referential constraint on a column or set of columns, and an index already exists on that column or set of columns, the index is shared.

If you own the table or have the Alter privilege on the table, you can create a check, primary-key, or unique constraint on the table and specify yourself as the owner of the constraint. To add a referential constraint, you must have the References privilege on either the referenced columns or the referenced table. When you have the DBA privilege, you can create constraints for other users.

## Recovery from Constraint Violations

If you use the ADD CONSTRAINT clause to add a constraint in the enabled mode, you receive an error message because existing rows would violate the constraint. For a procedure to add the constraint successfully, see [Adding a Constraint That Existing Rows Violate on page 153](#).

## ADD TYPE Clause

Use the ADD TYPE clause to convert a table that is not based on a named ROW data type into a typed table.

This clause is an extension to the ANSI/ISO standard for SQL.

### **ALTER TABLE**

*table synonym*

ADD TYPE Clause

ADD TYPE Clause

**ADD TYPE** *row\_type*

| Element         | Description  | Restrictions  | Syntax                                  |
|-----------------|--|---|---|
| <i>row_type</i> | Identifier of an existing named ROW data type for this table | The <i>row_type</i> fields must exactly match the existing columns in their data types, order, and number | <a href="#">Identifier on page 1456</a> |
| <i>synonym</i>  | Synonym for the table that becomes a typed table             | Synonym and its table must exist, and <b>USETABLENAME</b> must not be set                                 | <a href="#">Identifier on page 1456</a> |
| <i>table</i>    | Identifier of the table that becomes a typed table           | Must exist in the current database  | <a href="#">Identifier on page 1456</a> |

## Usage

If the new ROW type is a subtype of an existing named ROW type, you must hold the UNDER privilege for that named ROW type.

When you use the ADD TYPE clause, you assign the specified named ROW data type to a table whose columns must exactly match the fields of that ROW data type

- in their names,
- in their individual data types,
- and in their order.

In addition to the requirements common to all ALTER TABLE operations (namely DBA privilege on the database, Alter privilege on the table, and ownership of the table), all of the following must be also true when you use the ADD TYPE clause to convert an untyped table to the specified named ROW data type:

- The named ROW data type is already registered in the database.
- You hold the Usage privilege on the named ROW data type.
- There must be a 1-to-1 correspondence between the ordered set of column data types of the untyped table and the ordered set of field data types of the named ROW data type.
- The table cannot be a fragmented table that has **rowid** values.

You cannot combine the ADD TYPE clause with any clause that changes the schema of the table. No other ADD, DROP, or MODIFY clause is valid in the same ALTER TABLE statement that has the ADD TYPE clause. The ADD TYPE clause does not allow you to change column data types. (To change the data type of a column, use the MODIFY clause in a separate ALTER TABLE statement from the ADD TYPE operation.)

## ALTER TABLE operations on typed tables

Most options of the ALTER TABLE statement are restricted to untyped tables.

The database server supports only the following storage, locking, and constraint syntax options when *table\_object* is the name or synonym of a typed table. As noted below, however, for some CONSTRAINT options in a typed-table inheritance hierarchy

- the scope of the operation includes all subtables of *table\_object*,
- or the operation is not supported if *table\_object* is a subtable.

Figure 3. ALTER TABLE options for typed tables

**ALTER TABLE***table\_object*Typed-table options

Typed-Table options

,  
ADD CONSTRAINT Clause<sup>87</sup>

DROP CONSTRAINT Clause<sup>88</sup>

<sup>89</sup>MODIFY NEXT SIZE Clause<sup>90</sup>

<sup>89</sup>LOCK MODE Clause<sup>91</sup>

Two additional considerations apply to typed tables of named ROW types that are part of inheritance hierarchies:

- For subtables, ADD CONSTRAINT and DROP CONSTRAINT are not valid on inherited constraints.
- For supertables, ADD CONSTRAINT and DROP CONSTRAINT propagate to all subtables.

### Example of the ALTER TABLE . . . ADD TYPE statement

The following example changes an untyped table into a typed table by the following steps:

- Use the CREATE TABLE statement to create an table that will become the typed table.
- Use the CREATE ROW TYPE statement to create a named ROW type with fields exactly matching the untyped table schema.
- Use the ALTER TABLE . . . ADD TYPE statement to change the untyped table to a typed table.

```
CREATE TABLE postal(
  name    VARCHAR(30),
  address VARCHAR(20),
  city    VARCHAR(20),
  state   CHAR(2),
  zip     INTEGER,
);

. . .

CREATE ROW TYPE postal_t
(
  name    VARCHAR(30),
  address VARCHAR(20),
  city    VARCHAR(20),
  state   CHAR(2),
  zip     INTEGER,
);
```

87. See [ADD CONSTRAINT Clause on page 119](#)

88. See [DROP CONSTRAINT Clause on page 135](#)

89. Use path no more than once

90. See [MODIFY NEXT SIZE clause on page 155](#)

91. See [LOCK MODE Clause on page 141](#)

```
ALTER TABLE postal ADD TYPE postal_t;
```

You could achieve the same result if the order of the first two DDL statements were reversed.

In that case, however, the ALTER TABLE statement could be avoided, if instead of defining columns individually, the CREATE TABLE instead included the OF TYPE clause to use the `postal_t` ROW type as a template for the six fields of a single named ROW type column:

```
CREATE TABLE postal OF TYPE postal_t;
```

By either path, table `postal` becomes a typed table of ROW type `postal_t`.

In the example above, as elsewhere in the documentation of typed tables, the database server does not require any similarity between the SQL identifier of the table and the SQL identifier of the ROW type. Table objects and named ROW data types have separate and uncorrelated name spaces, but mnemonic names can make SQL code examples easier for some human readers to understand.

## DROP AUDIT Clause

Use the DROP AUDIT clause with the ALTER TABLE command to remove it from the set of tables that is audited when selective row-level auditing is enabled.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

```
-----+>
|               |
+-- Drop AUDIT -+
```

The DROP AUDIT clause affects only tables that have been flagged for inclusion in selective row-level auditing. If you have not created or altered the table with the WITH AUDIT clause or ADD AUDIT clause, it is not necessary to use DROP AUDIT to exclude it from the set of tables that are audited at the row level.

Removing the AUDIT attribute from a table does not disable or change selective row-level auditing of other tables in the database.

You must be a DBSSO to run the ALTER TABLE command with the DROP AUDIT clause.

## DROP CONSTRAINT Clause

Use the DROP CONSTRAINT clause to destroy an existing constraint whose name you specify.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

DROP CONSTRAINT Clause

### DROP CONSTRAINT

```
(
, constraint
)
```

| Element           | Description              | Restrictions               | Syntax                                  |
|-------------------|--------------------------|----------------------------|---|
| <i>constraint</i> | Constraint to be dropped | Must exist in the database | <a href="#">Identifier on page 1456</a> |

### Usage

To drop an existing constraint, specify the `DROP CONSTRAINT` keywords and the identifier of the constraint. To drop multiple constraints on the same table, the constraint names must be in comma-separated list that is delimited by parentheses.

The constraint that you drop can have an ENABLED, DISABLED, or FILTERING mode.

Here is an example of dropping a constraint:

```
ALTER TABLE manufact DROP CONSTRAINT con_name;
```

The following example destroys both a referential constraint and a check constraint that had been defined on the **orders** table:

```
ALTER TABLE orders DROP CONSTRAINT (con_ref, con_check);
```

The Informix® implementation of SQL includes no DROP CONSTRAINT statement. This clause of the ALTER TABLE statement, however, provides functionality that one might expect of the DROP CONSTRAINT statement, if that statement existed.

The DROP TABLE statement implicitly drops all constraints on the specified table when it destroys that table.

### Retrieving constraint names

The DROP CONSTRAINT clause requires the identifier of the constraint. If no name was declared when the constraint was created, the database server generated the identifier of the new constraint. You can query the **sysconstraints** system catalog table for the name and the owner of a constraint. For example, to find the name of the constraint placed on the **items** table, you can issue the following statement:

```
SELECT constrname FROM sysconstraints
WHERE tabid = (SELECT tabid FROM systables
WHERE tablename = 'items');
```

### Dependencies between constraints

When you drop a primary-key constraint or a unique constraint that has a corresponding foreign key, any associated referential constraints are also dropped.

For example, in the **stores\_demo** database, there is a primary-key constraint on the **order\_num** column in the **orders** table. A corresponding foreign-key constraint is also defined on the **order\_num** column in the **items** table. These constraints define a referential relationship between the **order\_num** columns in both tables.

Suppose that you run the `ALTER TABLE orders DROP CONSTRAINT` statement to drop the primary-key constraint on the `order_num` column in the `orders` table. Because this referential-integrity relationship between the two tables can no longer be enforced without the primary-key constraint, the database server takes these actions if the `ALTER TABLE` statement in this example succeeds:

- It destroys the specified primary-key constraint on the `order_num` column in the `orders` table.
- It also destroys the corresponding referential constraint on the `order_num` column in the `items` table.
- It deletes from the system catalog all references to the primary key constraint on the `orders` table, or to the referential constraint on the `items` table.

## System catalog effects of dropping constraints

The database maintains information about existing constraints in these system catalog tables:

- **sysconstraints** (all constraints)
- **sysobjstate** (all constraints)
- **syschecks** (check constraints)
- **syscoldepend** (check constraints and NOT NULL constraints)
- **syscheckudrdep** (check constraints that UDRs reference)
- **sysreferences** (referential constraints)
- **sysindices** (referential, primary-key, or unique constraints that have no corresponding Index entry in **sysindices**)

After the `DROP CONSTRAINT` clause successfully destroys a constraint, the database server deletes or updates at least one row in one or more of the above tables.

## Data type considerations

By default, every `IDSSECURITYLABEL` column has an implicit NOT NULL constraint, but the `DROP CONSTRAINT` clause cannot reference columns of type `IDSSECURITYLABEL`.

You can include the `DROP CONSTRAINT` clause in `ALTER TABLE` operations on typed tables of ROW data types, but with these restrictions for table hierarchies.

- For a typed table with no supertable, `DROP CONSTRAINT` propagates to its child tables.
- For the child table of a supertable, `DROP CONSTRAINT` fails for inherited constraints.

For example, suppose ROW type `people_t` exists in the database. The following DDL statements respectively

- create a typed table called **MyPeople**,
- add a UNIQUE constraint on **MyPeople** called **very\_unique** on all the fields of the ROW type column,
- and create a child table called **LittlePeople**:

```
CREATE TABLE IF NOT EXISTS MyPeople OF TYPE (people_t);
ALTER TABLE MyPeople ADD CONSTRAINT UNIQUE (people_t.*)
    CONSTRAINT very_unique;
CREATE TABLE IF NOT EXISTS LittlePeople OF TYPE (people_t)
    UNDER MyPeople;
```

Because **LittlePeople** inherited the **very\_unique** constraint from its parent supertable **MyPeople**, the following ALTER TABLE DROP CONSTRAINT statement fails:

```
ALTER TABLE LittlePeople
  DROP CONSTRAINT very_unique; --cannot drop an inherited constraint
```

But because **MyPeople** is a typed table with no parent, the following statement destroys the **very\_unique** constraint instances on both the **MyPeople** and the **LittlePeople** tables within their table hierarchy:

```
ALTER TABLE MyPeople DROP CONSTRAINT very_unique;
```

## Restoring a referential constraint

For some operations, such as relocating a table to another database, you might require that a referential constraint temporarily have no effect on its table. After you complete that work without the constraint, however, the referential integrity of the database typically requires that the functionality of the constraint be restored. One possible option is this:

- Use the DROP CONSTRAINT clause to destroy the constraint.
- Complete the tasks that need to avoid the effects of the constraint.
- Use ALTER TABLE ADD CONSTRAINT to re-create the constraint.

For a very large table that already conforms to the dropped foreign-key or check constraint, using the NOVALIDATE option to the ALTER TABLE ADD CONSTRAINT statement can avoid the substantial cost of using a full-table scan to validate the constraint while it is being re-created. This NOVALIDATE option requires using the Multi-Column Constraint Format syntax to define the constraint.

Similarly, rather than destroying a referential constraint on a large table, you can temporarily disable it, and then complete tasks that require fewer resources with the constraint disabled. To resume enforcement of the constraint, you can use the SET CONSTRAINTS option of the SET Database Object Mode statement to reset the object mode to ENABLED NOVALIDATE, or to FILTERING WITH ERROR NOVALIDATE or to FILTERING WITHOUT ERROR NOVALIDATE. In each of these constraint modes, the `NOVALIDATE` keyword avoids the overhead of validating the constraint while its mode is being reset.

## DROP Column Clause

Use the DROP Column clause to remove one or more columns from the schema of a table.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

DROP Column Clause

**DROP**

```
(
  , column
)
column
```

| Element       | Description                    | Restrictions   | Syntax                                  |
|---------------|--------------------------------|--|---|
| <i>column</i> | Name of a column to be dropped | Must exist in the table. No fragment expression can reference the column, and it cannot be the last column in the table. | <a href="#">Identifier on page 1456</a> |

You cannot issue an ALTER TABLE DROP statement that would drop every column from the table. At least one column must remain in the table.

You cannot drop a column that is part of the fragmentation key of a fragmentation strategy.

A column that is protected by a security label can be dropped by the ALTER TABLE DROP statement, but the user must be DBSECADM and must also hold the usual CONNECT, RESOURCE, and ALTER access privileges for modifying the schema of the table.

## How Dropping a Column Affects Constraints

When you drop a column, all constraints on that column are also dropped, unless the same ALTER TABLE statement also adds the same column in the same order within the table schema.

Dropping a column has these effects on its constraints:

- All single-column constraints are dropped.
- All referential constraints that reference the column are dropped.
- All check constraints that reference the column are dropped.
- If the column is part of a multiple-column primary-key or unique constraint, the constraints that are placed on the multiple columns are also dropped. This action, in turn, triggers the dropping of all referential constraints that reference the multiple columns.
- The **syscolumns** and **sysconstraints** system catalog tables are updated to remove all the rows corresponding to the dropped columns and the dropped constraints.

Because any constraints that are associated with a column are dropped when the column is dropped, the structure of other tables might also be altered when you use this clause. For example, if the dropped column is a unique or primary key that is referenced in other tables, those referential constraints also are dropped. Therefore, the structure of those other tables is also altered.

### Dropping columns without changing the table schema

The same ALTER TABLE statement can include both a DROP Column clause that drops a column (or drops several columns), followed by an ADD Column clause that adds columns of the same name, data type, and ordinal position among the columns of the table. In this case, the database server takes no action to reorganize the schema of the table, or to drop constraints that are defined on the columns that were dropped and restored in the same ALTER TABLE statement. That is, nothing happens to the table or to its data.

For example, suppose that table **UnsTable** is created with five columns:

```
CREATE TABLE IF NOT EXISTS UnsTable (
  col1 CHAR(18),
  col2 INT NOT NULL,
  col3 CHAR(32) UNIQUE,
  col4 INT NOT NULL,
  col5 DATETIME YEAR TO MONTH);
```

The following ALTER TABLE statement instructs the database server to drop both INTEGER columns **col2** and **col4**, and also to add two columns with the same names and data type:

```
ALTER TABLE UnsTable (
  DROP (col2, col4)
  ADD (col2 INT NOT NULL BEFORE col3,
      col4 INT NOT NULL BEFORE col5);
```

This ALTER TABLE statement has no effect on the schema or the data in the **UnsTable** table, nor on any existing constraints that reference those columns, because the database server takes no action. Therefore, DDL statements that resemble the example that are generated by analytic tools do not affect the database server or the data.

When you need to reorganize a table and drop constraints by replacing one or more columns with new columns that have the same names, the same data types, and the same ordinal positions within the table schema, run two separate ALTER TABLE statements, as in the following example:

```
ALTER TABLE UnsTable (
  DROP (col2, col4);

ALTER TABLE UnsTable (
  ADD (col2 INT NOT NULL BEFORE col3,
      col4 INT NOT NULL BEFORE col5);
```

The ALTER TABLE DROP statement drops any existing constraints that reference columns **col2** or **col4** of the **UnsTable** table.

## How Dropping a Column Affects Triggers

In general, when you drop a column from a table, the triggers based on that table remain unchanged. If the column that you drop appears in the action clause of a trigger, however, dropping the column can invalidate the trigger. The following statements illustrate the possible effects on triggers:

```
CREATE TABLE tab1 (i1 int, i2 int, i3 int);
CREATE TABLE tab2 (i4 int, i5 int);
CREATE TRIGGER col1trig UPDATE OF i2 ON tab1
  BEFORE(INSERT INTO tab2 VALUES(1,1));
ALTER TABLE tab2 DROP i4;
```

After the ALTER TABLE statement, **tab2** has only one column. The **col1trig** trigger is invalidated because the action clause as it is currently defined with values for two columns cannot occur.

If you drop a column that occurs in the triggering column list of an UPDATE trigger, the database server drops the column from the triggering column list. If the column is the only member of the triggering column list, the database server drops the trigger from the table. For more information on triggering columns in an UPDATE trigger, see [CREATE TRIGGER statement on page 405](#).

If a trigger is invalidated when you alter the underlying table, drop and then re-create the trigger.

## How Dropping a Column Affects Views

When you drop a column from a table, the views based on that table remain unchanged. That is, the database server does not automatically drop the corresponding columns from associated views.

The view is not automatically dropped because ALTER TABLE can change the order of columns in a table by dropping a column and then adding a new column with the same name. In this case, views based on the altered table continue to work, but retain their original sequence of columns.

If a view is invalidated when you alter the underlying table, you must rebuild the view by using the DROP VIEW and CREATE VIEW statements.

## LOCK MODE Clause

Use the LOCK MODE keywords to change the locking granularity of an existing table.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

LOCK MODE Clause

**LOCK MODE**

(

**PAGE ROW**

)

The following table describes the locking-granularity options available.

### Granularity

#### Effect

#### PAGE

Obtains and releases one lock on a whole page of rows

If no system default locking granularity has been set by the `IFX_DEF_TABLE_LOCKMODE` environment variable or by the `DEF_TABLE_LOCKMODE` configuration parameter, this is the default. Page-level locking is especially useful when you know that the rows are grouped into pages in the same order that you are using to process all the rows. For example, if you are processing the contents of a table in the same order as its cluster index, `PAGE` is usually more appropriate setting than `ROW`.

#### ROW

Obtains and releases one lock per row

Row-level locking supports the highest level of concurrency. Only tables with row-level locking support the LAST COMMITTED feature, which can improve performance in the Committed Read and Dirty Read isolation levels when another session holds an exclusive lock on a row that you attempt to read. If you are using many rows at one time, however, the lock-management overhead of row-level locking can become significant. You

can also exceed the maximum number of locks available, depending on the configuration of your database server.

The following statement changes the lock mode for the **customer** table to page-level locking:

```
ALTER TABLE customer LOCK MODE(PAGE);
```

The next example changes the lock mode for the **customer** table to row-level locking:

```
ALTER TABLE customer LOCK MODE(ROW);
```

### Important:

The SET LOCK MODE statement of SQL has no effect on the locking granularity of tables. You can use that statement, however, to define how the database server resolves locking conflicts when one process tries to access a row or a table that has been locked by a concurrent process. For the syntax and semantics, see [SET LOCK MODE statement on page 982](#).

The term *lock mode* also has a third meaning for smart large objects in JDBC contexts, when a row contains one or more smart large objects. Here the scope of a lock can be either only a subset the smart large object, or else it can lock the entire BLOB or CLOB.

## Precedence and Default Behavior

The LOCK MODE setting in an ALTER TABLE statement takes precedence over the settings of the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable and the DEF\_TABLE\_LOCKMODE configuration parameter. For information about the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable, refer to the *Informix® Guide to SQL: Reference*. For information about the DEF\_TABLE\_LOCKMODE configuration parameter, refer to the *Informix® Administrator's Reference*.

---

## Logging TYPE Options

Use the Logging TYPE options to specify that the table has particular characteristics that can improve various bulk operations on it.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

Logging TYPE Options

**TYPE**

```
(
STANDARD RAW
)
```

Here STANDARD, the default option of the CREATE TABLE statement, specifies a logged table, and RAW specifies an unlogged table.

A table can have any of the following logging characteristics.

### Option

#### Effect

#### STANDARD

Logging table that allows rollback, recovery, and restoration from archives. This is the default. Use this type for recovery and constraints functionality on OLTP databases.

#### RAW

Nonlogging table that do not support primary key constraints, unique constraints, or referential constraints.

RAW tables can have NOT NULL constraints and NULL constraints (but not on the same set of columns). They can be indexed and updated. Use this type for quickly loading data.

**Warning:** Use RAW tables for fast loading of data. It is recommended that you alter the logging type to STANDARD and perform a level-0 backup before you use the table in a transaction or modify the data within the table. If you must use a RAW table within a transaction, either set the isolation level to Repeatable Read or lock the table in exclusive mode to prevent concurrency problems.

The Logging TYPE option can convert a non-logging table, such as a RAW table, to a STANDARD table that supports transaction logging. If you use this feature, you should be aware that the database server does not check to see whether a level 0 archive has been performed on the table.

Operations on a RAW table are not logged and are not recoverable, so RAW tables are always at risk. When the database server converts a table that is not logged to a STANDARD table type, it is your responsibility to perform a level-0 backup before using the table in a transaction or modifying data in the table. Failure to do this might lead to recovery problems in the event of a server crash.

For more information on these logging types of tables, refer to your *Informix® Administrator's Guide*.

The Logging TYPE options have the following restrictions:

- You must perform a level-0 archive before the logging type of a table can be altered to STANDARD from any other logging type.
- The table cannot be a TEMP table, and you cannot change any of these types of tables to a TEMP table.

The following example changes a nonlogging table to a table that uses transaction logging:

```
ALTER TABLE tabnolog TYPE (STANDARD);
```

The following example changes a logging table to a nonlogging table.

```
ALTER TABLE tablog TYPE (RAW);
```

## MODIFY Clause

Use the MODIFY clause to change the data type, length, or default value of a column, to add or remove the security label of a column, to allow or disallow NULL values in a column, or to reset the serial counter of a SERIAL, SERIAL8, or BIGSERIAL column.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

MODIFY Clause

**MODIFY**

```
(
, Modify Column Clause
)
```

Modify Column Clause

*column*

Data Type <sup>92</sup>

<sup>96</sup> DEFAULT Clause <sup>93</sup>

<sup>96</sup> Single-Column Constraint Format <sup>94</sup>

Modify Column Security <sup>95</sup>

| Element       | Description      | Restrictions   | Syntax                                  |
|---------------|------------------|--|---|
| <i>column</i> | Column to modify | Must exist in table. Cannot be a collection or IDSSECURITYLABEL data type. | <a href="#">Identifier on page 1456</a> |

### Usage

When you modify a column, all attributes previously associated with the column (that is, default value, single-column check constraint, or referential constraint) are dropped. When you want certain attributes of the column to persist, such as PRIMARY KEY, you must respect those attributes in the same MODIFY clause.

For example, consider the **items** table in the **stores\_demo** database, whose schema includes this original definition of the **quantity** column:

```
CREATE TABLE items (item_num INT . . . -- primary key of this table
                    order_num . . . -- foreign key to orders table
                    . . . -- two additional columns
                    quantity SMALLINT DEFAULT 1 NOT NULL,
                    total price MONEY(8) . . . );
```

If you are changing the data type of the existing **quantity** column to INT, but you want to keep the default value (in this case, 1) and the NOT NULL constraint, you can issue this statement:

```
ALTER TABLE items MODIFY (quantity INT DEFAULT 1 NOT NULL);
```

92. See [Data Type on page 1163](#)

93. See [DEFAULT clause of ALTER TABLE on page 107](#)

94. See [Single-Column Constraint Format on page 111](#)

95. See [Modify Column Security clause on page 148](#)

96. Use this path no more than once

**Note:** Both the `DEFAULT` and `NOT NULL` attributes are specified again in the `MODIFY` clause. If you omit those keywords, both attributes are dropped from the modified column, and the modified table would accept `NULL` values in new or updated data rows in which the **quantity** value is missing.

When you specify a `PRIMARY KEY` constraint in the `MODIFY` clause, the database server also silently creates a `NOT NULL` constraint on the same column, or on the same set of columns that makes up the primary key

When you change the data type of a column, the database server does not perform the modification in place. The next example changes a `VARCHAR(15)` column to an `LVARCHAR(3072)` column:

```
ALTER TABLE stock MODIFY (description LVARCHAR(3072));
```

When you modify a column that has column constraints that are associated with it, the following constraints are dropped:

- All single-column constraints are dropped.
- All referential constraints that reference the column are dropped.
- If the modified column is part of a multiple-column primary-key or unique constraint, all referential constraints that reference the multiple columns also are dropped.

For example, if you modify a column that has a unique constraint, the unique constraint is dropped. If this column was referenced by columns in other tables, those referential constraints are also dropped. In addition, if the column is part of a multiple-column primary-key or unique constraint, the multiple-column constraints are not dropped, but any referential constraints that are placed on the column by other tables are dropped.

For another example, suppose that a column is part of a multiple-column primary-key constraint. This primary key is referenced by foreign keys in two other tables. When this column is modified, the multiple-column primary-key constraint is not dropped, but the referential constraints that are placed on it by the two other tables are dropped.

Consider the table that this statement defines:

```
CREATE TABLE tab1(c1 INT, c2 INT);
```

To add the `NOT NULL` constraint, an `ALTER TABLE MODIFY` statement is required:

```
ALTER TABLE tab1 MODIFY (c1 INT NOT NULL);
```

You cannot add a `NULL` or a `NOT NULL` constraint with the `ADD CONSTRAINT` clause.

### Restrictions on changing column data types

You cannot use the `ALTER TABLE MODIFY` statement to change the data type of a column to a `COLLECTION` type or to a `ROW` type.

If the schema of a table exactly matches the order of data types in the fields of an existing named `ROW` type, however, you can use the `ALTER TABLE ADD TYPE` statement to change that table into a typed table, as the topic [ADD TYPE Clause on page 132](#) describes.

The `IDSSECURITYLABEL` column of a protected table cannot be altered to a different data type, nor can an existing column be altered to be of type `IDSSECURITYLABEL`.

In general, the database server does not validate the resulting column values when you change the data types of columns in tables that contain data. The database server does not validate the values when you convert a column from an INTEGER or SMALLINT data type to a SERIAL, SERIAL8, or BIGSERIAL column.

## Altering BYTE and TEXT Column data types

You can use the MODIFY clause to change a BYTE column to a TEXT column, and vice versa. You can also use the MODIFY clause to change a BYTE column to a BLOB column and a TEXT column to a CLOB column.

Except for these operations, however, you cannot use the MODIFY clause to change a BYTE or TEXT column to any other type of column, nor to change any other type of column to a BYTE or TEXT column.

When you use this clause to change a BYTE column to a BLOB column, or to change a TEXT column to a CLOB column, you can also use the [PUT Clause on page 156](#) of the ALTER TABLE statement to specify an sbspace and to define its characteristics for storing the BLOB or CLOB objects.

## Altering the Next Serial Value

You can use the MODIFY clause to reset the next value of a SERIAL, BIGSERIAL, or SERIAL8 column. You cannot set the next value below the current maximum value in the column because that action can cause the database server to generate duplicate numbers. You can set the next value, however, to any value higher than the current maximum, which creates a gap in the series of values.

If the new serial value that you specify is less than the current maximum value in the serial column, the maximum value is not altered. If the maximum value is less than what you specify, the next serial number will be what you specify. The next serial value is not equivalent to one greater than the maximum serial value in the column in two situations:

- There are no rows in the table, and an initial serial value was specified when the table was created (or by a previous ALTER TABLE statement).
- There are rows in the table, but the next serial value was modified by a previous ALTER TABLE statement.

The following example sets the next serial value to 1000:

```
ALTER TABLE my_table MODIFY (serial_num SERIAL (1000));
```

As an alternative, you can use the INSERT statement to create a gap in the series of serial values in the column. For more information, see [Inserting Values into Serial Columns on page 645](#).

## Altering the Next Serial Value in a Typed Table

You can set the initial serial number or modify the next serial number for a ROW-type field with the MODIFY clause of the ALTER TABLE statement. (You cannot set the initial number for a serial field when you create a ROW data type.)

Suppose you have ROW types **parent**, **child1**, **child2**, and **child3**.

```
CREATE ROW TYPE parent (a int);
CREATE ROW TYPE child1 (s serial) UNDER parent;
CREATE ROW TYPE child2 (b float, s8 serial8) UNDER child1;
CREATE ROW TYPE child3 (d int) UNDER child2;
```

You then create corresponding typed tables:

```
CREATE TABLE OF TYPE parent;
CREATE TABLE OF TYPE child1 UNDER parent;
CREATE TABLE OF TYPE child2 UNDER child1;
CREATE TABLE OF TYPE child3 UNDER child2;
```

To change the next SERIAL and SERIAL8 numbers to 75, you can issue the following statement:

```
ALTER TABLE child3 MODIFY (s serial(75), s8 serial8(75));
```

When the ALTER TABLE statement executes, the database server updates corresponding serial columns in the **child1**, **child2**, and **child3** tables.

## Altering character columns

You can use the MODIFY clause to change the declared length of an existing CHAR, LVARCHAR, NCHAR, NVARCHAR, or VARCHAR column.

Similarly, the MODIFY clause can change the data type of a character column to a non-character data type.

For modified columns that you declare as built-in character data types, explicit or default size specifications are interpreted in units of bytes, unless the database was created with the SQL\_LOGICAL\_CHAR configuration parameter set to enable logical character semantics in character type declarations. For more information about logical character semantics when the ALTER TABLE statement declares size specifications for character columns, see [Logical Character Support in Character Columns on page 106](#). For more information about the SQL\_LOGICAL\_CHAR configuration parameter, see your . For additional information about multibyte locales and logical characters, see the *Informix® GLS User's Guide*.

In a database that was created as NLSCASE INSENSITIVE, changing a character column of type NCHAR or NVARCHAR into type CHAR, LVARCHAR, or VARCHAR causes the database server to process values in the modified column as case-sensitive.

Conversely, in the same case-insensitive database, changing a character column of type CHAR, LVARCHAR, or VARCHAR into type NCHAR or NVARCHAR results in case-insensitive processing of values in the modified column. (The data values are not changed, but variations in letter case are ignored in comparison and collation operations on those values.)

## Altering the Structure of Tables

### About this task

When you use the MODIFY clause, you can also alter the structure of other tables. If the modified column is referenced by other tables, those referential constraints are dropped. You must add those constraints to the referencing tables again, using the ALTER TABLE statement.

When you change the data type of an existing column, all data is converted to the new data type, including numbers to characters and characters to numbers (if the characters represent numbers). The following statement changes the data type of the **quantity** column:

```
ALTER TABLE items MODIFY (quantity CHAR(6));
```

When a primary-key or unique constraint exists, however, conversion takes place only if it does not violate the constraint. If a data type conversion would result in duplicate values (by changing FLOAT to SMALLFLOAT, for example, or by truncating CHAR values), the ALTER TABLE statement fails.

## Modifying Tables for NULL Values

### About this task

You can modify an existing column that formerly permitted NULLs to disallow NULLs, provided that the column contains no NULL values. To do this, specify MODIFY with the same column name and data type and the NOT NULL keywords. Those keywords create a NOT NULL constraint on the column.

You can modify an existing column that did not permit NULLs to permit NULLs. To do this, specify MODIFY with the column name and the existing data type, and omit the NOT NULL keywords. The omission of the NOT NULL keywords drops the NOT NULL constraint on the column. If a unique index exists on the column, you can remove it using the DROP INDEX statement.

An alternative method of permitting NULL values in an existing column that did not permit NULL values is to use the DROP CONSTRAINT clause to drop the NOT NULL constraint on the column.

When you define a PRIMARY KEY constraint, the database server also silently creates a NOT NULL constraint on the same column, or on the same set of columns that make up the primary key.

## Adding a Constraint on a Non-Opaque Column

ALTER TABLE ... MODIFY operations that use the Single Column Constraint format to implicitly create an index on a non-opaque column also automatically calculate the distribution of the specified column. The distribution statistics are available to the query optimizer when it designs query plans for the table on which the constraint is defined:

- For columns on which the new constraint is implemented as a B-tree index, the recalculated column distribution statistics are equivalent to distributions created by the UPDATE STATISTICS statement in HIGH mode.
- If the new constraint is not implemented as a B-tree index, the automatically recalculated statistics correspond to distributions created by the UPDATE STATISTICS statement in LOW mode.

See also the section [Automatic Calculation of Distribution Statistics on page 280](#) in the description of the CREATE INDEX statement for additional information about statistical distributions that are produced automatically when an index or constraint is created on an existing table.

## Modify Column Security clause

The DBSECADM can use this clause of the ALTER TABLE statement to modify the column-level security of a column, either by associating the column with an LBAC security label, or by dropping an existing association between the column and a security label.

This clause is valid only for tables that are protected by an LBAC security policy. This syntax fragment is part of the [MODIFY Clause on page 143](#).

Modify Column Security Clause

### COLUMN

**SECURED WITH***label*

**DROP COLUMN SECURITY**

| Element      | Description                    | Restrictions   | Syntax                                  |
|--------------|--------------------------------|--|---|
| <i>label</i> | Name of an LBAC security label | Must exist and must belong to the same LBAC security policy that protects the table. | <a href="#">Identifier on page 1456</a> |

### Usage

The DBSECADM can use this clause to add or drop column-level protection for a table. This clause can add row-level protection by associating the column with an LBAC security label, or it can use the `DROP COLUMN SECURITY` keywords to drop existing column-level security protection that a label was currently providing for the column.

- To establish column-level protection to a column, specify `SECURED WITH label` (or equivalently, `COLUMN SECURED WITH label`) to associate a security label with the column.
- To drop the column-level protection that an existing label is providing for a column, specify the `DROP COLUMN SECURITY` keywords.

The security label can be the same label that protects other rows or columns of the table, or it can be a different label of the same security policy. The following restrictions apply to the `SECURED WITH label` option:

- The table must be protected by an LBAC security policy.
- The data type of the protected column cannot be `IDSSECURITYLABEL`.
- The *label* must be a label of the same security policy that secures the table.
- Any number of columns can be protected by a security label, but no more than one security label can protect a given column.
- No more than one column name can precede each `SECURED WITH` or `DROP COLUMN SECURITY` specification of the [MODIFY Clause on page 143](#),
- Specify the *label* without the policy qualifier, rather than as *policy.label*.

When the ALTER TABLE MODIFY COLUMN SECURED WITH statement or the ALTER TABLE MODIFY DROP COLUMN SECURITY statement run successfully, the database server registers the change in column security in the `syscolumns` system catalog table.

For example, if the table **Argoknot** is protected by a security policy called **Medea** that has a security label called **fleece**, the following ALTER TABLE statement defines column-level protection with the **Medea.fleece** label for the column **Argoknot.ColJ**:

```
ALTER TABLE Argoknot
  MODIFY (ColJ JSON SECURED WITH fleece);
```

When DBSECADM successfully runs this DDL statement, the new column-level security of column **Argoknot.ColJ** is registered in the **syscolumns** system catalog table. To do this, the database server takes this action:

- It updates the row in **syscolumns** that describes column **Argoknot.ColJ**
- by replacing the **NULL** value in column **syscolumns.seclabelid**
- with the numeric value in column **sysseclabels.seclabelid**
- for the row describing the **Medea.fleece** security label.

Similarly, DBSECADM can later detach the **Medea.fleece** security label from the **Argoknot.ColJ** column by running the following ALTER TABLE statement:

```
ALTER TABLE Argoknot
  MODIFY (ColJ JSON DROP COLUMN SECURITY);
```

After this DDL statement executes successfully, the database server registers the now unprotected status of column **ColJ** by updating column **seclabelid** to a **NULL** value in the row of the **syscolumns** system catalog table that describes column **Argoknot.ColJ**.

### Example of enabling column-level security

Suppose that table **Alphanumeric** was created with the following columns but with no security policy:

```
CREATE TABLE Alphanumeric
  (Col1 CHAR(18),
   Col2 INT,
   Col3 CHAR (20));
```

The following ALTER TABLE statement

- attaches the **watchdog** security policy to the **Alphanumeric** table,
- and changes the column-level security status of column **Col1** from *unprotected* to *protected*, by using the **SECURED WITH** keywords to associate that column with the LBAC **watchdog.Label23** security label:

```
ALTER TABLE Alphanumeric
  MODIFY (Col1 CHAR(18) SECURED WITH Label23)
  ADD SECURITY POLICY watchdog;
```

Because the **Alphanumeric** table was created with no security policy, the **ADD SECURITY POLICY** clause is required for the **Modify Column Security** clause to be valid in the example above.

The result of the ALTER TABLE MODIFY operation would be the same if the **COLUMN** keyword had preceded the **SECURED WITH** keywords:

```
ALTER TABLE Alphanumeric
  MODIFY (Col1 CHAR(18) COLUMN SECURED WITH Label23)
  ADD SECURITY POLICY watchdog;
```

In either case, the **Alphanumeric** table now has column-level protection for column **Col1**, which is secured by the **Label23** security label of the **watchdog** security policy.

If the data in other columns of the **Alphanumeric** table besides **Col1** have the same security requirements as **Col1**, the following statements secure the other columns with the same **Label23** security label:

```
ALTER TABLE Alphanumeric
  MODIFY (Col2 INT COLUMN SECURED WITH Label23);

ALTER TABLE Alphanumeric
  MODIFY (Col3 CHAR(20) COLUMN SECURED WITH Label23);
```

DBSECADM can also grant that security label to the specific users who require access to the data that **Label23** is designed to protect:

```
GRANT SECURITY LABEL watchdog.Label23
  TO sam FOR READ ACCESS;

GRANT SECURITY LABEL watchdog.Label23
  TO peter, elaine, olan FOR WRITE ACCESS;

GRANT SECURITY LABEL watchdog.Label23
  TO lynette FOR ALL ACCESS;
```

For detailed examples of creating LBAC security labels and granting them to users, see [Examples of Granting User Security Labels on page 623](#).

### Dropping security-label protection from a column

Suppose table **Betanumeric** is a protected table that was created with **watchdog** as its security policy,

- with both column **Col1** and **Col3** secured by the column-level protection of label **labelK9**,
- and with column **Col4** providing row-level security for the table with a security label whose default value is **labelK2**;

```
CREATE TABLE Betanumeric
  (Col1 CHAR (18)SECURED WITH labelK9,
   Col2 INT,
   Col3 CHAR (20)SECURED WITH labelK9
   Col4 IDSSECURITYLABEL DEFAULT 'labelK2')
  SECURITY POLICY watchdog;
```

Here **labelK9** and **labelK2** must both be labels of the **watchdog** security policy.

**Tip:** For two or more columns of the same table to have column-level protection, it is not required that the same LBAC label secure all of those columns. If sensitive data in several columns logically require the same access restrictions, however, securing multiple columns with the same security label might be appropriate.

Suppose that DBSECADM subsequently determines that the sensitivity of the data stored in column **Col1** does not require the protection of **watchdog.labelK9**, but is sufficiently protected by the row-level protection of label **watchdog.labelK2**. In this case, DBSECADM might issue the following ALTER TABLE MODIFY statement, thereby dropping the association between security label **watchdog.labelK9** and **Col1** of table **Betanumeric**:

```
ALTER TABLE Betanumeric
  MODIFY (Col1 CHAR (18) DROP COLUMN SECURITY);
```

This ALTER TABLE MODIFY statement drops the security restriction that users cannot access column **Col1** unless their LBAC credentials include all the components of label **watchdog.labelK9**, or unless they hold equivalent LBAC security exemptions. Detaching the specified column from the specified security label is the entire scope of the `DROP COLUMN SECURITY` option to the Modify Column Security clause.

That is, disabling column-level security of a single column has no effect on the column-level protection of any other columns of the same table that are secured by the same LBAC label, such as column **Betanumeric.Col3** in this example. This `DROP COLUMN SECURITY` example also has no effect on any the following:

- On the row-level protection of table **Betanumeric** by the **watchdog.labelK2** label.
- On any other tables protected by the **watchdog** security policy,
- On any other tables protected by the **labelK9** security label.

Thus, only the column-level protection of column **Betanumeric.Col1** was dropped by the preceding ALTER TABLE MODIFY statement. The **watchdog** security policy, through row-level protection by the **labelK2** security label in column **Col4**, and column-level protection with the **labelK9** security label for column **Col3**, continues to protect table **Betanumeric**.

### Detaching a table from its security policy

The DROP SECURITY POLICY clause detaches only a single column from its security label. If you hold the DBSECADM role, it is important to avoid confusing the DROP COLUMN SECURITY clause with the DROP SECURITY POLICY clause.

The following example, based on the same **Betanumeric** table, illustrates the ALTER TABLE statement syntax to drop the association between a specific table and its LBAC security policy:

```
ALTER TABLE Betanumeric DROP SECURITY POLICY;
```

When this statement executes successfully, it removes all column-level and row-level protection from the table. The database server updates the system catalog to show these changes to database objects within the scope of this example:

- Table **Betanumeric** is no longer protected by any security policy. This change is registered in two columns of the row that describes **Betanumeric** in the **sysables** system catalog table:
  - In column **secpolicyid**, a `NULL` value replaces the numeric value of the **watchdog** security policy ID.
  - In column **protgranularity** of the same row, a blank character (ASCII 32) to indicate no protection replaces the `B` that had encoded both row-level and column-level protection as the former LBAC granularity of the **Betanumeric** table.
- Columns **Betanumeric.Col1** and **Betanumeric.Col3** are no longer protected by LBAC label **watchdog.labelK9**. This change is registered in two rows that describe those columns in the **syscolumns** system catalog table:
  - In column **seclabelid** of the row describing the **Betanumeric.Col1** column, a `NULL` value replaces the numeric value of the **labelK9** security label ID.
  - In column **seclabelid** of the row describing the **Betanumeric.Col3** column, a `NULL` value replaces the numeric value of the **labelK9** security label ID.
- Column **Col4** is automatically dropped from the schema of table **Betanumeric**, because a table with no security policy cannot include a column of type IDSECURITYLABEL. This change is registered in the system catalog by dropping the row that had described the **Betanumeric.Col4** column from the **syscolumns** system catalog table.

**!** **Important:** Except for the **Betanumeric** table and the data in its rows and columns, the ALTER TABLE DROP SECURITY POLICY statement in this example has no effect on any other database objects that the **watchdog** security policy or the **labelK2** or **labelK9** security labels protect. Only DROP SECURITY statements can destroy security objects. For more information about detaching a security policy from a table, see [SECURITY POLICY Clause on page 160](#).

## Adding a Constraint That Existing Rows Violate

If you use the MODIFY clause to add a constraint in the enabled mode and receive an error message because existing rows would violate the constraint, take the following steps to add the constraint successfully:

1. Add the constraint in the disabled mode.

Issue the ALTER TABLE statement again, but this time specify the DISABLED keyword in the MODIFY clause.

2. Start a violations and diagnostics table for the target table with the START VIOLATIONS TABLE statement.
3. Issue the SET CONSTRAINTS statement to switch the database object mode of the constraint to the enabled mode.

When you issue this statement, existing rows in the target table that violate the constraint are duplicated in the violations table; however, you receive an integrity-violation error message, and the constraint remains disabled.

4. Issue a SELECT statement on the violations table to retrieve the nonconforming rows that are duplicated from the target table.

You might need to join the violations and diagnostics tables to get all the necessary information.

5. Take corrective action on the rows in the target table that violate the constraint.
6. After you fix all the nonconforming rows in the target table, issue the SET statement again to enable the constraint that was disabled.

Now the constraint is enabled, and no integrity-violation error message is returned because all rows in the target table now satisfy the new constraint.

## How Modifying a Column Affects Triggers

If you modify a column that appears in the triggering column list of an UPDATE trigger, the trigger is unchanged.

When you modify a column in a table, the triggers based on that table remain unchanged, but the column modification might invalidate the trigger.

The following statements illustrate the possible effects on triggers:

```
CREATE TABLE tab1 (i1 INT, i2 INT, i3 INT);
CREATE TABLE tab2 (i4 INT, i5 INT);
CREATE TRIGGER col1trig UPDATE OF i2 ON tab1
  BEFORE(INSERT INTO tab2 VALUES(1,1));
ALTER TABLE tab2 MODIFY i4 CHAR;
```

After the ALTER TABLE statement, column **i4** accepts only character values. Because character columns accept only values enclosed in quotation marks, the action clause of the **col1trig** trigger is invalidated.

If a trigger is invalidated when you modify the underlying table, drop and then re-create the trigger.

## How Modifying a Column Affects Views

When you modify a column in a table, the views based on that table remain unchanged. If a view is invalidated when you alter the underlying table, you must rebuild the view.

## MODIFY EXTENT SIZE

Use the MODIFY EXTENT SIZE clause with the ALTER TABLE statement to change the size of the first extent of a table in a dbspace.

You cannot use the MODIFY EXTENT SIZE clause to change the size of the first extent:

- of a table in a blobspace
- of external tables, virtual tables, or system catalog tables
- in the tblspace **tblspace**

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

MODIFY EXTENT SIZE Clause

**MODIFY EXTENT SIZE***kilobytes*

| Element          | Description  | Restrictions   | Syntax                                  |
|------------------|--|--|---|
| <i>kilobytes</i> | Length (in kilobytes) assigned here to the first extent for this table | Specification cannot be a variable, and (4(page size)) <i>kilobytes</i> (chunk size) | <a href="#">Expression on page 1193</a> |

The minimum extent size is 4 times the disk-page size. For example, on a system with 2-kilobyte pages, the minimum length is 8 kilobytes. The maximum length is the chunk size.

The following example specifies an extent size of 32 kilobytes:

```
ALTER TABLE customer MODIFY EXTENT SIZE 32;
```

When you change the size of the first extent, the database server records the change in the system catalog and on the partition page, but only makes the actual change when the table is rebuilt or a new partition or fragment is created.

For example, if a table has a first extent size of 8 kilobytes and you use the ALTER TABLE statement to change this to 16 kilobytes, the server does not drop the current first extent and recreate it with the new size. Instead, the new first extent size of 16 kilobytes takes effect only when the server rebuilds the table after actions such as creating a cluster index on the table or detaching a fragment from the table.

If a TRUNCATE TABLE statement without the REUSE option is executed before the ALTER TABLE statement with the MODIFY EXTENT SIZE clause, there is no change in the size of the current first extent.

If an existing table in a dbspace has data in it, the first and next extents are already allocated for the table and you will not be able to change the size of the first or next extent. If you want to change the size of existing extents, you must drop the table, recreate it with a storage clause indicating the desired size, and load the data again.

You can change the size of the first and next extent at the same time. The following example specifies changing the size of the first and next extent:

```
ALTER TABLE customer MODIFY EXTENT SIZE 32 NEXT SIZE 32
```

The first and next extent sizes are recorded in the PNSIZES logical log record.

---

#### Related reference

[MODIFY NEXT SIZE clause on page 155](#)

## MODIFY NEXT SIZE clause

Use the MODIFY NEXT SIZE clause to change the size of the next extent.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

MODIFY NEXT SIZE clause

**MODIFY NEXT SIZE** *kilobytes*

| Element          | Description   | Restrictions   | Syntax                                  |
|------------------|---|--|---|
| <i>kilobytes</i> | Length (in kilobytes) assigned here to the next extent for this table | Specification cannot be a variable, and (4(page size)) <i>kilobytes</i> ; (chunk size) | <a href="#">Expression on page 1193</a> |

The minimum extent size is 4 times the disk-page size. For example, on a system with 2-kilobyte pages, the minimum length is 8 kilobytes. The maximum length is the chunk size. The following example specifies an extent size of 32 kilobytes:

```
ALTER TABLE customer MODIFY NEXT SIZE 32;
```

This clause cannot change the size of existing extents. You cannot change the size of existing extents without unloading all of the data.

To change the size of existing extents, you must unload all the data, drop the table, modify the *first-extent* and *next-extent* sizes in the CREATE TABLE definition in the database schema, re-create the table, and reload the data. For information about how to optimize extent sizes, see your *Informix® Performance Guide*.

## PUT Clause

Use the PUT clause of the ALTER TABLE statement to define sbspace storage for a column that contains smart large objects. This clause can define BLOB or CLOB storage attributes for a new column, or it can modify the current settings of those storage attributes for an existing column.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

PUT Clause

**PUT** *column*

**IN**

(

, *sbspace*

)

(

,

**EXTENT SIZE** *kilobytes*

**NO LOG LOG**

**HIGH INTEG MODERATE INTEG**

**NO KEEP ACCESS TIME KEEP ACCESS TIME**

)

| Element          | Description   | Restrictions   | Syntax                                      |
|------------------|---|--|---|
| <i>column</i>    | Column to store in the specified sbspace            | Must be a UDT, or a complex, BLOB, or CLOB data type   | <a href="#">Identifier on page 1456</a>     |
| <i>kilobytes</i> | Number of kilobytes to allocate for the extent size | Must be an integer value   | <a href="#">Literal Number on page 1419</a> |
| <i>sbspace</i>   | Name of an area of storage for smart large objects  | The sbspace must exist. See also <b>Usage</b> for <i>sbspace</i> restrictions on tables in tenant databases. | <a href="#">Identifier on page 1456</a>     |

### Usage

The data type of the *column* can be BLOB or CLOB, or it can be a complex data type or a user-defined data type (UDT) that can store smart large objects.

The format *column.field* is not valid here. That is, the smart large object that you are storing cannot be one field of a ROW type.

If the table that the PUT clause of the ALTER TABLE statement is modifying is in a tenant database, the *sbspace* must be a dedicated sbspace in the tenant database properties list. If the table is not in a tenant database, the *sbspace* cannot be the name of an sbspace that is dedicated to a tenant database.

Specifying more than one *sbspace* distributes the storage of the BLOB or CLOB objects in a round-robin distribution scheme. When a new row is inserted, the database server favors the *sbspace* with the most available storage space.

When more than one *sbspace* name follows the `IN` keyword, parentheses must delimit the comma-separated list of *sbspaces* that store the BLOB or CLOB objects. Unless you accept default values for all of the storage options that can follow the *sbspace* list, delimiting parentheses must also enclose the list of storage options, as in the following example:

```
ALTER TABLE MyClobs ADD (c5 CLOB)
  PUT c5 IN (sbs3,sbs4) (EXTENT SIZE 64, HIGH INTEG);
```

Here the `ADD` clause above appends a new column **c5** of type CLOB to table **MyClobs**. The `PUT` clause stores each CLOB object in *sbspace* **sbs3** or **sbs4**, in a round-robin distribution. The first extent size is 64 kilobytes, and the data pages will include page headers and page footers in `HIGH` data integrity mode. By default, the column is unlogged, and access times are not recorded.

When the `PUT` clause modifies a BLOB or CLOB column, the storage characteristics of smart large objects already stored in the column are unchanged. The new characteristics apply only to BLOB or CLOB objects in rows inserted into the table after the `PUT` clause takes effect.

This syntax resembles the `PUT` clause of the `CREATE TABLE` statement, but the `PUT` clause of `ALTER TABLE` can specify only a single column, rather than a list of columns. Changes made to storage attributes of BLOB or CLOB objects by the `PUT` clauses of the `ALTER TABLE` statement or the `CREATE TABLE` statement are registered in the **syscolattns** system catalog table.

### Using the `PUT` clause with a new or modified column

When you use this clause to specify storage attributes for smart large objects in a new column that the `ALTER TABLE` statement is adding to the table schema, or for an existing column whose *sbspace* storage the `ALTER TABLE` statement is modifying, these keyword options of the `PUT` clause can define explicit or default characteristics for one or more existing *sbspace*:

#### `IN ( sbspace_list )`

Here *sbspace\_list* is a comma-separated list of one or more *sbspace* names. If you omit `IN sbspace_list` from the `PUT` clause, the **SBSPACENAME** configuration parameter specifies the system default *sbspace* in which smart large objects are stored. If the *sbspace\_list* of the `PUT` clause specifies more than one *sbspace*, the smart blob objects are distributed round-robin among those *sbspaces*. Each smart large object is stored in a single *sbspace*.

#### `EXTENT SIZE integer`

This sets a lower limit on how many kilobytes can be stored in a smart-large-object extent. If you omit the `EXTENT SIZE` keywords, the database server calculates a default extent size.

#### `NO LOG`

This prevents the same logging procedure that is applied to other columns from being applied to the smart large objects. This default reduces log traffic, and reduces the risk of filling the logical log.

**LOG**

This alternative option to `NO LOG` applies the logging procedure used with the current database for smart large objects in the sbspaces that this PUT clause assigns.

**HIGH INTEG**

This high data-integrity option produces user-data pages that each contains a page header and a page trailer to detect incomplete writes and data corruption. This option is the default data-integrity behavior.

**MODERATE INTEG**

This alternative data-integrity option to `HIGH INTEG` produces user-data pages that each contains a page header but no page trailer. This option reduces operational costs, but cannot detect incomplete writes or data corruption by comparing the page header with a page trailer.

**NO KEEP ACCESS TIME**

This does not record the system time when the smart large object was last read or written. This option provides better performance than the `KEEP ACCESS TIME` option, and is the default tracking behavior.

**KEEP ACCESS TIME**

This alternative tracking option to `NO KEEP ACCESS TIME` maintains a record in the smart-large-object metadata of the system time when the smart large object was last read or written.

The PUT clause cannot specify a buffering mode or a locking granularity for the smart large object. The system default buffering mode is `OFF`, and the system default locking granularity is the entire smart large object. The `-Df` option of the `onspaces` utility can override these defaults for specific sbspaces that store BLOB or CLOB objects that require other settings.

When you modify the storage characteristics of an existing column, by default *all* attributes previously associated with the storage space for that column are dropped. If you want the same settings for certain attributes to persist, you must explicitly specify the settings for those attributes again. For example,

- to retain logging, you must specify the `LOG` keyword again. Otherwise, the default `NO LOG` option takes effect.
- to retain the less costly level of data-integrity, you must specify the `MODERATE INTEG` keywords again. Otherwise, the default `HIGH INTEG` option takes effect.
- to maintain a smart-large-object metadata record of when the smart large object was last read or written, you must specify `KEEP ACCESS TIME` keywords again. Otherwise, the default `NO KEEP ACCESS TIME` option takes effect.

Sections that follow illustrate ALTER TABLE operations that use these options of the PUT clause.

Suppose that permanent table `sbt` was created with the following schema:

```
CREATE TABLE sbtab (c2 INT);
```

**Example 1: Adding a new BLOB column to a table**

The following ALTER TABLE statement alters the schema of table `sbt` by adding BLOB column `c1` as the new first column, and stores its BLOB objects in existing sbspace `sbs1`, for which the PUT clause defines additional attributes:

```
ALTER TABLE shtab ADD (c1 BLOB BEFORE c2)
  PUT c1 IN (sbs1) (EXTENT SIZE 32,
                 NO LOG,
                 MODERATE INTEG,
                 KEEP ACCESS TIME);
```

The PUT clause specifies these storage attributes for new column **c1**:

- allocates 32 kilobytes for the first extent of each BLOB object,
- disables transaction logging for the new column in sbspace **sbs1**,
- uses the data-integrity option of data page headers without footers,
- and maintains a record of when each BLOB object was last read or written.

### Examples 2 and 3: Modifying sbspace attributes

Suppose that the owner of table **shtab** subsequently decides to change the storage options for the BLOB objects in column **c1**. The following ALTER TABLE statement alters the storage attributes of BLOB column **c1** by changing the extent size in the sbspace **sbs1** to 64 kilobytes, and turning on transaction logging:

```
ALTER TABLE shtab PUT c1 IN (sbs1) (EXTENT SIZE 64, LOG);
```

Because this example does not repeat the nondefault settings for the data integrity and access time attributes that *Example 1* specified, the new PUT clause sets these storage options for new BLOB objects in column **c1**:

- continues to store new BLOB objects in sbspace **sbs1**,
- increases to 64 kilobytes the first extent of each BLOB object,
- explicitly enables transaction logging for column **c1**,
- implicitly restores the default data-integrity option of data pages with headers and footers,
- and implicitly discontinues recording `ACCESS TIME` records.

But all of the storage attributes that the `ALTER TABLE shtab ADD` statement set for sbspace **sbs1** in *Example 1* persist in any rows that were added to the **shtab** table before *Example 2* reset those attributes.

The next example of the PUT clause modifies only one attribute of the same sbspace **sbs1** to change its logging mode for BLOB column **c1** to NO LOG:

```
ALTER TABLE shtab PUT c1 IN (sbs1) (EXTENT SIZE 64, NO LOG);
```

Because NO LOG is the default for smart large objects, this statement has the same effect if the `NO LOG` keywords are omitted, as in this equivalent example:

```
ALTER TABLE shtab PUT c1 IN (sbs1) (EXTENT SIZE 64);
```

### Example 4: Distributing storage across sbspaces

This example alters the **shtab** table to distribute the storage of BLOB column **c1** in sbspaces **sbs1** and **sbs2**.

```
ALTER TABLE shtab PUT c1 IN (sbs1, sbs2)
  (EXTENT SIZE 100, LOG, KEEP ACCESS TIME);
```

The PUT clause also

- changes the extent size to 100 kilobytes,
- turns on transaction logging,
- and records the system times of the last read access and write access in the smart-large-object metadata.

For more information on the storage characteristics for smart large objects when database tables are created, refer to the counterpart of this topic in the [PUT Clause on page 378](#) of the CREATE TABLE statement. For a discussion of large-object characteristics, refer to [Large-Object Data Types on page 1180](#).

## SECURITY POLICY Clause

Use the Security Policy clause of the ALTER TABLE statement to drop the security policy that is currently associated with the table, or to associate a security policy with a table that has none.

This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

SECURITY POLICY Clause

**ADD SECURITY POLICY***policy*

**DROP SECURITY POLICY**

| Element       | Description               | Restrictions                        | Syntax                                  |
|---------------|---------------------------|-------------------------------------|---|
| <i>policy</i> | Name of a security policy | Must be an existing security policy | <a href="#">Identifier on page 1456</a> |

### Usage

Only DBSECADM can use this clause to add a security policy to an existing table, or to remove from the table the protection of the security policy that currently protects a table.

### Restrictions on adding a security policy

The following guidelines apply to tables that can be protected by executing the ADD SECURITY POLICY clause of the ALTER TABLE statement:

- A table is not protected unless it has a security policy associated with it and has either rows secured, or has at least one column secured.
  - Having rows secured indicates that the table is a *protected table* with *row-level* granularity.
  - Having at least one column secured indicates that the table is a *protected table* with *column-level* granularity.
- Securing rows by using the ALTER TABLE ... ADD *column* statement to add an IDSSECURITYLABEL column to an existing table fails if the table does not have a security policy associated with it.
- Securing a column with the ALTER TABLE ... MODIFY *column* SECURED WITH *label* clause fails if the table does not have a security policy associated with it.
- A table can have at most one security policy. The ALTER TABLE ... ADD SECURITY POLICY statement fails if the table already has a security policy.
- A table can have any number of protected columns. Each protected column can have a different security label, or several protected columns can share the same security label, but all labels must have the same security policy.

- This clause cannot add a security policy to protect any of the following table objects
  - a temporary table,
  - a table outside the current database,
  - a typed table in a table hierarchy,
  - an object defined by the CREATE EXTERNAL TABLE statement.
- A table can have at most one column of type IDSSECURITYLABEL.
- The IDSSECURITYLABEL column cannot have column-level protection (that is, a security label).
- The IDSSECURITY LABEL column cannot have single column constraints.
- The IDSSECURITY LABEL column cannot be part of the multiple column key of a referential constraint or of a check constraint.
- The IDSSECURITYLABEL column cannot be encrypted.
- The IDSSECURITYLABEL column has an implicit DEFAULT NOT NULL constraint. The default column value is the value of the security label of the user for write access.
- The IDSSECURITYLABEL column cannot be modified by the ALTER TABLE MODIFY statement.

### Security policies and tables with distributed storage

Detaching a fragment of a protected table creates a new table that is protected by the same security policy for the same row security label column, and the same set of protected columns.

Some restrictions apply to associating a fragmented table with a security policy. Attaching a fragment to a protected fragmented table fails if any of these conditions are true:

- if the source table and the target table are not protected using the same security policy;
- if the tables do not have the same protection granularity;
- if the tables do not have the same set of protected columns, each protected by the same security label.

For more information on using the ALTER FRAGMENT statement to attach fragments to protected tables, see [Additional Restrictions on the ATTACH Clause on page 30](#).

### Associating a security policy with a table

In a database in which the LBAC security policy **Watchdog** is defined, consider an unprotected table with the following schema:

```
CREATE TABLE IF NOT EXISTS MyData
  (C1 CHAR (8),
   C2 INT,
   C3 CHAR (10));
```

The DBSECADM can change this to a table with row-level protection of the **Watchdog** security policy by issuing the following ALTER TABLE statement:

```
ALTER TABLE MyData
  ADD C4 IDSSECURITYLABEL,
  ADD SECURITY POLICY Watchdog;
```

Here no security label is specified, so the default security label for the rows of the **MyData** table is the label of the **Watchdog** security policy that the current user holds for write access. This example illustrates a requirement that if the table is

protected by no security policy, both the ADD COLUMN IDSSECURITYLABEL clause and the ADD SECURITY POLICY clause must be included in the same ALTER TABLE statement.

An alternative to the syntax illustrated by the previous example is that the DBSECADM can instead change the **MyData** table to a table protected by a specific security label of the **Watchdog** security policy, rather than by a default security label, as in this ALTER TABLE statement:

```
ALTER TABLE MyData
  ADD C4 IDSSECURITYLABEL DEFAULT 'canine',
  ADD SECURITY POLICY Watchdog;
```

Here the security label **canine** must be part of the **Watchdog** security policy.

### Dropping a security policy from a table

Conversely, in a database in which the LBAC security policy **Watchdog** is defined, consider a protected table called **MyOtherData** with the same schema that resulted after the ALTER TABLE statement in the previous example modified for the **MyData** table:

```
CREATE TABLE IF NOT EXISTS MyOtherData
  (C1 CHAR (8),
   C2 INT,
   C3 CHAR (10)
   C4 IDSSECURITYLABEL DEFAULT canine NOT NULL)
  SECURITY POLICY Watchdog;
```

The DBSECADM can change this **MyOtherData** table to an unprotected table with no security policy by issuing the following statement:

```
ALTER TABLE MyOtherData
  DROP SECURITY POLICY Watchdog;
```

When a security policy is dropped from a table by the ALTER TABLE DROP SECURITY POLICY statement, the IDSSECURITYLABEL column **C4** that provided row-level protection is automatically dropped. If labels table had protected any columns, those columns become unprotected when the security policy was dropped.

The DROP SECURITY POLICY option requires the Connect, Resource, and Alter discretionary access privileges for dropping columns, because this option drops the IDSSECURITYLABEL column that only tables associated with a security policy can include in their schema.

### Replacing the security policy of an existing table

If the DROP SECURITY POLICY clause of the ALTER TABLE statement executes successfully, the table is no longer protected by any security policy. Other tables that are associated with the same security policy, however, are not affected by the alterations to this table. The IDSSECURITYLABEL column and any security label associated with the dropped security policy are no longer part of the table schema.

If no protection of a security policy is needed for the data in the table, no further action is needed.

If either row-level or column-level protection is needed for the table, however, a user who holds DBSECADM credentials should take steps to attach another security policy to the table :

- Replace the security policy that was dropped with another security policy, using the ADD SECURITY POLICY clause in an ALTER TABLE statement that also establishes row-level or column-level security. The following example establishes both row-level and column-level protection for the **MyOtherData** table, based on the **Robodog** security policy:

```
ALTER TABLE MyOtherData
  ADD (C4 IDSSECURITYLABEL DEFAULT),
  MODIFY (C2 INT COLUMN SECURED WITH label7),
  ADD SECURITY POLICY Robodog;
```

- If the new security design requires only row-level protection, then instead of the previous example, the **C2** column need not be associated with **label7**:

```
ALTER TABLE MyOtherData
  ADD (C4 IDSSECURITYLABEL DEFAULT),
  ADD SECURITY POLICY Robodog;
```

- If the new security design requires only column-level protection, use the MODIFY . . . COLUMN SECURED WITH clause to protect one of more columns with labels of the new security policy.

```
ALTER TABLE MyOtherData
  MODIFY (C1 CHAR (8) COLUMN SECURED WITH label9),
  ADD SECURITY POLICY Robodog;
```

## Dropping a security policy from a table or from the database

Do not confuse this DROP SECURITY POLICY clause of the ALTER table statement with the DROP SECURITY POLICY statement of SQL.

- When the DROP SECURITY POLICY clause of the ALTER TABLE statement executes successfully, its immediate effects include these:
  - It terminates the association of that table with the security policy,
  - and it drops the IDSSECURITYLABEL column from that table,
  - and it removes LBAC protection from data that had been protected in that table.

It has no effect, however, on the security policy, nor on other tables protected by the policy.

- When the DROP SECURITY POLICY statement executes successfully, the scope of its effects depends on whether the policy is dropped in `RESTRICT` mode or in `CASCADE` mode, but in either mode, it destroys the specified policy.

See the description of [DROP SECURITY statement on page 526](#) for more information on the DROP SECURITY POLICY statement of SQL, and about restrictions on that statement.

## Statistics options of the ALTER TABLE statement

Use the Statistics Options clause of the ALTER TABLE statement to change values of the STATCHANGE property of a fragmented or nonfragmented table, and the STATLEVEL property of a fragmented table. These table properties control the threshold for recalculation in automatic mode, and the granularity of data distribution statistics.

This clause supports the same syntax options as the Statistics Options clause of the CREATE TABLE statement. This syntax fragment is part of the [ALTER TABLE statement on page 99](#).

## Statistics Options

**STATCHANGE****AUTO** *change\_threshold***STATLEVEL****FRAGMENT TABLE AUTO**

| Element                 | Description  | Restrictions                            | Syntax                                      |
|-------------------------|--|---|---|
| <i>change_threshold</i> | Percentage of changed data rows that defines stale distribution statistics | Must be an integer in the range 0 - 100 | <a href="#">Literal Number on page 1419</a> |

**Usage**

The Statistics Options clause of the ALTER TABLE statement can define or modify table statistics properties that can affect these operations while the automatic mode of UPDATE STATISTICS is enabled:

- UPDATE STATISTICS statements without the **FOR** keyword
- UPDATE STATISTICS FOR TABLE statements in **LOW**, **MEDIUM**, or **HIGH** mode.

The ALTER TABLE statement can modify the specified or default values of the STATCHANGE and STATLEVEL properties that were set when the table was created, or that were set by a previous ALTER TABLE statement.

**The STATCHANGE property**

The STATCHANGE table property specifies the minimum percentage of changes (from UPDATE, DELETE, LOAD, and INSERT operations) on the rows in the table or fragment since the previous calculation of distribution statistics) to consider the statistics stale. You can specify the percentage change as either an integer value in the range 0 - 100, or you can use the **AUTO** keyword to apply the current STATCHANGE configuration parameter setting in the ONCONFIG file, or the setting in the session environment, as the default change threshold value.

The **AUTO** keyword of the UPDATE STATISTICS statement also enables comparing the proportion of rows with changed values to the STATCHANGE setting to determine whether the statistics in the system catalog are stale. Including the **AUTO** keyword in the UPDATE STATISTICS statement enables checking for stale statistics (and selectively updating only the tables or fragments with stale or missing statistics) during the current UPDATE STATISTICS operation.

When the AUTO\_STAT\_MODE configuration parameter or the AUTO\_STAT\_MODE session environment variable enables the automatic mode, the UPDATE STATISTICS statement uses the explicit or default STATCHANGE value to identify table, index, or fragment distributions whose statistics are missing or stale, and updates only the missing or stale statistics. For more information about the automatic mode for UPDATE STATISTICS operations, see information about the AUTO\_STAT\_MODE configuration parameter in the *Informix® Administrator's Reference*.

The STATCHANGE property and the automatic mode of UPDATE STATISTICS do not directly affect the optimization of SPL execution plans, or UPDATE STATISTICS statements that include the **FORCE**, **FOR FUNCTION**, **FOR PROCEDURE**, **FOR ROUTINE**, or **FOR SPECIFIC** keywords.

## The STATLEVEL property

The STATLEVEL property can determine the level of granularity of the data distributions and index statistics of fragmented tables. It can take one of the following three values, with `AUTO` being the default, if no value is specified at creation time:

- `TABLE` specifies that all distributions for the table be created at the table level.
- `FRAGMENT` specifies that distributions be created and maintained for each fragment.
- `AUTO` specifies that the database server apply criteria at run time to determine whether fragment-level distributions are necessary. These criteria require that the following conditions are true:
  - The SYSSBSPACENAME configuration parameter setting specifies an existing sbspace
  - The table is fragmented by an EXPRESSION, INTERVAL, Rolling Window, or LIST strategy
  - The table has more than a million rows.

If any of these criteria are not satisfied, the database server creates table-level distributions, rather than fragment-level.

These properties are always applied. If the STATLEVEL setting is `AUTO`, this setting overrides the default values.

**Note:** The SYSSBSPACENAME configuration parameter, which must be set when the database server instance is initialized, specifies the sbspace in which the database server stores fragment-level data distribution statistics. These are stored as BLOB objects in the `enclist` column of the `syfragsdist` system catalog table. For the database server to support fragment level statistics, the SYSSBSPACENAME configuration parameter setting must specify an existing sbspace.

If you use the Statistics Options clause to set the STATLEVEL property to `FRAGMENT`, the database server returns an error -9814 ("`invalid default sbspace name`") if either of the following is true:

- The SYSSBSPACENAME configuration parameter is not set
- The sbspace that SYSSBSPACENAME specifies was not properly allocated by the `onspaces -c -S` command.

## Example of changing the STATLEVEL

Suppose that table `tabFrag` uses a fragmented distribution strategy other than `ROUND ROBIN`, and includes a BLOB or CLOB column called `smartblob`. You decide to keep the storage distribution strategy, but to use `TABLE`, rather than `FRAGMENT`, as the STATLEVEL granularity.

The following SQL statements implement those changes:

```
ALTER TABLE tabFrag STATLEVEL TABLE;

UPDATE STATISTICS LOW
  FOR TABLE tabFrag (smartblob) DROP DISTRIBUTIONS;

UPDATE STATISTICS HIGH
  FOR TABLE tabFrag (smartblob);
```

The statements above have these respective effects:

- Change the STATLEVEL to TABLE, by using the Statistics Options clause of ALTER TABLE.
- Discard the current fragment-level distributions of **tabFrag.smartblob** in the **sysfragdist** system catalog table, by using UPDATE STATISTICS LOW.
- Create new table-level statistics for **tabFrag** in the **sysdistrib** system catalog table, by using UPDATE STATISTICS HIGH.

In the last statement above, the default HIGH resolution of 0.5 implies that the **tabFrag.smartblob** distribution statistics are based on approximately 200 bins.

### Example of resetting the STATCHANGE value

For the same **tabFrag** table whose STATLEVEL property was changed from FRAGMENT to TABLE in the previous section, suppose that you also decide to change its STATCHANGE value to AUTO from whatever setting it currently has, and to replace the HIGH mode distribution statistics with a MEDIUM mode.

The following SQL statements implement those changes:

```
ALTER TABLE tabFrag STATCHANGE AUTO;

UPDATE STATISTICS LOW
  FOR TABLE tabFrag (smartblob) DROP DISTRIBUTIONS;

UPDATE STATISTICS MEDIUM
  FOR TABLE tabFrag (smartblob) AUTO;
```

In the last s

These are the respective effects on the **tabFrag** table of the statements above:

- The Statistics Options clause of ALTER TABLE changes the STATCHANGE setting to AUTO.
- The UPDATE STATISTICS LOW statement discards the current fragment-level distributions of **tabFrag.smartblob** from the **sysfragdist** system catalog table, but recalculates no table-level statistics. (Here the **LOW** keyword is required syntax to enable the **DROP DISTRIBUTIONS** operation.)
- The UPDATE STATISTICS MEDIUM statement refresh the table-level statistics for **tabFrag** in the **sysdistrib** system catalog table in automatic mode, by including the **AUTO** keyword.

tatement above, the default MEDIUM resolution of 2.5 implies that the **tabFrag.smartblob** distribution statistics are based on approximately 40 bins.

In this example, the **AUTO** setting for STATCHANGE in the ALTER TABLE statement and the **AUTO** keyword in the UPDATE STATISTICS MEDIUM apply automatic mode to the recalculation of **tabFrag.smartblob** statistics. Although no **tabFrag.smartblob** data values changed since the UPDATE STATISTICS HIGH operation in the STATLEVEL example, the preceding UPDATE STATISTICS LOW statement dropped the HIGH mode statistics, so the statistics for 100% of the rows became "missing" during the DROP DISTRIBUTIONS operation. In this case, no selective recalculation of **tabFrag.smartblob** statistics occurs, despite the automatic mode.

The examples above illustrate some effects of ALTER TABLE options for redefining the statistics properties of a table, and the effects of those modified properties on some UPDATE STATISTICS operations in automatic mode. They do not

necessarily illustrate a recommended or efficient sequence of decisions for redefining the granularity or the resolution of column statistics for tables and for table fragments in the system catalog.

---

## **ALTER TRUSTED CONTEXT statement**

Use the ALTER TRUSTED CONTEXT statement to modify the current options and attributes (including the ENABLED or DISABLED mode) of a trusted-context object.

This statement is an extension to the ANSI/ISO standard for the SQL language.

**Syntax****ALTER TRUSTED CONTEXT***context***ALTER**<sup>97</sup>**SYSTEM AUTHID***user*<sup>97</sup>**ATTRIBUTES**(,  
**ADDRESS***address*

)

<sup>97</sup>**NO DEFAULT ROLE****DEFAULT ROLE***role*<sup>97</sup>**DISABLE ENABLE**<sup>97</sup>**ADD ATTRIBUTES**(,  
**ADDRESS***address*

)

<sup>97</sup>**DROP ATTRIBUTES**(,  
**ADDRESS***address*

)

<sup>97</sup>**ADD USE FOR**

, Authorized User Clause

<sup>97</sup>**REPLACE USE FOR**

, Authorized User Clause

<sup>97</sup>**DROP USE FOR**

,

*user***PUBLIC**

Authorized User Clause

*user***ROLE***role***PUBLIC****WITHOUT AUTHENTICATION WITH AUTHENTICATION**

| Element        | Description   | Restrictions  | Syntax                                     |
|----------------|---|---|--|
| <i>address</i> | Communication address of the client connection to the database server | Must be unique among communication addresses of clients for this trusted-context object. For additional <i>address</i> restrictions, see <b>ADDRESS attributes</b> below. | <a href="#">Quoted String on page 1424</a> |

97. Use this path no more than once

| Element        | Description                               | Restrictions   | Syntax                                  |
|----------------|---|--|---|
| <i>context</i> | Name of the trusted-context object        | Must exist among trusted contexts of the database server instance, and cannot begin with the characters <code>sys</code>   | <a href="#">Identifier on page 1456</a> |
| <i>role</i>    | An existing user-defined or built-in role | Must exist in the database, and must be unique among attributes of this trusted-context object   | <a href="#">Owner name on page 1488</a> |
| <i>user</i>    | Authorization identifier of a user        | Must be a valid authorization identifier. Cannot be longer than 32 bytes. Must not be the authorization ID of the user who issues this statement. The REPLACE USE FOR clause must not specify this <i>user</i> more than once. | <a href="#">Owner name on page 1488</a> |

### Usage

You must hold the database security administrator (DBSECADM) role to run this statement. If the statement is embedded in an application program, the privileges are those of the owner. If the statement is run in a trusted context with a role, the set of privileges is the union of these discretionary access privileges:

- the set of privileges held by the role that is associated with the primary authorization ID,
- and the set of privileges held by each role that the statement references.

When the ALTER TRUSTED CONTEXT statement executes successfully, any changes to the trusted-context object, its attributes, and its list of authorized users are registered in these tables in the sysuser database of the Informix® database server instance:

- **systrustedcontext**
- **systcxattributes**
- **systcxusers**.

### ADDRESS attributes

The ALTER ATTRIBUTES, ADD ATTRIBUTES, and DROP ATTRIBUTES options can specify lists of one or more communication addresses for connections to the database server, whose status as connection trust attributes, on which the trusted-context object is defined, are to be modified. The following restrictions apply to communication addresses that the ALTER TRUSTED CONTEXT or the CREATE TRUSTED CONTEXT statements reference:

- Each must be unique among communication addresses of clients for this trusted-context object.
- Each must conform to the TCP/IP protocol.
- Each must be an IPv4 address, an IPv6 address, or a secure domain name.
- An IPv4 address or IPv6 address must be a real host address (not a local host), and must not contain leading blank spaces.
- An IPv6 address, in addition, must not be an IPv4-mapped IPv6 address.
- A secure domain name must not be a Dynamic Host Configuration Protocol (DHCP) address.

If a new *address* value is the name of a secure domain, that name is converted to an IP address by the domain-name server, where a resulting IPv4 or IPv6 address is determined. When a domain name is converted to an IP address, the result of this conversion might be a set of one or more IP addresses. In this case, the database server interprets a subsequent incoming connection request as matching the ADDRESS attribute of a trusted-context object if the IP address from which the connection originates matches any of the IP addresses to which the domain name was converted.

The ALTER ATTRIBUTES clause replaces existing values for specified attributes with the new values. If an attribute is not currently part of the trusted-context object definition, an error is returned. Attributes that are not specified retain their previous values.

Specified ADDRESS values for the trusted-context object are removed by the ALTER ATTRIBUTES clause and by the DROP ATTRIBUTES clause. The ADDRESS attribute can be specified multiple times, but each *address* value must be unique for the set of attributes.

If a new *address* value is the name of a secure domain, that name is converted to an IP address by the domain-name server, where a resulting IPv4 or IPv6 address is determined. When a domain name is converted to an IP address, the result of this conversion might be a set of one or more IP addresses. In this case, the database server interprets a subsequent incoming connection request as matching the ADDRESS attribute of a trusted-context object if the IP address from which the connection originates matches any of the IP addresses to which the domain name was converted.

The ADD ATTRIBUTES clause specifies a list of one or more new trust attributes on which the trusted-context object is defined.

The DROP ATTRIBUTES clause specifies that one or more attributes are to be dropped from the definition of the trusted-context object. If the attribute is not currently part of the trusted-context object definition, an error is returned.

#### Attention:

If you have an existing application with an ALTER TRUSTED CONTEXT statement that includes the `ENCRYPTION` or `WITH ENCRYPTION` options in the ATTRIBUTES clause, the database server does not issue an SQL error. Except, however, for the `WITH ENCRYPTION 'NONE'` and the `ENCRYPTION 'NONE'` keyword options, the encryption options of the ALTER TRUSTED CONTEXT statement are not supported for Informix® database servers.

## DEFAULT ROLE attributes

The `DEFAULT ROLE role` option to the ALTER clause identifies a role that already exists on the current database server. This role can be used by a user who does not hold a user-specific role that was defined as part of the definition of the trusted-context object.

The `NO DEFAULT ROLE` keywords specify that the trusted-context object does not have a default role.

If a trusted connection for this trusted context is active, changes to the DEFAULT ROLE attribute take effect on the next new connection request, or on the next request to switch users.

## ENABLE and DISABLE options of the ALTER clause

The ENABLE attribute specifies that the trusted-context object is enabled.

The DISABLE attribute specifies that the trusted-context object is in a disabled state, and is not enabled for any new trusted connections that are established.

You cannot use the SET Database Object Mode statement of SQL to change the ENABLE or DISABLE attributes of trusted contexts.

### **ADD USE FOR clause**

The ADD USE FOR clause specifies additional users who can establish a trusted connection based on this trusted-context object. The PUBLIC attribute specifies that a trusted connection that is based on this trusted-context object can be used by any user.

The PUBLIC attribute must not already be specified for the trusted-context object, and PUBLIC must not be specified more than once in the ADD USE FOR clause. If the definition of a trusted-context object allows access by PUBLIC and also by one or more users, the user specifications override the PUBLIC specifications.

### **REPLACE USE FOR clause**

The REPLACE USE FOR clause specifies that the way in which a specified user or the PUBLIC group uses the trusted-context object is to change. When you use the REPLACE USE FOR clause on PUBLIC, the trusted-context object must already be defined to allow use by PUBLIC, and PUBLIC must not be specified more than once in the REPLACE USE FOR clause.

The REPLACE USE FOR can specify a different role name, which must be a role that is defined on the database server. The role explicitly specified for the user overrides the default role, if a default role is currently associated with the trusted context.

The REPLACE USE FOR clause can also change the current authentication requirement for a user or for the PUBLIC group.

### **AUTHENTICATION attributes**

The REPLACE USE FOR and ADD USE FOR clause can specify the authentication requirement for trusted connections based on this trusted-context object. The default is WITHOUT AUTHENTICATION.

The WITH AUTHENTICATION attribute specifies that switching the current user on a connection based on this trusted-context object to this user requires authentication.

The WITHOUT AUTHENTICATION attribute specifies that switching the current user does not require authentication.

### **DROP USE FOR clause**

The DROP USE FOR clause specifies who can no longer use the trusted-context object. The users who are removed from the definition of the trusted-context object are those users who are currently allowed to use the trusted-context object. If one or more, but not all, users can be removed from the definition of the trusted-context object, the specified users are removed and a warning is returned. If none of the specified users can be removed from the definition of the trusted-context object, an error is returned.

If you use the DROP USE FOR clause on PUBLIC, it removes the ability of all users (except the SYSTEM AUTHID user ID, and any other individual users whose identifiers have been explicitly enabled) to use this trusted-context object.

## Examples of modifying a trusted-context

For the following example, assume that trusted-context object `appserver` exists and that it is enabled. The following ALTER TRUSTED CONTEXT statement resets the object mode of the `appserver` trusted-context object to `DISABLE`. While in that mode, the `appserver` trusted context continues to exist, but it cannot be used to access the database server.

```
ALTER TRUSTED CONTEXT appserver
  DISABLE;
```

For the following example, assume that trusted-context object `secure_role` exists. Issue an ALTER TRUSTED CONTEXT statement to modify the existing user `joe` to use the trusted-context object with authentication and to add everyone else to use the trusted-context object without authentication.

```
ALTER TRUSTED CONTEXT securerole
  REPLACE USE FOR joe WITH AUTHENTICATION
  ADD USE FOR PUBLIC WITHOUT AUTHENTICATION;
```

The following example modifies the trusted-context object `securerole` to use an IPv4 address that is different from what it was originally defined to use.

```
ALTER TRUSTED CONTEXT securerole
  ALTER ATTRIBUTES (ADDRESS '9.12.155.200');
```

| <i>surrog_user</i>     | Name of an existing OS user account (surrogate user) on the Informix® host computer having the permissions to which you want to map <i>user</i> .  | Must conform to the rules of your operating system  | <a href="#">Owner name on page 1488</a>     |
| <i>user</i>            | Authorization identifier of the specific user that you are mapping to user properties.   | Must be an authenticated authorization identifier   | <a href="#">Owner name on page 1488</a>     |

| Element        | Description   | Restrictions  | Syntax                                      |
|----------------|---|---|---|
| <i>user_ID</i> | User identifier number to which you want to map <i>user</i> . | <i>user_ID</i> cannot be the one that belongs to user <b>root</b> or user <b>informix</b> . | <a href="#">Literal Number on page 1419</a> |

## Usage

Only a DBSA can run the ALTER USER statement. With a non-root installation, the user who installs the server is the equivalent of the DBSA, unless the user delegates DBSA privileges to a different user.

The USERMAPPING configuration parameter must be set to a value (ADMIN or BASIC) that enables support for mapped users before users created with the CREATE USER statement can connect to the database server.

The USERMAPPING configuration parameter must be set to ADMIN to enable the AUTHORIZATION clause. For more information about this deprecated syntax, see the [CREATE USER statement \(UNIX, Linux\) on page 447](#) description of the AUTHORIZATION clause.

You must also enter values in the SYSUSERMAP table of the **sysusers** database to map users with the appropriate user properties so that the mapped user statements of SQL to work correctly.

Mapped users can connect to Informix® with the surrogate user properties if they authenticate with pluggable authentication module (PAM) or single sign-on (SSO).

The best practice is to map *user* to a specific *surrog\_user* that is reserved as a surrogate user identity only. You can add groups associated with the surrogate user identity with the GROUP keyword, and change the home directory with the HOME keyword.

The ALTER USER statement does not affect any active operations with the same surrogate user or user ID. Only subsequent operations that require authentication are affected.

An ALTER USER statement can add a password for a user with the ADD keyword only if that user does not have a password. To change an existing password, use the MODIFY option in the ALTER USER statement.

The total number of groups after the ALTER USER operation cannot exceed 16, which is the maximum number of allowed groups.

An ALTER USER statement can only add a home directory with the ADD keyword if no home directory exists. To modify an existing home directory, use the MODIFY keyword.

In a single ALTER USER statement, a specific property can only be specified once. For example, you cannot drop a GROUP property and add a GROUP property in the same statement.

After the ALTER USER statement, the user must have either one USER property or one UID property.

Execution of the ALTER USER statement can be audited with the ALUR audit code.

## Example

## Examples

### Example 1: Replace a USER property with a UID property

The following statement replaces the USER property with a UID property for the user **bill**:

```
ALTER USER bill DROP USER, ADD UID 1360;
```

### Example 2: Change and add properties

The following statement changes a UID property, adds the DBSA group, and adds a home directory for the user **bill**:

```
ALTER USER bill MODIFY UID 1361, ADD GROUP (dbsa), ADD HOME "/u/user1";
```

### Example 3: Unlock an account and drop an authorization property

The following statement unlocks the account and drops the DBSSO authorization for the user **bill**:

```
ALTER USER bill ACCOUNT UNLOCK DROP AUTHORIZATION (dbssso);
```

### Example 4: Drop a home directory

The following statement drops the home directory for the user **bill**:

```
ALTER USER bill DROP HOME;
```

## BEGIN WORK statement

Use the BEGIN WORK statement to start a *transaction*, which is a series of database operations that the COMMIT WORK or ROLLBACK WORK statement terminates, and that the database server treats as a single unit of work. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**BEGIN**

**WORK**

<sup>99</sup> **WITHOUT REPLICATION**

### Usage

The BEGIN WORK statement is valid only in a database that supports transaction logging. This statement is not valid in an ANSI-compliant database.

99. ESQL/C only

Each row that an UPDATE, DELETE, INSERT, or MERGE statement affects during a transaction is locked and remains locked throughout the transaction. A transaction that contains many such statements or that contains statements that affect many rows can exceed the limits that your operating system or the database server configuration imposes on the number of simultaneous locks.

If no other user is accessing the table, you can avoid locking limits and reduce locking overhead by locking the table with the LOCK TABLE statement after you begin the transaction. Like other locks, this table lock is released when the transaction terminates. The example of a transaction on [Example of BEGIN WORK on page 178](#) includes a LOCK TABLE statement.

**Important:** Issue the BEGIN WORK statement only if a transaction is not in progress. If you issue a BEGIN WORK statement while you are in a transaction, the database server returns an error.

The WORK keyword is optional. The following two statements are equivalent:

```
BEGIN;
BEGIN WORK;
```

In reading SQL source code that omits the WORK keyword, do not confuse the BEGIN statement of SQL with the SPL keyword BEGIN, which, together with the END keyword, can be used as a delimiter to define a statement block within an SPL routine

In Informix® ESQL/C, if you use the BEGIN WORK statement within a UDR called by a WHENEVER statement, specify WHENEVER SQLERROR CONTINUE and WHENEVER SQLWARNING CONTINUE before the ROLLBACK WORK statement.

These statements prevent the program from looping endlessly if the ROLLBACK WORK statement encounters an error or a warning.

---

## BEGIN WORK and ANSI-Compliant Databases

In an ANSI-compliant database, you do not need the BEGIN WORK statement because transactions are implicit; every SQL statement occurs within a transaction. The database server generates a warning when you use a BEGIN WORK statement immediately after any of the following statements:

- DATABASE
- COMMIT WORK

- CREATE DATABASE
- ROLLBACK WORK

The database server returns an error when you use a BEGIN WORK statement after any other statement in an ANSI-compliant database.

## BEGIN WORK WITHOUT REPLICATION (ESQL/C)

When you use Enterprise Replication for data replication, you can use the BEGIN WORK WITHOUT REPLICATION statement to start a transaction that does not replicate to other database servers.

You cannot execute BEGIN WORK WITHOUT REPLICATION as a stand-alone embedded statement in Informix® ESQL/C applications. Instead you must execute this statement indirectly. You can use either of the following methods:

- You can use a combination of the PREPARE and EXECUTE statements to prepare and execute the BEGIN WORK WITHOUT REPLICATION statement.
- You can use the EXECUTE IMMEDIATE statement to prepare and execute BEGIN WORK WITHOUT REPLICATION in a single step.

You cannot use the DECLARE *cursor* CURSOR WITH HOLD statement with the BEGIN WORK WITHOUT REPLICATION statement.

For more information about data replication, see the .

## Example of BEGIN WORK

When consecutive SQL statements perform what is logically a single unit of work, you can define a transaction by grouping them between the BEGIN WORK and COMMIT WORK statements. If the business requirements dictate that either all of the statements be performed successfully, or else that none of them be performed, you can enclose the statements of the transaction between BEGIN WORK to start a transaction and COMMIT WORK to complete the transaction successfully (or ROLLBACK WORK, to cancel the transaction, if the program detects an error).

In the following program fragment, the transaction locks the **stock** table (LOCK TABLE), updates rows in the **stock** table (UPDATE), deletes rows from the **stock** table (DELETE), and inserts a row into the **manufact** table (INSERT). In this example (with no error handling), the database server executes each of these SQL statements in sequence:

```
BEGIN WORK;
LOCK TABLE stock;
UPDATE stock SET unit_price = unit_price * 1.10
  WHERE manu_code = 'KAR';
DELETE FROM stock WHERE description = 'baseball bat';
INSERT INTO manufact (manu_code, manu_name, lead_time)
  VALUES ('LYM', 'LYMAN', 14);
COMMIT WORK;
```

Each statement itself is atomic; it either completes successfully or else the database is unchanged afterwards. If any of these statements fail, the other statements will still be executed and the net result is as if the failed statement was never attempted. When the COMMIT WORK statement is executed, the successful changes are made permanent.

Typically, however, transactions are defined with error handling, so that the database server must perform a sequence of operations either completely or not at all. In this case, when you include all of the operations within a single transaction, the database server guarantees that all the statements are completely and perfectly committed to disk, or else the database can be restored to the same state that it was in before the transaction began.

By adding appropriate error handling (for example, by setting the **DBACCNOIGN** environment variable in DB-Acess, or by adding EXEC SQL WHENEVER ERROR STOP in ESQL/C), the transaction can be implicitly rolled back because the program stops on an error without executing COMMIT WORK. More careful conditional coding in a programming language such as ESQL/C allows the programmer to explicitly roll back the transaction while continuing the larger program.

Error-handling and business logic in applications and UDRs can also delimit one or more portions of a transaction by including SAVEPOINT and ROLLBACK TO SAVEPOINT statements. If the ROLLBACK TO SAVEPOINT statement is issued after an error is encountered, or after the results of part of the transaction indicate a conflict with a business rule or with some other criterion, only the changes that were made to the database between the ROLLBACK statement and its specified or default savepoint are cancelled, rather than the entire transaction. The current transaction continues at the statement that follows the ROLLBACK statement, with any uncommitted changes to the data or to the schema of the database from operations that preceded the savepoint remain pending, until the entire transaction is either committed or rolled back. Any locks held by statements that were rolled back are retained until the complete transaction ends.

## CLOSE statement

Use the CLOSE statement when you no longer need to refer to the set of rows associated with a Select cursor or with a Function cursor. With ESQL/C, this statement can also flush and close an Insert cursor. Use this statement with Informix® ESQL/C or SPL.

### Syntax

#### CLOSE

*cursor\_id*

<sup>100101</sup>*cursor\_id\_var*

| Element              | Description   | Restrictions                     | Syntax   |
|----------------------|---|----------------------------------|--|
| <i>cursor_id</i>     | Name of cursor to be closed                               | Must have been declared          | <a href="#">Identifier on page 1456</a>            |
| <i>cursor_id_var</i> | Host variable that contains the value of <i>cursor_id</i> | Must be of a character data type | Must conform to language-specific rules for names. |

### Usage

Closing a cursor makes the cursor unusable in any statements except OPEN or FREE and releases resources that the database server had allocated to the cursor.

100. Informix® extension

101. ESQL/C only

In a database that is not ANSI-compliant, you can close a cursor that has not been opened or that has already been closed. No action is taken in these cases.

In an ANSI-compliant database, the database server returns an error if you close a cursor that was not open.

## Examples

The following statement closes the cursor, *democursor*.

```
EXEC SQL close democursor;
```

The following is ESQL/C Source code example from demo1.ec:

```
#include <stdio.h>

EXEC SQL define FNAME_LEN      15;
EXEC SQL define LNAME_LEN      15;

main()
{

EXEC SQL BEGIN DECLARE SECTION;
    char fname[ FNAME_LEN + 1 ];
    char lname[ LNAME_LEN + 1 ];
EXEC SQL END DECLARE SECTION;

    printf( "DEM01 Sample ESQL Program running.\n\n");

EXEC SQL WHENEVER ERROR STOP;

EXEC SQL connect to 'stores7';

EXEC SQL declare democursor cursor for
    select fname, lname
        into :fname, :lname
        from customer
        where lname < "C";

EXEC SQL open democursor;
for (;;)
    {
EXEC SQL fetch democursor;
if (strncmp(SQLSTATE, "00", 2) != 0)
    break;
printf("%s %s\n",fname, lname);
    }
if (strncmp(SQLSTATE, "02", 2) != 0)
    printf("SQLSTATE after fetch is %s\n", SQLSTATE);

EXEC SQL close democursor;
EXEC SQL free democursor;
EXEC SQL create routine from 'del_ord.sql';
EXEC SQL disconnect current;
printf("\nDEM01 Sample Program over.\n\n");
exit(0);
}
```

## Closing a Select or Function Cursor

When a cursor is associated with a SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE statement of SQL, closing the cursor terminates the associated SQL statement.

The database server releases all resources that it might have allocated to the active set of rows, for example, a temporary table that the cursor used to hold an ordered set. The database server also releases any locks that it might have held on rows that were selected through the cursor. If a transaction contains the CLOSE statement, however, the database server does not release the locks until you issue the COMMIT WORK or ROLLBACK WORK statement.

After you close a Select cursor or a Function cursor, the FETCH statement cannot reference that cursor until you reopen it.

In an SPL routine, the built-in **SQLCODE** function can indicate the result of the CLOSE statement for a Select cursor or a Function cursor. This function returns a value equivalent to the **SQLCODE** field of the **sqlca** structure. Informix® issues an error, however, if you invoke the built-in **SQLCODE** function outside the calling context of an SPL routine.

## Closing an Insert Cursor

Because Informix® does not support Insert cursors in SPL routines, the discussion of Insert cursors in this section applies only to Informix® ESQL/C. In SPL routines, the CLOSE statement can reference only a Select cursor or a Function cursor that the DECLARE statement defined. (A FOREACH statement of SPL that has an INSERT statement in its statement block can declare a *direct cursor* that functionally resembles an Insert cursor, but the CLOSE statement cannot reference a direct cursor that FOREACH declared. Informix® closes the direct cursor automatically at runtime when program control exits from the FOREACH loop where the direct cursor was defined.)

In Informix® ESQL/C, the CLOSE statement treats a cursor that is associated with an INSERT statement differently from one that is associated with a SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE statement. When a cursor identifier is associated with an INSERT statement, the CLOSE statement writes any remaining buffered rows into the database.

The number of rows that were successfully inserted into the database is returned in the third element of the **sqlerrd** array,

**sqlca.sqlerrd[2]**, in the **sqlca** structure. For information on how to use **SQLERRD** to count the total number of rows that were inserted, see [Error Checking on page 707](#).

The **SQLCODE** field of the **sqlca** structure indicates the result of the CLOSE statement for an Insert cursor. If all buffered rows are successfully inserted, **SQLCODE** is set to zero. If an error is encountered, the **SQLCODE** field is set to a negative error message number.

When **SQLCODE** is zero, the row buffer space is released, and the cursor is closed; that is, you cannot execute a PUT or FLUSH statement that names the cursor until you reopen it.

**Tip:** When you encounter an **sqlca.SQLCODE** error, a corresponding **SQLSTATE** error value also exists. For information about how to get the message text, check the GET DIAGNOSTICS statement.

If the insert is not successful, the number of successfully inserted rows is stored in **sqlerrd**. Any buffered rows that follow the last successfully inserted row are discarded. Because the insert fails, the CLOSE statement fails also, and the cursor is not closed. For example, a CLOSE statement can fail if insufficient disk space prevents some of the rows from being inserted. In this case, a second CLOSE statement can be successful because no buffered rows exist. An OPEN statement can also be successful because the OPEN statement performs an implicit close.

## Closing a Collection Cursor

You can declare both Select and Insert cursors on collection variables. Such cursors are called Collection cursors. Use the CLOSE statement to deallocate resources that have been allocated for the Collection cursor. Only ESQL/C routines can use CLOSE to reference Insert cursors on collection variables. The CLOSE statement in SPL routines cannot reference direct Collection cursors that the FOREACH statement of SPL can declare.

For more information on how to use a Collection cursor, see [Fetching from a Collection Cursor on page 569](#) and [Inserting into a Collection Cursor on page 705](#).

## Using End of Transaction to Close a Cursor

The COMMIT WORK and ROLLBACK WORK statements close all cursors except those that are declared with a hold. It is better to close all cursors explicitly, however. For Select or Function cursors, this action simply makes the intent of the program clear. It also helps to avoid a logic error if the WITH HOLD clause is later added to the declaration of a cursor.

For an Insert cursor in ESQL/C routines, it is important to use the CLOSE statement explicitly so that you can test the error code. Following the COMMIT WORK statement, **SQLCODE** reflects the result of the COMMIT statement, not the result of closing cursors. If you use a COMMIT WORK statement without first using a CLOSE statement, and if an error occurs while the last buffered rows are being written to the database, the transaction is still committed.

For how to use Insert cursors and the WITH HOLD clause, see [DECLARE statement on page 467](#).

In an ANSI-compliant database, a cursor cannot be closed implicitly. You must issue the CLOSE statement.

## CLOSE DATABASE statement

Use the CLOSE DATABASE statement to close the implicit connection to the current database. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### CLOSE DATABASE

### Usage

When you issue a CLOSE DATABASE statement, you can issue only the following SQL statements immediately after it:

- CONNECT
- CREATE DATABASE
- DATABASE
- DROP DATABASE
- DISCONNECT

(The DISCONNECT statement is valid here only if an explicit connection existed before CLOSE DATABASE was executed.)

Issue the CLOSE DATABASE statement before you drop the current database.

If your current database supports transaction logging, and if you have started a transaction, you must issue a COMMIT WORK or ROLLBACK WORK statement before you can use the CLOSE DATABASE statement.

The following example shows how to use the CLOSE DATABASE statement before you drop the current database to which your session had established an implicit connection:

```
DATABASE stores_demo;
. . .
CLOSE DATABASE;
DROP DATABASE stores_demo;
```

In Informix® ESQL/C, the CLOSE DATABASE statement cannot appear in a multistatement PREPARE operation.

If a previous CONNECT statement has established an explicit connection to a database, and that connection is still your current connection, you cannot use the CLOSE DATABASE statement to close that explicit connection. (You can use the DISCONNECT statement to close the explicit connection.)

If you use the CLOSE DATABASE statement within a UDR called by a WHENEVER statement, specify WHENEVER SQLERROR CONTINUE and WHENEVER SQLWARNING CONTINUE before the ROLLBACK WORK statement. This action prevents the program from looping endlessly if the ROLLBACK WORK statement encounters an error or a warning.

When you issue the CLOSE DATABASE statement, any declared cursors are no longer valid. You must re-declare any cursors that you want to use.

In an ANSI-compliant database, if no error is encountered while you exit from DB-Access in non-interactive mode without issuing the CLOSE DATABASE, COMMIT WORK, or DISCONNECT statement, the database server automatically commits any open transaction.

---

**Related reference**[CREATE DATABASE statement on page 201](#)[DROP DATABASE statement on page 510](#)[DATABASE statement on page 461](#)[CONNECT statement on page 185](#)[DISCONNECT statement on page 505](#)

## COMMIT WORK statement

Use the COMMIT WORK statement to commit all modifications made to the database from the beginning of a transaction.

### Syntax

**COMMIT  
WORK**

### Usage

The COMMIT WORK statement informs the database server that you reached the end of a series of statements that must succeed as a single unit. The database server takes the required steps to make sure that all modifications that the transaction makes are completed correctly and saved to disk.

Use COMMIT WORK only at the end of a multistatement operation in a database with transaction logging, when you are sure that you want to keep all changes made to the database from the beginning of a transaction.

The COMMIT WORK statement releases all row and table locks.

The WORK keyword is optional in a COMMIT WORK statement. The following two statements are equivalent:

```
COMMIT;  
COMMIT WORK;
```

The following example shows a transaction bounded by BEGIN WORK and COMMIT WORK statements.

```
BEGIN WORK;  
  DELETE FROM call_type WHERE call_code = 'O';  
  INSERT INTO call_type VALUES ('S', 'order status');  
COMMIT WORK;
```

In this example, the user first deletes the row from the **call\_type** table where the value of the **call\_code** column is **O**. The user then inserts a new row in the **call\_type** table where the value of the **call\_code** column is **S**. The database server guarantees that both operations succeed or else neither succeeds.

In Informix® ESQL/C, the COMMIT WORK statement closes all open cursors except those that were declared using the WITH HOLD option.

---

**Related reference**

[BEGIN WORK statement on page 176](#)

[ROLLBACK WORK statement on page 759](#)

[DECLARE statement on page 467](#)

[LOCK TABLE statement on page 659](#)

[UNLOCK TABLE statement on page 1036](#)

## Issuing COMMIT WORK in a Database That Is Not ANSI Compliant

In a database that is not ANSI compliant, but that supports transaction logging, if you initiate a transaction with a `BEGIN WORK` statement, you must issue a `COMMIT WORK` statement at the end of the transaction. If you fail to issue a `COMMIT WORK` statement in this case, the database server rolls back any modifications that the transaction made to the database.

If you do not issue a `BEGIN WORK` statement, however, each statement executes within its own transaction. These single-statement transactions do not require either a `BEGIN WORK` statement or a `COMMIT WORK` statement.

## Explicit DB-Access Transactions

When you use DB-Access in interactive mode with a database that is not ANSI-compliant but that supports transaction logging, if you select the **Commit** menu but do not issue the `COMMIT WORK` statement after a transaction has been started by the `BEGIN WORK` statement, DB-Access automatically commits the data, but issues the following warning:

```
Warning: Data commit is a result of unhandled exception in TXN PROC/FUNC
```

The purpose of this warning is to remind you to issue `COMMIT WORK` explicitly to end a transaction that `BEGIN WORK` initiated.

In non-interactive mode, however, DB-Access rolls back the current transaction if you end a session without issuing the `COMMIT WORK` statement.

## Issuing COMMIT WORK in an ANSI-Compliant Database

In an ANSI-compliant database, you do not need `BEGIN WORK` to mark the beginning of a transaction. You only need to mark the end of each transaction, because a transaction is always in effect. A new transaction starts automatically after each `COMMIT WORK` or `ROLLBACK WORK` statement.

You must, however, issue an explicit `COMMIT WORK` statement to mark the end of each transaction. If you fail to do so, the database server rolls back any modifications that the transaction made to the database.

In an ANSI-compliant database, however, if no error is encountered while you exit from DB-Access in non-interactive mode without issuing the `CLOSE DATABASE`, `COMMIT WORK`, or `DISCONNECT` statement, the database server automatically commits any open transaction.

## CONNECT statement

Use the CONNECT statement to connect to a database environment. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### CONNECT TO

Database Environment<sup>102</sup>

<sup>105</sup>USER Clause<sup>104</sup>

#### TRUSTED

#### DEFAULT

<sup>103</sup>WITH CONCURRENT TRANSACTION

### Usage

The CONNECT statement connects an application to a *database environment*, which can be a database, a database server, or a database and a database server. If the application successfully connects to the specified database environment, the connection becomes the *current connection* for the application. The SQL statements fail if the application has no current connection to a database server. If you specify a database name, the database server opens that database. You cannot include CONNECT within a PREPARE statement.

An application can connect to several database environments at the same time, and it can establish multiple connections to the same database environment, provided each connection has a unique connection name.

On UNIX™, the only restriction on establishing multiple connections to the same database environment is that an application can establish only one connection to each local server that uses the shared-memory connection mechanism. To find out whether a local server uses the shared-memory connection mechanism or the local-loopback connection mechanism, examine the `$INFORMIXDIR/etc/sqlhosts` file. For more information on the `sqlhosts` file, refer to your *Informix® Administrator's Guide*.

On Windows™, the local connection mechanism is named pipes. Multiple connections to the local server from one client can exist.

Only one connection is current at any time; other connections are dormant. The application cannot interact with a database through a dormant connection. When an application establishes a new connection, that connection becomes current, and the previous current connection becomes dormant. You can make a dormant connection current with the SET CONNECTION statement. See also [SET CONNECTION statement on page 865](#).

For connections between databases of different Informix® instances, you cannot establish multiple active connections between the same two database servers using different server aliases. At any time, there can be only one active connection from the local server to a remote server. If you use CONNECT TO *dbserveralias* statements to specify different server aliases to connect to the same remote server, where the *dbserveralias* identifiers are declared in setting of the DBSERVERALIASES configuration parameter setting, no error message is issued, but the initial connection is reused.

102. See [Database Environment on page 187](#)

103. ESQ/C only

104. See [USER Authentication Clause on page 190](#)

105. ESQ/C and DB-Access only

**Related reference**[CREATE DATABASE statement on page 201](#)[SET SESSION AUTHORIZATION statement on page 996](#)[DROP DATABASE statement on page 510](#)[DISCONNECT statement on page 505](#)[SET CONNECTION statement on page 865](#)[DATABASE statement on page 461](#)[CLOSE DATABASE statement on page 182](#)

## Privileges for Executing the CONNECT Statement

The current user, or PUBLIC, must hold the Connect privilege on the database that the CONNECT statement specifies.

The user who executes the CONNECT statement cannot have the same authorization identifier as an existing role in that database.

For information on how to use the USER Authentication clause to specify an alternate user name when the CONNECT statement connects to a database server on a remote host, see [USER Authentication Clause on page 190](#).

## Connection Context

Each connection encompasses a set of information that is called the *connection context*. The connection context includes the name of the current user, the information that the database environment associates with this name, and information on the state of the connection (such as whether an active transaction is associated with the connection). The connection context is saved when an application becomes dormant, and this context is restored when the application becomes current again. (For more information, see [Making a dormant connection as the current connection on page 866](#).)

## Database Environment

The CONNECT statement, like the SET CONNECTION statement, can use the Database Environment syntax segment to specify the database or the database server to which the application is attempting to establish a connection. Unlike the SET CONNECTION statement, the CONNECT statement can also declare a name for this connection to the specified database environment.

Database Environment

```
'dbname' '@dbservername' 'dbname@dbservername'
```

```
106db_var
```

```
106 AS
```

```
'connection' connection_var
```

106. ESQL/C only

| Element               | Description  | Restrictions  | Syntax                                  |
|-----------------------|--|---|---|
| <i>connection</i>     | Optional case-sensitive name that you declare here for a connection                                    | Must be unique among connection names   | <a href="#">Identifier on page 1456</a> |
| <i>connection_var</i> | Host variable that stores the name of <i>connection</i>  | Must be a fixed-length character data type  | Language specific                       |
| <i>db_var</i>         | Host variable that contains a valid database environment (in one of the formats in the syntax diagram) | Must be a fixed-length character data type, whose contents are in a format from the syntax diagram  | Language specific                       |
| <i>dbname</i>         | Database to which to connect   | Must already exist  | <a href="#">Identifier on page 1456</a> |
| <i>dbservername</i>   | Name of the database server to which a connection is made  | Must already exist; blank space is not valid between @ symbol and <i>dbservername</i> . See also <a href="#">Restrictions on dbservername on page 188</a> . | <a href="#">Identifier on page 1456</a> |

If the **DELIMITED** environment variable is set, any quotation ( ' ) marks in the database environment must be single. If **DELIMITED** is not set, then either single ( ' ) or double ( " ) quotation marks are valid here.

## Restrictions on dbservername

If you specify *dbservername*, it must satisfy the following restrictions.

- If the database server that you specify is not online, you receive an error.
- The database server that you specify in *dbservername* must match the name of a database server in the **sqlhosts** file.

**Note:** If the name of a database server is a delimited identifier, or if it includes uppercase letters, that database server cannot participate in cross-server distributed DML operations. (If the server name includes uppercase letters, it also cannot participate in cross-database distributed DML operations by SQL statements that specify the server name as a qualifier to a database name. These statements fail with error -908, because the SQL parser downshifts all uppercase letters in server names to lowercase characters.) To avoid this restriction, specify only un delimited names with no uppercase letters when you declare the name or the alias of a database server that will participate in distributed queries.

## Specifying the Database Environment

You can specify a database server and a database, or a database server only, or a database only. How a database is located and opened depends on whether you specify a database server name in the database environment expression.

## Only Database Server Specified

The `@dbservername` option establishes a connection to the database server only; it does not open a database. When you use this option, you must subsequently use the `DATABASE` or `CREATE DATABASE` statement (or a `PREPARE` statement for one of these statements and an `EXECUTE` statement) to open a database.

## Database Server and Database Specified

If you specify both a database server and a database, your application connects to the database server, which locates and opens the database.

## Only Database Specified

The `dbname` option establishes a connection to the default database server or to another database server in the `DBPATH` environment variable. It also locates and opens the specified database. (The same is true of the `db_var` option if this specifies only a database name.)

If you specify only `dbname`, its database server is read from the `DBPATH` environment variable. The database server in the `INFORMIXSERVER` environment variable is always added before the `DBPATH` value.

On UNIX™, set the `INFORMIXSERVER` and `DBPATH` environment variables as the following example (for the C shell) shows:

```
setenv INFORMIXSERVER srvA
setenv DBPATH //srvB://srvC
```

On Windows™, choose **Start > Programs > Informix® > setnet32** from the Task Bar and set the `INFORMIXSERVER` and `DBPATH` environment variables:

```
set INFORMIXSERVER = srvA
set DBPATH = //srvA://srvB://srvC
```

The next example shows the resulting `DBPATH` that your application uses:

```
//srvA://srvB://srvC
```

The application first establishes a connection to the database server that `INFORMIXSERVER` specifies. The database server uses parameters in the configuration file to locate the database. If the database does not reside on the default database server, or if the default database server is not online, the application connects to the next database server in `DBPATH`. In the previous example, that database server would be `srvB`.

## Declaring a Connection Name

In ESQL/C applications, you can declare an identifier for the connection to the database environment by including the `AS` keyword, followed by a quoted string or by a host variable that stores the identifier. The host variable must be a fixed-length character data type.

## Connection Identifiers

The optional *connection* name is a unique identifier that an ESQL/C application can use to refer to a connection in subsequent SET CONNECTION and DISCONNECT statements. If the application does not provide a connection name (or a connection host variable), it can refer to the connection using the database environment. If the application makes more than one connection to the same database environment, however, each connection must have a unique name.

Only the CONNECT statement can use the AS keyword to declare a connection name. The CONNECT statement cannot, however, reference a previously declared connection name to specify a connection to a database environment.

## USER Authentication Clause

The USER Authentication clause specifies information that is used to determine whether the application can access the target computer on a remote host.

USER Authentication Clause

### USER

*'user\_id' user\_id\_var*

**USING***validation\_var*

| Element               | Description   | Restrictions   | Syntax                                     |
|-----------------------|---|--|--|
| <i>user_id</i>        | Valid login name  | See <a href="#">Restrictions on the User Identifier Parameter on page 191</a> .  | <a href="#">Quoted String on page 1424</a> |
| <i>user_id_var</i>    | Host variable that contains <i>user_id</i>  | Must be a fixed-length character data type; same restrictions as <i>user_id</i>  | Language specific                          |
| <i>validation_var</i> | Host variable that contains a valid password for login name in <i>user_id</i> or <i>user_id_var</i> | Must be a fixed-length character type. See <a href="#">Restrictions on the Validation Variable Parameter on page 190</a> . | Language specific                          |

The USER Authentication clause is required when the CONNECT statement connects to the database server on a remote host. Subsequent to the CONNECT statement, all database operations on the remote host use the specified user name.

In DB-Access, the USING clause is valid within files executed from DB-Access. In interactive mode, DB-Access prompts you for a password, so the USING keyword and *validation\_var* are not used.

## Restrictions on the Validation Variable Parameter

On UNIX™, the password stored in *validation\_var* must be a valid password and must exist in the **/etc/passwd** file. If the application connects to a remote database server, the password must exist in this file on both the local and remote database servers.

On Windows™, the password stored in *validation\_var* must be valid and must be the password entered in **User Manager**. If the application connects to a remote database server, the password must exist in the domain of both the client and the server.

## Restrictions on the User Identifier Parameter

The connection is rejected if any of the following conditions occur:

- The specified user lacks the privileges to access the database specified in the database environment.
- The specified user lacks the permissions to connect to the remote host.
- You supply a USER Authentication clause but omit the USING *validation\_var* specification.

In compliance with the X/Open standard for the CONNECT statement, the Informix® ESQL/C preprocessor supports a CONNECT statement that has a USER Authentication clause without the USING *validation\_var* specification. If the *validation\_var* is not present, however, the database server rejects the connection at runtime.

On UNIX™, the *user\_id* that you specify must be a valid login name and must exist in the **/etc/passwd** file. If the application connects to a remote server, the login name must exist in this file on both the local and remote database servers.

On Windows™, the *user\_id* that you specify must be a valid login name and must exist in **User Manager**. If the application connects to a remote server, the login name must exist in the domain of both the client and the server.

## Use of the Default User ID

If you do not supply the USER Authentication clause, the default user ID is used to attempt the connection.

The default user ID is the login name of the user running the application. In this case, you obtain network permissions with the standard authorization procedures. For example, on UNIX™, the default user ID must match a user ID in the trusted-host file (the */etc/hosts.equiv* file or the file specified by the REMOTE\_SERVER\_CFG configuration parameter). On Windows™, you must be a member of the domain, or if the database server is installed locally, you must be a valid user on the computer where it is installed.

---

## The DEFAULT Connection Specification

Instead of specifying an explicit database environment, you can use the DEFAULT keyword to request a *default connection* to a default database server. The default database server can be local or remote. To designate the default database server, set its name in the **INFORMIXSERVER** environment variable. This option of CONNECT does not open a database.

If the CONNECT TO DEFAULT statement succeeds, you must use the DATABASE statement or the CREATE DATABASE statement to open or create a database in the default database environment.

## The Implicit Connection with DATABASE Statements

If you do not execute a CONNECT statement in your application, the first SQL statement must be one of the following *database statements* (or a single statement PREPARE for one of the following statements):

- DATABASE
- CREATE DATABASE
- DROP DATABASE

If one of these database statements is the first SQL statement in an application, the statement establishes a connection to a database server, which is known as an *implicit* connection. If the database statement specifies only a database name, the database server name is obtained from the **DBPATH** environment variable. This situation is described in [Specifying the Database Environment on page 188](#).

An application that makes an implicit connection can establish other connections explicitly (using the **CONNECT** statement) but cannot establish another implicit connection unless the original implicit connection is closed. An application can terminate an implicit connection using the **DISCONNECT** statement. After you create an explicit connection, you cannot use any database statement to create implicit connections until after you close the explicit connection.

After *any* implicit connection is made, that connection is considered to be the default connection, regardless of whether the database server is the default that the **INFORMIXSERVER** environment variable specifies. This feature allows the application to refer to the implicit connection if additional explicit connections are made, because the implicit connection has no identifier.

For example, if you establish an implicit connection followed by an explicit connection, you can make the implicit connection current by issuing the **SET CONNECTION DEFAULT** statement. This means, however, that once you establish an implicit connection, you cannot use the **CONNECT DEFAULT** statement, because the implicit connection is now the default connection.

The database statements can always be used to open a database or create a new database on the current database server.

## WITH CONCURRENT TRANSACTION Option

The **WITH CONCURRENT TRANSACTION** clause enables you to switch to a different connection while a transaction is active in the current connection. If the current connection was *not* established using the **WITH CONCURRENT TRANSACTION** clause, you cannot switch to a different connection if a transaction is active; the **CONNECT** or **SET CONNECTION** statement fails, returning an error, and the transaction in the current connection continues to be active.

In this case, the application must commit or roll back the active transaction in the current connection before it switches to a different connection.

The **WITH CONCURRENT TRANSACTION** clause supports the concept of multiple concurrent transactions, where each connection can have its own transaction and the **COMMIT WORK** and **ROLLBACK WORK** statements affect only the current connection. The **WITH CONCURRENT TRANSACTION** clause does not support global transactions in which a single transaction spans databases over multiple connections. The **COMMIT WORK** and **ROLLBACK WORK** statements do not act on databases across multiple connections.

The following example illustrates how to use the **WITH CONCURRENT TRANSACTION** clause:

```
main()
{
EXEC SQL connect to 'a@srv1' as 'A';
EXEC SQL connect to 'b@srv2' as 'B' with concurrent transaction;
```

```

EXEC SQL connect to 'c@srv3' as 'C' with concurrent transaction;

/*
  Execute SQL statements in connection 'C' , starting a transaction
*/
EXEC SQL set connection 'B'; -- switch to connection 'B'

/*
  Execute SQL statements starting a transaction in 'B'.
  Now there are two active transactions, one each in 'B' and 'C'.
*/

EXEC SQL set connection 'A'; -- switch to connection 'A'

/*
  Execute SQL statements starting a transaction in 'A'.
  Now there are three active transactions, one each in 'A', 'B' and 'C'.
*/

EXEC SQL set connection 'C'; -- ERROR, transaction active in 'A'

/*
  SET CONNECTION 'C' fails (current connection is still 'A')
  The transaction in 'A' must be committed or rolled back because
  connection 'A' was started without the CONCURRENT TRANSACTION
  clause.
*/

EXEC SQL commit work; -- commit tx in current connection ('A')

/*
  Now, there are two active transactions, in 'B' and in 'C',
  which must be committed or rolled back separately
*/

EXEC SQL set connection 'B'; -- switch to connection 'B'
EXEC SQL commit work; -- commit tx in current connection ('B')

EXEC SQL set connection 'C'; -- go back to connection 'C'
EXEC SQL commit work; -- commit tx in current connection ('C')

EXEC SQL disconnect all;
}

```

**Warning:** When an application uses the WITH CONCURRENT TRANSACTION clause to establish multiple connections to the same database environment, a deadlock condition can occur.

## TRUSTED clause

Use the TRUSTED clause to specify that the application can connect to a database environment as a trusted connection.

## CREATE ACCESS\_METHOD statement

Use the CREATE ACCESS\_METHOD statement to register a new primary or secondary access method in the **sysams** system catalog table.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**CREATE**

**SECONDARY PRIMARY**

**ACCESS\_METHOD** **IF NOT EXISTS** *access\_method*

(  
 , Purpose Options<sup>107</sup>  
 )

| Element              | Description                                  | Restrictions   | Syntax                                  |
|----------------------|--|--|---|
| <i>access_method</i> | Name declared here for the new access method | Must be unique among access-method names in the <b>sysams</b> system catalog table | <a href="#">Identifier on page 1456</a> |

### Usage

The CREATE ACCESS\_METHOD statement adds a user-defined access method to a database. To create an access method, you specify *purpose functions* (or *purpose methods*), *purpose flags*, or *purpose values* as attributes of the access method, and you associate keywords (based on column names in the **sysams** system catalog table) with UDRs. You must have the DBA or Resource privilege to create an access method.

For information on setting purpose options, including a list of all the purpose function keywords, refer to [Purpose Options on page 1493](#).

The PRIMARY keyword specifies a user-defined primary-access method for a virtual table. The SECONDARY keyword specifies creating a user-defined secondary-access method for a virtual index. The SECONDARY keyword (and creating virtual indexes) is not supported in the Java™ Virtual-Table Interface.

The following statement creates a secondary-access method named **T\_tree**:

```
CREATE SECONDARY ACCESS_METHOD T_tree
(
  am_getnext = ttree_getnext,
  . . .
  am_unique,
  am_cluster,
  am_sptype = 'S'
);
```

In the preceding example, the **am\_getnext** keyword in the Purpose Options list is associated with the **ttree\_getnext()** UDR as the name of a method to scan for the next item that satisfies a query. This example indicates that the **T\_tree** secondary access method supports unique keys and clustering, and resides in an sbpace.

107. See [Purpose Options on page 1493](#)

Any UDR that the CREATE ACCESS\_METHOD statement associates with the keyword for a purpose function task, such as the association of `tree_getnext()` with `am_getnext` in the preceding example, must already have been registered in the database by the CREATE FUNCTION statement (or by a functionally equivalent statement, such as CREATE PROCEDURE FROM).

The following statement creates a primary-access method named `am_tabprops` that resides in an extspace.

```
CREATE PRIMARY ACCESS_METHOD am_tabprops
(
  am_open = FS_open,
  am_close = FS_close,
  am_beginscan = FS_beginScan,
  am_create = FS_create,
  am_scancost = FS_scanCost,
  am_endscan = FS_endScan,
  am_getnext = FS_getNext,
  am_getbyid = FS_getById,
  am_drop = FS_drop,
  am_truncate = FS_truncate,
  am_rowids,
  am_sptype = 'x'
);
```

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an access method of the specified name is already registered in the current database.

## CREATE AGGREGATE statement

Use the CREATE AGGREGATE statement to create a new aggregate function and register it in the `sysaggregates` system catalog table.

User-defined aggregates (UDA) extend the functionality of the database server by performing aggregate calculations that the user implements.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****CREATE AGGREGATEIF NOT EXISTS**Owner Name <sup>108</sup>.*aggregate***WITH**(
  
, Modifiers
  
)

Modifiers

**INIT**=*init\_func***ITER**=*iter\_func***COMBINE**=*comb\_func***FINAL**=*final\_func***HANDLENULLS**

| Element           | Description   | Restrictions  | Syntax                                  |
|-------------------|---|---|---|
| <i>aggregate</i>  | Name of the new aggregate   | Must be unique among names of built-in aggregates and UDRs  | <a href="#">Identifier on page 1456</a> |
| <i>comb_func</i>  | Function that merges one partial result into the other and returns the updated partial result | Must specify the combined function both for parallel queries and for sequential queries                                   | <a href="#">Identifier on page 1456</a> |
| <i>final_func</i> | Function that converts a partial result into the result type                                  | If this is omitted, then the returned value is the final result of <i>iter_func</i>                                       | <a href="#">Identifier on page 1456</a> |
| <i>init_func</i>  | Function that initializes the data structures required for the aggregate computation          | Must be able to handle NULL arguments   | <a href="#">Identifier on page 1456</a> |
| <i>iter_func</i>  | Function that merges a single value with a partial result and returns updated partial result  | Must specify an iterator function. If <i>init_func</i> is omitted, <i>iter_func</i> must be able to handle NULL arguments | <a href="#">Identifier on page 1456</a> |

**Usage**

You can specify the INIT, ITER, COMBINE, FINAL, and HANDLENULLS modifiers in any order.

**Important:** You must specify the ITER and COMBINE modifiers in a CREATE AGGREGATE statement. You do not need to specify the INIT, FINAL, and HANDLENULLS modifiers in a CREATE AGGREGATE statement.

The ITER, COMBINE, FINAL, and INIT modifiers specify the support functions for a user-defined aggregate. These support functions do not need to exist at the time when you create the user-defined aggregate.

108. See [Owner name on page 1488](#)

If you omit the `HANDLENULLS` modifier, rows with `NULL` aggregate argument values do not contribute to the aggregate computation. If you include the `HANDLENULLS` modifier, you must define all the support functions to handle `NULL` values as well.

**Important:** A `SELECT` statement can include no more than one UDA expression whose first argument is the `DISTINCT` or `UNIQUE` keyword (rather than the `ALL` keyword, or no keyword). In a query that includes subqueries, however, you can specify either zero or one `DISTINCT` or `UNIQUE` user-defined aggregate expression at each level of the query. Built-in aggregates are not subject to this restriction.

If you include the optional `IF NOT EXISTS` keywords, the database server takes no action (rather than sending an exception to the application) if an aggregate of the specified name is already registered in the current database.

[User-Defined Aggregates on page 1368](#)

## Extending the Functionality of Aggregates

Informix® provides two ways to extend the functionality of aggregates. Use the `CREATE AGGREGATE` statement only for the second of the two cases.

- Extensions of built-in aggregates

A built-in aggregate is an aggregate that the database server provides, such as **COUNT**, **SUM**, or **AVG**. These only support built-in data types. To extend a built-in aggregate so that it supports a user-defined data type (UDT), you must create user-defined routines that overload the binary operators for that aggregate. For further information on extending built-in aggregates, see the *Informix® User-Defined Routines and Data Types Developer's Guide*.

- Creation of user-defined aggregates

A user-defined aggregate is an aggregate that you define to perform an aggregate computation that the database server does not provide. You can use user-defined aggregates with built-in data types, extended data types, or both. To create a user-defined aggregate, use the `CREATE AGGREGATE` statement. In this statement, you name the new aggregate and specify the support functions that compute the aggregate result. These support functions perform initialization, sequential aggregation, combination of results, and type conversion.

## Example of Creating a User-Defined Aggregate

The following example defines a user-defined aggregate named **average**:

```
CREATE AGGREGATE average
WITH (
```

```

INIT = average_init,
ITER = average_iter,
COMBINE = average_combine,
FINAL = average_final
);

```

Before you use the **average** aggregate in a query, you must also use CREATE FUNCTION statements to create the support functions specified in the CREATE AGGREGATE statement.

The following table gives an example of the task that each support function might perform for **average**.

| Keyword | Support Function       | Effect   |
|---------|------------------------|--|
| INIT    | <b>average_init</b>    | Allocates and initializes an extended data type storing the current sum and the current row count                |
| ITER    | <b>average_iter</b>    | For each row, adds the value of the expression to the current sum and increments the current row count by one    |
| COMBINE | <b>average_combine</b> | Adds the current sum and the current row count of one partial result to the other and returns the updated result |
| FINAL   | <b>average_final</b>   | Returns the ratio of the current sum to the current row count and converts this ratio to the result type         |

## Parallel Execution

The database server can break up an aggregate computation into several pieces and compute them in parallel.

The database server uses the INIT and ITER support functions to compute each piece sequentially. Then the database server uses the COMBINE function to combine the partial results from all the pieces into a single result value. Whether an aggregate is parallel is an optimization decision that is transparent to the user.

## CREATE CAST statement

Use the CREATE CAST statement to register a cast that converts data from one data type to another.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**CREATE**

**EXPLICIT IMPLICIT**

**CASTIF NOT EXISTS**

*(source\_type***A***target\_type*

**WITH***function*

)

| Element            | Description                                 | Restrictions   | Syntax                                  |
|--------------------|---|--|---|
| <i>function</i>    | UDR that you register to implement the cast | See <a href="#">WITH Clause on page 201</a> .  | <a href="#">Identifier on page 1456</a> |
| <i>source_type</i> | Data type to be converted                   | Must exist in the database at the time the cast is registered. See also <a href="#">Source and Target Data Types on page 200</a> . | <a href="#">Data Type on page 1163</a>  |
| <i>target_type</i> | Data type that results from the conversion  | The same restrictions that apply for the <i>source_type</i> (as listed above) also apply for the <i>target_type</i>                | <a href="#">Data Type on page 1163</a>  |

## Usage

A cast is a mechanism that the database server uses to convert one data type to another. The database server uses casts to perform the following tasks:

- To compare two values in the WHERE clause of a SELECT, UPDATE, or DELETE statement
- To pass values as arguments to user-defined routines
- To return values from user-defined routines

To create a cast, you must have the necessary privileges on both the *source* data type and the *target* data type. All users have access privileges to use the built-in data types. To create a cast to or from an OPAQUE, DISTINCT, or named ROW data type, however, requires the Usage privilege on that data type.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a cast between the two specified data types is already registered in the current database.

The CREATE CAST statement registers a cast in the **syscasts** system catalog table. For more information on **syscasts**, see the chapter on system catalog tables in the *Informix® Guide to SQL: Reference*.

### Related information

[Data types and expressions on page 1139](#)

## Source and Target Data Types

The CREATE CAST statement defines a cast that converts a *source* type to a *target* type. Both the *source* and *target* data types must exist in the database when you execute the CREATE CAST statement to register the cast.

The *source* and the *target* data types have the following restrictions:

- Either the *source* or the *target* type, but not both, can be a built-in data type.
- Neither the *source* nor the *target* type can be a DISTINCT type of the other.
- Neither the *source* nor the *target* types can be a COLLECTION data type.

## Explicit and Implicit Casts

Processing queries with multiple data types often requires casts that convert data from one data type to another.

You can use the CREATE CAST statement to create the following kinds of casts:

- Use the CREATE EXPLICIT CAST statement to define an *explicit* cast.
- Use the CREATE IMPLICIT CAST statement to define an *implicit* cast.

The database server invokes built-in casts to convert from one built-in data type to another built-in type that is not directly substitutable. For example, the database server performs conversion of a character type such as CHAR to a numeric type such as INTEGER through a built-in cast.

## Explicit Casts

An explicit cast is a cast that you must specifically invoke, with either the CAST AS keywords or with the cast operator ( :: ). The database server does *not* automatically invoke an explicit cast to resolve data type conversions. The EXPLICIT keyword is optional; by default, the CREATE CAST statement creates an explicit cast.

The following CREATE CAST statement defines an explicit cast from the **rate\_of\_return** opaque data type to the **percent** distinct data type:

```
CREATE EXPLICIT CAST (rate_of_return AS percent
    WITH rate_to_prct);
```

The following SELECT statement explicitly invokes this explicit cast in its WHERE clause to compare the **bond\_rate** column (of type **rate\_of\_return**) to the **initial\_APR** column (of type **percent**):

```
SELECT bond_rate FROM bond
    WHERE bond_rate::percent > initial_APR;
```

## Implicit Casts

An implicit cast is a cast that the database server can invoke automatically when it encounters data types that cannot be compared with built-in casts. This type of cast enables the database server to automatically handle conversions between other data types.

To define an implicit cast, specify the `IMPLICIT` keyword in the `CREATE CAST` statement. For example, the following `CREATE CAST` statement specifies that the database server should automatically use the `prcnt_to_char()` function to convert from the `CHAR` data type to a distinct data type, **percent**:

```
CREATE IMPLICIT CAST (CHAR AS percent WITH char_to_prCNT);
```

This cast only supports automatic conversion *from* the `CHAR` data type to **percent**. For the database server to convert *from percent* to `CHAR`, you also need to define another implicit cast, as follows:

```
CREATE IMPLICIT CAST (percent AS CHAR WITH prCNT_to_char);
```

The database server automatically invokes the `char_to_prCNT()` function to evaluate the `WHERE` clause of the following `SELECT` statement:

```
SELECT commission FROM sales_rep WHERE commission > "25"
```

Users can also invoke implicit casts explicitly. For more information on how to explicitly invoke a cast function, see [Explicit Casts on page 200](#).

When a built-in cast does not exist for conversion between data types, you can create user-defined casts to make the necessary conversion.

## WITH Clause

The `WITH` clause of the `CREATE CAST` statement specifies the name of the user-defined function to invoke to perform the cast. This function is called the cast function.

You must specify a *function name* unless the *source data type* and the *target data type* have identical representations. Two data types have identical representations when the following conditions are met:

- Both data types have the same length and alignment.
- Both data types are passed by reference or both are passed by value.

The cast function must be registered in the same database as the cast at the time the cast is invoked, but need not exist when the cast is created. The `CREATE CAST` statement does not check privileges on the specified *function name*, or even verify that the cast function exists. Each time a user invokes the cast explicitly or implicitly, the database server verifies that the user has the `Execute` privilege on the cast function.

## CREATE DATABASE statement

Use the `CREATE DATABASE` statement to create a new database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****CREATE DATABASE***IF NOT EXISTS**database**IN**dbspace***WITH****BUFFERED****LOG****LOG MODE ANSI****NLSCASE SENSITIVE NLSCASE INSENSITIVE**

| Element         | Description   | Restrictions  | Syntax                                     |
|-----------------|---|---|--|
| <i>database</i> | Name that you declare here for the new database that you are creating               | Must be unique among names of databases of the database server                        | <a href="#">Database Name on page 1449</a> |
| <i>dbspace</i>  | The dbspace to store the data for this database; default is the <b>root</b> dbspace | Must exist<br>Cannot be the name of a dbspace that is dedicated to a tenant database. | <a href="#">Identifier on page 1456</a>    |

**Usage**

This statement is an extension to ANSI-standard syntax. (The ANSI/ISO standard for the SQL language does not specify any syntax for construction of a database, the process by which a database comes into existence and has its name declared.)

**Important:** If you plan to use UTF-8 character encoding, including the Chinese GB18030-2000 code set, you must set the `GL_USEGLU` environment variable before you create the database.

The *database* that **CREATE DATABASE** specifies becomes the current database.

You cannot create a tenant database with the **CREATE DATABASE** statement. To create a tenant database, run the `admin()` or `task()` SQL administration API command with the `tenant create` argument.

If the `DBCREATE_PERMISSION` configuration parameter is not set, any user can create a database. If the configuration file includes one or more `DBCREATE_PERMISSION` specifications, however, only the specified users can create databases.

Whether `DBCREATE_PERMISSION` is set, user **informix** can use the **CREATE DATABASE** statement. For additional information about how to set the `DBCREATE_PERMISSION` parameter to control which users can create new databases.

The *database* name that you declare must be unique within the database server environment in which you are working. The database server creates the system catalog tables that describe the structure of the new database.

If you include the optional `IF NOT EXISTS` keywords, the database server takes no action (rather than sending an exception to the application) if a database of the specified name exists among the databases that are managed by the database server instance to which you are connected.

When you create a database, you alone can access it. It remains inaccessible to other users until you, as DBA, grant database privileges by running the **GRANT** statement.

If a previous `CONNECT` statement established an explicit connection to a database, and that connection is still your current connection, you cannot use the `CREATE DATABASE` statement (nor any SQL statement that creates an implicit connection) until after you use the `DISCONNECT` statement to close the explicit connection.

In Informix® ESQL/C, the `CREATE DATABASE` statement cannot appear in a multistatement `PREPARE` operation.

The `SQL_LOGICAL_CHAR` configuration parameter setting for the database server instance to which you are connected is recorded in the system catalog of the new database. The `SQL_LOGICAL_CHAR` configuration parameter controls the expansion of size specifications in declarations of built-in character data types. This setting cannot be changed, and persists until the database is dropped, even if the Informix® instance that manages the database is stopped and restarted with a new `SQL_LOGICAL_CHAR` value. The **flags** column of the **systables** system catalog table encodes the `SQL_LOGICAL_CHAR` setting for the database.

If you do not specify a *dbspace*, the database server creates the system catalog tables in the **root** dbspace by default. However, if you enabled the automatic location of databases, databases are created by default in the dbspace that is chosen by the server. To enable the automatic location of databases, set the `AUTOLOCATE` configuration parameter or session environment variable to a positive integer.

The following statement creates the **vehicles** database in the **root** dbspace or in a dbspace that is chosen by the server, depending on whether automatic location is enabled:

```
CREATE DATABASE vehicles;
```

Because the example above includes no logging specification and no `NLSCASE` specification, then by default

- the **vehicles** database cannot support transaction logging,
- and if its locale uses a code set that distinguishes between uppercase and lowercase letters, the database is case-sensitive for all built-in character data types.

The following statement defines the **vehicles** database in the **research** dbspace:

```
CREATE DATABASE vehicles IN research;
```

But if no `DROP DATABASE` statement dropped existing the **vehicles** database that the first example created, the second example fails with an error, and no new database is created, because the identifier of the **vehicles** database is not unique for the database server instance.

---

## Logging Options

The logging options of the CREATE DATABASE statement determine the type of transaction logging for the database. In the event of a failure, the database server uses the log to re-create all committed transactions in your database, unless CREATE DATABASE statement does not include the `WITH LOG` keywords.

To create a database that supports transaction logging, the CREATE DATABASE statement provides three syntax options:

- **WITH BUFFERED LOG**

This option records transaction log information in a shared-memory buffer. This can allow the current transaction to complete sooner than in unbuffered logging mode, which requires that all the log information must be written to disk before the transaction can be completed. For a database using buffered logging, the database server does not write the contents of the logical-log buffer from shared memory to the logical log on disk until one of these events occurs:

- The buffer becomes full,
- or the connection is closed,
- or a checkpoint occurs,
- or a commit on a another database with unbuffered logging closes a distributed transaction, thereby flushing the buffer to disk.

The following example uses the `WITH BUFFERED LOG` option to create a database with buffered logging:

```
CREATE DATABASE bufDatabase WITH BUFFERED LOG;
```

- **WITH LOG**

This option writes the log information directly to permanent storage, to reduce the risk of losing data if the server crashes while data rows are being modified. The following statement uses the `WITH LOG` keywords to create a database with unbuffered logging:

```
CREATE DATABASE unbufDatabase WITH LOG;
```

- **WITH LOG MODE ANSI**

This option enables implicit transactions. This mode also imposes certain requirements of the ANSI/ISO standard for the SQL language that the database server does not enforce in unlogged databases, or in databases that use explicit transactions.

The following statement uses the `WITH LOG MODE ANSI` keywords to create an ANSI-compliant database with implicit transaction logging:

```
CREATE DATABASE ansiDatabase WITH LOG MODE ANSI;
```

## Unlogged databases

If you do not specify the `WITH LOG` keywords Informix® creates an unlogged database that cannot use transactions, and cannot run these SQL statements that support transaction logging:

- BEGIN WORK
- COMMIT WORK
- ROLLBACK WORK
- RELEASE SAVEPOINT
- ROLLBACK TO SAVEPOINT
- SET IMPLICIT TRANSACTION
- SET LOG
- SET ISOLATION.

The following example creates an unlogged database:

```
CREATE DATABASE unlogDatabase;
```

An unlogged database can improve performance in contexts where the cost of lost data is small. Alternatively, to move existing rows outside a transaction, you can create a database that supports transaction logging, but use RAW tables or light appends for unlogged operations on data that can be recovered from backup sources, if for some reason your load or unload operation fails.

## Restrictions on logging modes

Some distributed operations require participating databases to have the same logging mode as the database from which the operation is initiated.

You must use the `WITH LOG` option when you create a database on a secondary server in a high-availability cluster.

## Specifying Buffered Logging

The following example creates a database that uses a buffered log:

```
CREATE DATABASE vehicles WITH BUFFERED LOG;
```

If transactions are made against a database that uses buffered logging, the transaction log records are held in a logical-log memory buffer for as long as possible. They are not flushed from this logical-log buffer in shared memory to the logical log on disk until one of the following situations occurs:

- The buffer is full.
- A transaction is committed on the database with unbuffered logging.
- A checkpoint occurs.
- The connection is closed.

If you use a buffered log, you marginally enhance the performance of logging at the risk of not being able to re-create the last few transactions after an assertion failure.

ANSI/ISO-compliant databases cannot support buffered logging, but must be created with the `LOG MODE ANSI` keywords:

```
CREATE IF NOT EXISTS DATABASE nobuficles WITH LOG MODE ANSI;
```

See also the discussion of buffered logging in the *Informix® Database Design and Implementation Guide*.

## ANSI-Compliant Databases

When you use the `LOG MODE ANSI` option in the `CREATE DATABASE` statement, the database that you create is an ANSI-compliant database that conforms to the ANSI/ISO standard for the SQL language.

The following example creates an ANSI-compliant database:

```
CREATE DATABASE employees WITH LOG MODE ANSI;
```

ANSI-compliant databases are different from databases that are not ANSI compliant in several ways, including the following features:

- All SQL statements are automatically contained in transactions.
- All databases use unbuffered logging.
- Owner naming is enforced.

You must qualify with the owner name any table, view, synonym, index, or constraint that you do not own. Unless you enclose the owner name between quotation marks, alphabetic characters in owner names default to uppercase. (To prevent this upshifting of lowercase letters in undelimited owner names, you can set the **ANSIOWNER** environment variable to `1`.)

In addition, the routine signature of a UDR includes the name of the owner; in databases that are not ANSI compliant, this is true only for the **sysdbopen()** and **sysdbclose()** procedures.

- For sessions, the default isolation level is REPEATABLE READ.
- Default privileges on objects differ from those in databases that are not ANSI compliant. When you create a table or a synonym, other users do not receive access privileges (as members of the PUBLIC group) on the object by default.
- All DECIMAL data types are fixed-point values. If you declare a column as DECIMAL(*p*), the default scale is zero, meaning that only integer values can be stored. (In a database that is not ANSI compliant, DECIMAL(*p*) is a floating-point data type of a scale large enough to store the exponential notation for a value.)

Other slight differences exist between databases that are ANSI compliant and those that are not. These differences are noted with the related SQL statement in this document. For a detailed discussion of the differences between ANSI compliant databases and databases that are not ANSI-compliant, see the *Informix® Database Design and Implementation Guide*.

Creating an ANSI-compliant database does not mean that you automatically receive warnings for Informix® extensions to the ANSI/ISO standard for SQL syntax when you run the database. You must also use the **-ansi** flag or the **DBANSIWARN** environment variable to receive such warnings.

For additional information about **-ansi** and **DBANSIWARN**, see the *Informix® Guide to SQL: Reference*.

## Specifying NLSCASE case sensitivity

You can explicitly create a case-sensitive or case insensitive database.

By default, in databases where the locale classifies disjunct subsets of the code set as *uppercase letters* and as *lowercase letters*, Informix® databases are created as case-sensitive. The database locale is defined by setting the **DB\_LOCALE** environment variable. An example of a locale whose code set recognizes letter case is the default US English locale, where lowercase letters precede uppercase letters in the ascending order of collation. In the default locale, the following statement creates a case-sensitive database:

```
CREATE DATABASE employees IN dbspaceYee WITH BUFFERED LOG;
```

To explicitly create a case-sensitive database, include the `NLSCASE SENSITIVE` keywords as the last specification of the `CREATE DATABASE` statement, as in the following example:

```
CREATE DATABASE stores IN dbsp1 WITH LOG NLSCASE SENSITIVE;
```

Because case sensitivity is enabled by default, the following statement has the same effect:

```
CREATE DATABASE stores IN dbsp1 WITH LOG;
```

In a database that is case sensitive, for a table in which column **col3** is of type NCHAR or NVARCHAR, for example, the Boolean condition `col3 MATCHES 'SAM'` evaluates as false for rows where 'Sam' is the value in **col3**. In contrast, in a different database created with the `NLSCASE INSENSITIVE` keyword option, the same Boolean condition `col3 MATCHES 'SAM'` evaluates as true for the same rows of the same table. As this example implies, for tables that include NCHAR or NVARCHAR columns in which some row values differ only in letter case, query results depend on the `NLSCASE` setting of the database.

All Informix databases are case sensitive for operations on character strings of the built-in CHAR, LVARCHAR, and VARCHAR data types. If you create a case-sensitive database, whether by default, or explicitly with the `NLSCASE SENSITIVE` keywords, that database also treats strings of the National Language Support data types NCHAR and NVARCHAR as case-sensitive, if the database locale supports letter case.

### Creating a database that is not case sensitive

In some applications, the letter case of character strings can be disregarded. Data entry procedures, for example, might accept the strings 'M' and 'm' as logically equivalent within a record. For large data sets, applying conditional logic to convert both case variants to a single value can result in slower performance than storing the records in an NCHAR or NVARCHAR column of a case-insensitive database, in which the strings 'M' and 'm' encode the same case-insensitive value. Here the condition `'M' MATCHES 'm'` evaluates as true for NCHAR or NVARCHAR columns.

Every database created with the `NLSCASE INSENSITIVE` property stores uppercase and lowercase NCHAR and NVARCHAR letters exactly as they are loaded into their tables; any unmodified record that a query returns has its original lettercase. In all operations on NCHAR and NVARCHAR values, however, such as sorting, grouping, or identifying duplicate rows, the database server ignores any letter case variants, and treats, for example, the strings 'Mi' and 'mI' as the same value. Information about the case of letters not discarded, but it is also not used when the database server processes NLS data types.

When you include the `NLSCASE INSENSITIVE` keywords as the last specification of the `CREATE DATABASE` statement, the database server creates a database that always processes the following types of character strings without regard to letter case:

- Strings stored in columns of the NLS data types NCHAR and NVARCHAR
- Strings stored as a DISTINCT data type whose base type is NCHAR or NVARCHAR
- Strings stored as elements of these data types within a collection data type
- Strings stored in fields of the above data types in a named or unnamed ROW data type
- Strings stored as SPL variables of these data types
- Strings implicitly or explicitly cast to these data types
- Strings returned by functions as output parameters of these data types.

Here "these data types" refers to the character data types that are identified in the same list.

The following statement creates a database with the `NLSCASE` property set to `INSENSITIVE`:

```
CREATE DATABASE stores IN dbsp2 WITH BUFFERED LOG NLSCASE INSENSITIVE;
```

**Important:** A database created as `NLSCASE INSENSITIVE` treats all other built-in character data types (CHAR, LVARCHAR, and VARCHAR) as case sensitive. That is, a case-insensitive database can also perform case-sensitive processing of string values, if their data types are not among the NLS character data types in the list above.

To perform case-sensitive operations on a string of the NCHAR or NVARCHAR data type in a case-insensitive database, you must first explicitly cast the string to a CHAR, LVARCHAR, or VARCHAR data type, and then perform the case-sensitive operation. (See, however, the topic [Return Types from CONCAT and String Functions on page 1328](#), which identifies contexts in which the database server automatically casts the result of built-in string-manipulation functions and string operators to NCHAR or NVARCHAR data types.)

### Examples of NLSCASE INSENSITIVE queries

In a case-insensitive database, when a query calls an aggregate function or includes the GROUP BY clause for an NCHAR or NVARCHAR column, the database server treats letter-case variants in the data as duplicate column values, as in the following program fragment.

```
CREATE DATABASE casedb WITH LOG NLSCASE INSENSITIVE;
CREATE TABLE foo (cc CHAR(5), nc NCHAR(5));
INSERT INTO foo VALUES ('IBM', 'iBM');

SELECT COUNT(nc) FROM foo
  GROUP BY nc;
SELECT COUNT(nc) FROM foo
  WHERE nc = 'iBM' GROUP BY nc;
```

In both of the queries above, the **COUNT** aggregate function returns 4, the total number of rows that the INSERT statements loaded into **foo**. Because column **nc** is an NLS data type, all of the rows satisfy the `nc = 'iBM'` condition in the WHERE clause, despite variations in letter case among the **nc** values.

For the following query on the same tables,

```
SELECT nc FROM foo GROUP BY nc;
```

the output can be any of the string values from the INSERT statements (namely 'IBM', 'iBM', 'ibm', 'iBm', or 'Ibm'), depending on the order in which the server processes or scans the rows.

The next query on the same table excludes duplicate rows from the result set by including the DISTINCT keyword in the projection clause:

```
SELECT DISTINCT nc FROM foo;
```

This returns a single row, because from the NLSCASE INSENSITIVE perspective, all of the rows have the same value, despite the variations in letter case. As in the previous example, the first row retrieved from among the inserted rows will be returned by the query.

The next example includes the DISTINCT keyword as one of the arguments to the COUNT aggregate function:

```
SELECT COUNT(DISTINCT nc) FROM foo;
```

This returns a count of 1, again because in this case-insensitive database, all of the rows in table **foo** evaluate as duplicates.

### Restrictions on NLSCASE INSENSITIVE databases

The following restrictions apply to databases that are created with the NLSCASE INSENSITIVE property:

- They support distributed cross-database and cross-server queries only with databases that also have the NLSCASE INSENSITIVE property.
- Case-sensitive databases cannot connect to NLSCASE INSENSITIVE databases. Attempts to do so fail with this error:

```
-26801 Cannot reference an external database that is not case sensitive.
```

- NLSCASE INSENSITIVE databases cannot connect to case-sensitive databases. Attempts to do so fail with this error:

```
-26802 Cannot reference an external database that is case sensitive.
```

The only exception is that the NLSCASE setting does not prevent connections to the case-sensitive system databases, such as **sysmaster**, **sysadmin**, **sysutils**, **sysusers**, and **syscdr**, of the same Informix® database server instance. The results of operations that access a system database depends on the NLSCASE setting of the other database.

- The **onload** and **onunload** utilities do not support databases that have the NLSCASE INSENSITIVE property.
- In an Enterprise Replication cluster, no error or warning is issued if you specify a replication pair in whose databases differ in their NLSCASE property. To reduce the risk of data inconsistencies, replicate case-sensitive databases only with case-sensitive databases. and replicate NLSCASE INSENSITIVE databases only with NLSCASE INSENSITIVE databases.

## CREATE DEFAULT USER statement (UNIX™, Linux™)

Use the CREATE DEFAULT USER statement to define the properties set of the default internally authenticated user. This statement is an extension to the ANSI/ISO standard for the SQL language.

### Syntax

**CREATE DEFAULT USER WITH** Properties <sup>109</sup>

109. See the Properties clause in the [CREATE USER statement \(UNIX, Linux\)](#) on page 447

## Usage

CREATE DEFAULT USER is a special case of the CREATE USER statement. After you use the CREATE DEFAULT USER statement to define default user properties, you can use the CREATE USER statement (but omitting the PROPERTIES clause) to create new users who have default user properties.

Only a DBSA can issue the CREATE DEFAULT USER statement. With a non-root installation, the user who installs the server is the equivalent of the DBSA, unless the user delegates DBSA privileges to a different user.

The USERMAPPING configuration parameter must be set to a value (ADMIN or BASIC) that enables support for mapped users before default users who were created with the CREATE DEFAULT USER statement can connect to the database server. A DBSA can issue the CREATE DEFAULT USER statement to map default users to properties that correspond to the appropriate level of authorization. The USERMAPPING configuration parameter must be set to ADMIN to enable a default user to have a server administrative privilege with the AUTHORIZATION keyword, where `AAO`, `BARGROUP`, `DBSA`, and `DBSSO` are the keyword options for specific administrative privileges.

You must also enter values in the SYSUSERMAP table of the **sysusers** database to map users with the appropriate user properties, so that the mapped user statements of SQL can work correctly.

You cannot specify a password, or account lock, or account unlock information in the CREATE DEFAULT USER statement. This statement is equivalent to the `GRANT ACCESS TO PUBLIC PROPERTIES` statement. The equivalent syntax to

```
REVOKE ACCESS TO PUBLIC;
```

is this:

```
DROP DEFAULT USER;
```

To alter the properties of the default internally authenticated user, you can issue the `ALTER DEFAULT USER WITH PROPERTIES` statement.

Execution of the CREATE DEFAULT USER statement can be audited with the CRUR audit code, which is the same mnemonic as for the CREATE USER statement.

For more information about the PROPERTIES options to the CREATE DEFAULT USER statement, see the [CREATE USER statement \(UNIX, Linux\) on page 447](#).

[CREATE USER statement \(UNIX, Linux\) on page 447](#)

[ALTER USER statement \(UNIX, Linux\) on page 172](#)

## CREATE DISTINCT TYPE statement

Use the CREATE DISTINCT TYPE statement to create a new distinct data type.

This statement is an extension to the ANSI/ISO standard for SQL.

## Syntax

**CREATE DISTINCT TYPE** *IF NOT EXISTS* *distinct\_type*

**AS** *source\_type*

| Element              | Description   | Restrictions   | Syntax                                 |
|----------------------|---|--|--|
| <i>distinct_type</i> | Name that you declare here for the new distinct data type | In an ANSI-compliant database, the combination of the owner and data type must be unique within the database. In a database that is not ANSI compliant, the name must be unique among names of data types in the database. | <a href="#">Data Type on page 1163</a> |
| <i>source_type</i>   | Name of existing type on which the new type is based      | Must be either a built-in data type or one created with the CREATE DISTINCT TYPE, CREATE OPAQUE TYPE, or CREATE ROW TYPE statement   | <a href="#">Data Type on page 1163</a> |

## Usage

A *distinct type* is a data type based on a built-in data type or on an existing opaque data type, a named ROW data type, or another distinct data type. Distinct data types are strongly typed. Although the distinct type has the same physical representation of data as its source type, values of the two types cannot be compared without an explicit cast from one type to the other.

To create a distinct data type, you must have the Resource privilege on the database. Any user with the Resource privilege can create a distinct type from one of the built-in data types, which user **informix** owns.

**Important:** You cannot create a distinct type on the SERIAL, BIGSERIAL, or SERIAL8 data types.

To create a distinct type from an opaque type, from a named ROW type, or from another distinct type, you must be the owner of the data type or have the Usage privilege on the data type.

By default, after a distinct type is defined, only the owner of the distinct type and the DBA can use it. The owner of the distinct type, however, can grant to other users the Usage privilege on the distinct type.

A distinct type has the same storage structure as its source type. The following statement creates the distinct type **birthday**, based on the built-in DATE data type:

```
CREATE DISTINCT TYPE birthday AS DATE;
```

Although Informix® uses the same storage format for the distinct type as it does for its source type, a distinct type and its source type cannot be compared in an operation unless one type is cast explicitly to the other type.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a DISTINCT data type of the specified name is already registered in the current database.

---

### Related reference

[CREATE CAST statement on page 198](#)

[CREATE OPAQUE TYPE statement on page 281](#)

[CREATE SCHEMA statement on page 313](#)

[CREATE FUNCTION statement on page 240](#)

[CREATE ROW TYPE statement on page 307](#)

[DROP TYPE statement on page 536](#)

[DROP ROW TYPE statement on page 524](#)

## Privileges on Distinct Types

To create a distinct type, you must have the Resource privilege on the database. When you create the distinct type, only you, the owner, have Usage privilege on this type. Use the GRANT or REVOKE statements to grant or revoke Usage privilege to other database users.

To find out what privileges exist on a particular type, check the **sysxdtypes** system catalog table for the owner name and the **sysxdtpeauth** system catalog table for additional data type privileges that might have been granted. For more information on system catalog tables, see the *Informix® Guide to SQL: Reference*.

The DB-Access utility can also display privileges on distinct types.

---

## Support Functions and Casts

When you create a distinct type, Informix® automatically defines two explicit casts:

- A cast from the distinct type to its source type
- A cast from the source type to the distinct type

Because the two data types have the same representation (the same length and alignment), no support functions are required to implement the casts.

You can create an implicit cast between a distinct type and its source type. To create an implicit cast, use the Table Options clause to specify the format of the external data. You must first drop the default explicit cast, however, between the distinct type and its source type.

All support functions and casts that are defined on the source type can be used on the distinct type. Casts and support functions that are defined on the distinct type, however, are not available to the source type. Use the Table Options clause to specify the format of the external data.

## Manipulating Distinct Types

When you compare or manipulate data of a distinct type and its source type, you must explicitly cast one type to the other in the following situations:

- To insert or update a column of one type with values of the other type
- To use a relational operator to add, subtract, multiply, divide, compare, or otherwise manipulate two values, one of the source type and one of the distinct type

For example, suppose you create a distinct type, **dist\_type**, that is based on the NUMERIC data type. You then create a table with two columns, one of type **dist\_type** and one of type NUMERIC.

```
CREATE DISTINCT TYPE dist_type AS NUMERIC;
CREATE TABLE t(col1 dist_type, col2 NUMERIC);
```

To directly compare the distinct type and its source type or assign a value of the source type to a column of the distinct type, you must cast one type to the other, as the following examples show:

```
INSERT INTO tab (col1) VALUES (3.5::dist_type);

SELECT col1, col2
FROM t WHERE (col1::NUMERIC) > col2;

SELECT col1, col2, (col1 + col2::dist_type) sum_col
FROM tab;
```

For information about queries and other distributed DML operations that access DISTINCT data types in tables outside the local database, see the topic [DISTINCT Types in Distributed Operations on page 1184](#).

## CREATE EXTERNAL TABLE Statement

Use the CREATE EXTERNAL TABLE statement to define an external source that is not part of your database to load and unload data for your database.

The implementation of the CREATE EXTERNAL TABLE statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**CREATE EXTERNAL TABLE** *IF NOT EXISTS* *table*

Column Definition<sup>110</sup>

**USING**(

Table Options<sup>111</sup>

DATAFILES Clause<sup>112</sup>

Table Options<sup>111</sup>

)

| Element      | Description                                  | Restrictions  | Syntax                                  |
|--------------|--|---|---|
| <i>table</i> | The name of the table to store external data | Must be unique among names of tables, views, and synonyms in the current database | <a href="#">Identifier on page 1456</a> |

110. See [Column Definition on page 214](#)

111. See [Table options on page 218](#)

112. See [DATAFILES Clause on page 216](#)

## Usage

You use external tables to load and unload data to or from your database. You can also use external tables to query data in text files that are not in Informix® databases.

The first portion of the syntax diagram declares the name of the table and defines its columns.

The portion that follows the USING keyword identifies external files that the database server opens when you use the external table, and specifies additional options for characteristics of the external table.

After executing the CREATE EXTERNAL TABLE statement, you can move data to and from the external source with an INSERT INTO ... SELECT statement. See the section [INTO EXTERNAL clause on page 857](#) for more information about loading the results of a query into an external table.

The CREATE EXTERNAL TABLE statement is not supported on secondary servers within a high-availability cluster.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an external table of the specified name is already registered in the **systables** system catalog table of the current database, or if the specified name is the identifier of a database table, view, sequence object, or synonym in the current database.

---

### Related reference

[CREATE TABLE statement on page 335](#)

## Column Definition

Use the column definition segment of the CREATE EXTERNAL TABLE statement to declare the name and data type of a single column of the new external table.

Column Definition

**SAMEAS***template*

, *column*

*data\_type*

Other Optional Clauses

Other Optional Clauses

**EXTERNALCHAR** (*size*)

**NULL** ' *null\_string* '

**NOT NULL**

| Element          | Description   | Restrictions  | Syntax                                  |
|------------------|---|---|---|
| <i>column</i>    | One column name for each column of the external table | For each column, you must specify a built-in data type            | <a href="#">Identifier on page 1456</a> |
| <i>data_type</i> | Data type of the column                               | The <i>data_type</i> can be any data type supported by Informix®. | <a href="#">Data Type on page 1163</a>  |

| Element            | Description   | Restrictions   | Syntax  |
|--------------------|---|--|---|
| <i>template</i>    | Existing table with the same schema as the external table | Cannot be a subset of columns nor differ in any column data type | <a href="#">Database Object Name on page 1450</a> |
| <i>size</i>        | Column size in bytes. Default is 1.                       | Integer; 1 size 32,767   | <a href="#">Literal Number on page 1419</a>       |
| <i>null_string</i> | Value to represent NULL                                   | See <a href="#">Defining NULL Values on page 216</a> .           | <a href="#">Quoted String on page 1424</a>        |

## Using the SAMEAS Clause

The SAMEAS *template* clause uses all the column names and data types from the *template* table in the definition of the new table.

You cannot use the SAMEAS clause for FIXED-format files.

### Example

Consider loading a delimited ASCII text file into a table with the following schema:

```
TABLE employee (
  name CHAR(18) NOT NULL,
  hiredate DATE DEFAULT TODAY,
  address VARCHAR(40),
  empno INTEGER);
```

The SQL statements used to load data into the employee table would be as follows:

```
CREATE EXTERNAL TABLE emp_ext
SAMEAS employee
USING (
  DATAFILES ("DISK:/work2/mydir/emp.dat"),
  REJECTFILE "/work2/mydir/emp.rej"
);
INSERT INTO employee SELECT * FROM emp_ext;
```

The external table has the same name, type, and default for each column because the CREATE statement includes the SAMEAS keyword. The default format is delimited, so no format keyword is required.

Check constraints defined on columns in database tables are not inherited by the external table. However, NOT NULL constraints are inherited by the external table.

Delimited files are ASCII by default. The default row delimiter is an end-of-line character unless you use the RECORDEND keyword to specify a different delimiter when you created the external table. (The RECORDEND keyword works for delimited format only.)

## Using the EXTERNAL Keyword

Use the EXTERNAL keyword to specify a CHAR data type for each column of your external table that has a data type different from the internal table.

For example, you might have a VARCHAR column in the internal table that you want to map to a CHAR column in the external table.

You must specify an external type for every column that is in fixed format. You cannot specify an external type for delimited format columns except for BYTE and TEXT columns where your specification is optional.

## Defining NULL Values

You can define a value to be interpreted as a NULL when loading or unloading data from an external source.

The database server uses the NULL representation for a FIXED-format external table to both interpret values as the data is loaded into the database and to format NULL values into the appropriate data type when data is unloaded to an external table.

The NULL representation must fit into the length of the external field.

## Manipulating Data in Fixed Format Files

A fixed format file is one in which all rows have the same length.

For files in FIXED format, you must declare the column name and the EXTERNAL item for each column to set the name and number of characters. For FIXED-format files, the only data type allowed is CHAR. You can use the keyword NULL to specify what string to interpret as a NULL value.

## DATAFILES Clause

The DATAFILES clause specifies the operating system file or pipe that is opened when you use an external table.

DATAFILES Clause

### **DATAFILES**

```
(  
,
```

### **DISK PIPE**

```
:  
fixed_path formatted_path
```

```
;  
;
```

### **BLOBDIR CLOBDIR**

```
:fixed_path
```

```
,  
)
```

| Element               | Description   | Restrictions                         | Syntax                                 |
|-----------------------|---|--------------------------------------|--|
| <i>fixed_path</i>     | Path name for input or output files in the definition of the external table | See the notes that follow this table | Must conform to operating-system rules |
| <i>formatted_path</i> | Formatted path name that uses pattern-matching characters                   | See the notes that follow this table | Must conform to operating-system rules |

The database server does not verify that any file or pipe exists at the specified *fixed\_path* or *formatted\_path*, that the specified pipe is open, nor that the user has permission to access that file system. Subsequent operations on the external table will fail, however, unless the path is valid and, if a named pipe is being used, that it is open, when the database server attempts to read or write to the external table.

For examples of the DATAFILES clause, see [External Table Examples on page 225](#).

### Keyword

#### Description

#### CLOBDIR

Specifies the server directory in which the CLOB file is stored.

#### BLOBDIR

Specifies the server directory in which the BLOB file is stored. When creating queries, specify DISK followed by BLOBDIR followed by CLOBDIR. If BLOBDIR is omitted, BLOB files are stored the same directory as specified by the DISK clause. If both BLOBDIR and CLOBDIR are omitted, a new file is created for each BLOB or CLOB column and stored in the directory in which the DISK clause is specified.

In the following example, rows stored in `/work1/exttab1.dat` have their BLOBs located in `/work1/blobdir1` and CLOBs in the `/work1/clobdir1` directory.

Rows stored in `/work1/exttab2.dat` have their BLOBs located in the `/work1` directory and CLOBs in the `/work1/clobdir2` directory. Because the BLOBDIR clause is omitted, the BLOBs are stored in the directory where `exttab2.dat` is stored.

Rows stored in the `/work1/exttab3.dat` have their BLOBs and CLOBs located in the `/work1` directory because both BLOBDIR and CLOBDIR are omitted.

```
CREATE EXTERNAL TABLE exttab (
  id    SERIAL,
  lobc  CLOB,
  lobb  BLOB)
USING (DATAFILES(
  "DISK:/work1/exttab1.dat;BLOBDIR:/work1/blobdir1;CLOBDIR:/work1/clobdir1",
  "DISK:/work1/exttab2.dat;CLOBDIR:/work1/clobdir2",
  "DISK:/work1/exttab3.dat"),
  DELIMITER '|');
```

## Using Formatting Characters with External Tables

You can use a formatted path name to designate a file name by using the substitution character `%r` (*first ..last*).

### Formatting String

#### Effect

#### `%r(first ..last)`

Specifies multiple files on the Informix® server for the external table.

The *first* and *last* arguments represent a range of values that are substituted in the expression when the statement is run. For example, specifying `my_file.%r(1..3)` expands to:

`my_file.1`

`my_file.2`

`my_file.3`

The only supported formatting character supported by Informix® is `%r`.

## Table options

These options specify additional characteristics that define the external table, and that define attributes of load or unload operations on that table.

## Table Options

,  
**FORMAT**  
 113.  
**DELIMITED INFORMIX FIXED**  
 ,

<sup>114</sup>**EXPRESS DELUXE**

| Element                 | Description   | Restrictions   | Syntax                                      |
|-------------------------|---|--|---|
| <i>field_delimiter</i>  | Character that separates fields.<br>Default is pipe (   ) character | For nonprinting characters, use octal notation.  | <a href="#">Quoted String on page 1424</a>  |
| <i>filename</i>         | Full path name for conversion error messages                        | See <a href="#">Reject Files on page 223</a> .   | Must conform to operating-system rules.     |
| <i>num_errors</i>       | Number of errors before load operations are terminated              | Value is ignored unless the REJECTFILE value is set.<br>This specification is ignored during unload tasks. | <a href="#">Literal Number on page 1419</a> |
| <i>num_rows</i>         | Approximate number of rows contained in the external table          | Must be a positive number.   | <a href="#">Literal Number on page 1419</a> |
| <i>record_delimiter</i> | Character to separate records. Default is Newline ( \n )            | For nonprinting characters, use octal.   | <a href="#">Quoted String on page 1424</a>  |

113. Use this path no more than once

114. The default loading mode depends on the table and database logging characteristics. See the keyword descriptions in the usage section for details.

## Usage

If no RECORDEND value is specified, *record\_delimiter* defaults to the Newline character ( `\n` ). To specify a nonprinting character as the record delimiter or field delimiter, you must encode it as the octal representation of the ASCII character. For example, `\006` can represent CTRL-F.

On Windows™ systems, if you use the DB-Access utility or the dbexport utility to unload a database table into a file and then plan to use the file as an external table datafile, you should define RECORDEND as `'\012'` in the CREATE EXTERNAL TABLE statement.

Use the table options keywords as the following table describes. You can use each keyword whenever you plan to either load or unload data except where noted.

### Keyword

#### Description

#### DBDATE

Specifies the date format when reading or writing an external table. You use the DBDATE clause to convert data during load and unload operations from external tables. In the following example, DBDATE is set to `DMY2-`. If the date value in the database table was stored as 06/24/2009, the value written to the external table is 24-06-09.

```
CREATE EXTERNAL TABLE ext_date (dob date)
USING ( DATAFILES ("DISK:/tmp/datedisk"),
        REJECTFILE "/tmp/datereject",
        DBDATE "DMY2-",
        FORMAT "delimited");

INSERT INTO ext_date SELECT * FROM basetab;
```

The DBDATE clause is also used when inserting date values from external tables into database tables. In the following example, data in the external table is converted to internal binary format based on the DBDATE value set by the CREATE EXTERNAL TABLE statement.

```
INSERT INTO basetab SELECT * FROM ext_date;
```

If the DBDATE keyword is not specified in the USING clause of the CREATE EXTERNAL TABLE statement, the date format is determined by the setting of the DBDATE environment variable. If the DBDATE environment variable is not specified, the date format is determined by the setting of the GL\_DATE environment variable. The value specified by the DBDATE clause takes precedence over the value specified by the DBDATE environment variable. The setting of the DBDATE variable takes precedence over that of the GL\_DATE environment variable. See the *Informix® Guide to SQL: Reference* for information about DBDATE and GL\_DATE values.

#### DBMONEY

Specifies the currency format when reading or writing an external table. You use the DBMONEY clause to convert data during load and unload operations from external tables. In the following example, DBMONEY is set to `DM, .` Currency is formatted as DM (deutsche mark) units, using the currency symbol `DM` and comma ( `,` ). If the currency value in the database table is stored as `100.50`, the value written to the external table is `100,50`.

```
CREATE EXTERNAL TABLE ext_money (sales money)
USING ( DATAFILES ( "DISK:/tmp/moneydisk" ),
        REJECTFILE "/tmp/moneyreject",
        DBMONEY "DM,",
        FORMAT "delimited");

INSERT INTO ext_money SELECT * FROM basetab;
```

When reading data from an external table into a database table, the currency symbol is not required in the external table. For example, if the external table contained the value `1000,78` and `DBMONEY` was set to `DM,` then the data is not rejected and the row is stored correctly.

If the decimal separator in the external table and the value set for `DBMONEY` do not match, then the row is rejected. For example, if the external table contained the value `1000,78` (with a comma instead of a decimal point) and the `DBMONEY` clause is set to `DM.` then the row is rejected. If the data file contains a currency symbol and the currency symbol does not match the `DBMONEY` currency symbol, the row is rejected.

When writing data from a database table into an external table, the currency symbol is not written to the external table.

If the `DBMONEY` clause is not specified, the data format is determined by the setting of the `DBMONEY` environment variable. The value specified by the `DBMONEY` clause takes precedence over the value specified by the `DBMONEY` environment variable. If the `DBMONEY` clause is not specified and the `DBMONEY` environment variable is not set, the decimal separator specified by the database locale is used. See the *Informix® Guide to SQL: Reference* for information about `DBMONEY` values.

#### **DEFAULT (load only)**

Specifies replacing missing values in delimited input files with column defaults (if they are defined) instead of NULLs, so input files can be sparsely populated. Files do not need an entry for every column in the file where a default is the value to be loaded.

#### **DELIMITED**

Specifies that the data file is a delimited text file. A delimiter character can be specified using the optional `DELIMITER` table option.

#### **DELIMITER**

Specifies the character that separates fields in a delimited text file. If the table options include no `DELIMITER` specification, the pipe ( `|` ) character is the default field separator.

#### **DELUXE (load only)**

The database server always uses `DELUXE` mode for `STANDARD` tables if the database uses transaction logging, and on any table on which an index is defined.

You can specify `DELUXE` mode to override the default `EXPRESS` load mode for `RAW` target tables without indexes if the database is logged.

The `DELUXE` mode updates indexes, performs constraint checking, and evaluates triggers as data is inserted into the table. `DELUXE` mode loads are not as fast as `EXPRESS` mode loads, but are more flexible. In `DELUXE` mode, you can access and update the table that is being loaded.

**ESCAPE**

Inserts the default escape character immediately before any instances of the *field\_delimiter* separator that DELIMITER specifies, where that character is a literal value in the data, rather than a separator. Whether you include or omit the ESCAPE keyword, this functionality is enabled by default, or you can specify the `ESCAPE ON` keywords to make it clearer to human readers of your SQL code that this feature is enabled. To prevent literal *field\_delimiter* separator characters in the data from being escaped, you must specify the `ESCAPE OFF` keywords.

By default, the escape character that the ESCAPE keyword inserts before literal *field\_delimiter* characters is the backslash ( \ ) character. But if the DEFAULTESCCHAR configuration parameter is set to a single-character value, that character replaces backslash ( \ ) for delimiter characters used as literals when `ESCAPE OFF` or `ESCAPE ON` is specified.

**Note:**

The default setting for ESCAPE is OFF in Informix® releases earlier than version 12.10.

**EXPRESS (load only)**

EXPRESS mode is always used if the database is not logged and the target table (of any table type) has no indexes.

EXPRESS is the default if the database is logged for RAW target tables without indexes; however, you can override that default by specifying the DELUXE keyword.

EXPRESS mode loads use light appends and are significantly faster than DELUXE mode loads, but less flexible. In EXPRESS mode you cannot update the table or read the new data entries until the load is complete.

An error message is generated and the load is stopped if EXPRESS mode is specified and the table contains objects of type BLOB, BYTE, CLOB, or TEXT.

When data is loaded using EXPRESS mode, the target table cannot be located within an Enterprise Replication (ER) replicate. In addition, the target database server must not have high-availability data replication (HDR) enabled.

**FIXED**

Specifies that the data file is fixed width. When using EXTERNAL data types in the external table, the FIXED format must be used.

**FORMAT**

Specifies the format of the data in the data files.

**INFORMIX**

Specifies that the format of the data file is internal Informix® format. Loading data from an external table saved in Informix® format is faster than loading data from a fixed or delimited external file. Use Informix® format when moving data from one Informix® database to another.

**MAXERRORS**

Sets the number of errors that are allowed before the database server stops loading data.

The minimum value for MAXERRORS is 1. Setting MAXERRORS to a value less than 1 produces an error. The maximum value for MAXERRORS is 2,147,483,647.

#### **RECORDEND**

Specifies the character that separates records in a delimited text file.

#### **REJECTFILE**

Sets the full path name where the database server writes data-conversion errors. If not specified or if files cannot be opened, any error ends the loading of data abnormally. See also [Reject Files on page 223](#).

#### **NUMROWS or SIZE**

The approximate number of rows in the external table.

Specifying NUMROWS (or its synonym, SIZE) can improve performance when an external table is used in a join query. This value cannot be NULL.

## Reject Files

Rows that have conversion errors during a load or rows that violate check constraints on the external table are written to a reject file. The REJECTFILE clause declares the path and file name of the reject file.

If you perform another load to the same table during the same session, any earlier reject file of the same name is overwritten.

Reject file entries have the following format:

```
filename, record, reason-code,  
field-name: bad-line
```

The following table describes these elements of the reject file:

#### **Element**

#### **Description**

##### ***filename***

Name of the input file.

##### ***record***

Record number in the input file where the error was detected.

##### ***reason-code***

Description of the error.

##### ***field-name***

External field name where the first error in the line occurred, or `<none>` if the rejection is not specific to a particular column.

**bad-line**

Line that caused the error (delimited or fixed-position character files only).

The reject file writes the *filename*, *record*, *field-name*, and *reason-code* in ASCII. The *bad-line* information varies with the type of input file.

- For delimited files or fixed-position character files, up to 80 characters of the bad line are copied directly into the reject file.
- For Informix® internal data files, the bad line information is not placed in the reject file because you cannot edit the binary representation in a file; but the *filename*, *record*, *reason-code*, and *field-name* are still reported in the reject file so you can isolate the problem. Use the Table Options clause to specify the format of the external data.

The following errors can cause a row to be rejected.

**Error Text****Explanation****CONSTRAINT *constraint name***

This constraint was violated.

**CONVERT\_ERR**

Any field encounters a conversion error.

**MISSING\_DELIMITER**

No delimiter was found.

**MISSING\_RECORDEND**

No end of record was found.

**NOT NULL**

A NULL was found in *field-name*.

**ROW\_TOO\_LONG**

The input record is longer than 32 kilobytes.

**Virtual Processors**

A FIFO virtual processor is used by external tables in Informix®. One FIFO virtual processor is created when the server is initialized. Additional FIFO virtual processors can be added using the `onmode -p` command. For example, use the following command to add three FIFO virtual processors:

```
onmode -p +3 fifo
```

FIFO virtual processors cannot be deleted.

The FIFO virtual processors are used to process I/O related to the pipes that are defined with the PIPE clause.

See the *Informix® Administrator's Guide* for more information about using FIFO virtual processors.

## External Table Examples

The examples in this section illustrate different ways to load and unload data using external tables.

### Example

The following is an example of the CREATE EXTERNAL TABLE syntax. In the example, an external table named `empdata` is created with two columns. The DATAFILES clause indicates the location of the data file, specifies that the file is delimited, indicates the location of the reject file, and indicates that the reject file can contain no more than 100 errors.

```
CREATE EXTERNAL TABLE empdata
(
  empname char(40),
  empdoj date
)
USING
(DATAFILES
(
  "DISK:/work/empdata.unl"
),
FORMAT "DELIMITED",
REJECTFILE "/work/errlog/empdata.rej",
MAXERRORS 100);
```

### Example

#### Creating an external table using the SAMEAS clause

The SAMEAS *template* clause uses all the column names and data types from the *template* table in the definition of the new table. The following example uses the column names and data types of the `empdata` table and uses them for the external table.

```
CREATE EXTERNAL TABLE emp_ext SAMEAS empdata
USING
(DATAFILES
(
  "DISK:/work/empdata2.unl"
),
REJECTFILE "/work/errlog/empdata2.rej",
DELUXE
);
```

### Example

#### Unloading data into an external table

The following example shows statements used to load data from a database table into an external table.

```
CREATE EXTERNAL TABLE ext1( col1 int )
USING
(DATAFILES
(
  "DISK:/tmp/ext1.unl"
)
);
```

```
CREATE TABLE base (col1 int);
INSERT INTO ext1 SELECT * FROM base;
```

You can also use the SELECT...INTO EXTERNAL syntax to unload data as in the following example.

```
SELECT * FROM base
INTO EXTERNAL emp_target
USING
  (DATAFILES
    (
      "DISK:/tmp/ext1.unl"
    )
  );
```

### Example

#### Selecting from an external table and loading into a database table

The following example selects from an external and shows various ways to load external data into a database table.

```
CREATE EXTERNAL TABLE ext1( col1 int )
USING
  (DATAFILES
    (
      "DISK:/tmp/ext1.unl"
    )
  );

CREATE TABLE target1 (col1 int);
CREATE TABLE target2 (col1 serial8, col2 int);

SELECT * FROM ext1;
SELECT col1,COUNT(*) FROM ext1 GROUP BY 1;
SELECT MAX(col1) FROM ext1;
SELECT col1 FROM ext1 a, systables b WHERE a.col1=b.tabid;

INSERT INTO target1 SELECT * FROM ext1;
INSERT INTO target2 SELECT 0,* FROM ext1;
```

### Example

#### Unloading from a database table to a text file using FIXED format

The next example creates an external table named `emp_ext`, defines the column names and data types, and unloads the data from the database using fixed format.

```
CREATE EXTERNAL TABLE emp_ext
( name CHAR(18) EXTERNAL CHAR(20),
  address VARCHAR(40) EXTERNAL CHAR(40),
  empno INTEGER EXTERNAL CHAR(6)
)
USING (
  FORMAT 'FIXED',
  DATAFILES
  (
    "DISK:/work2/mydir/emp.fix"
  )
);
```

```
INSERT INTO emp_ext SELECT * FROM employee;
```

### Example

#### Loading data from a data file into a database table using FIXED format

The next example creates an external table named `emp_ext` and loads data into the database from a fixed format file.

```
CREATE EXTERNAL TABLE emp_ext
( name CHAR(18) EXTERNAL CHAR(18),
  address VARCHAR(40) EXTERNAL CHAR(40),
  empno INTEGER EXTERNAL CHAR(6)
)
USING (
  FORMAT 'FIXED',
  DATAFILES
  (
    "DISK:/work2/mydir/emp.fix"
  )
);

INSERT INTO employee SELECT * FROM emp_ext;
```

### Example

#### Using formatting characters in the DATAFILES clause

To process three files, create the `DATAFILES` clause as in the following example.

```
DATAFILES
(
  "DISK:/work2/extern.dir/mytbl.%r(1..3)"
)
```

The following shows how the list is expanded when the statement is run:

```
DATAFILES
(
  "DISK:/work2/extern.dir/mytbl.1",
  "DISK:/work2/extern.dir/mytbl.2",
  "DISK:/work2/extern.dir/mytbl.3"
)
```

## Loading Data from External Tables into Informix®

To load data, you define the external data as an external table and then insert the data into the database.

The database server performs express-mode loads and deluxe-mode loads. You can perform express-mode loads only when the table is type `RAW` and does not have any active indexes. The database server allows constraint checking for both load modes.

Express® mode provides the highest performance during a load.

Deluxe mode combines fast parallel loading with evaluation of indexes and unique constraints, and is more efficient in the following situations:

- The cost of rebuilding an index is too high for the amount of data that you are loading.
- You want to use the empty space from deleted rows in the table that you are loading. database

If the table receiving the rows from the external table is a STANDARD table (that is, a database table that was not created by the CREATE TEMP TABLE or CREATE RAW TABLE statement), the EXPRESS keyword has no effect, and the table is loaded in DELUXE mode. The database server does not issue an exception when it ignores the EXPRESS keyword in load operations where the receiving table is not a RAW table.

## Loading Data in Express® Mode

Express® mode supports rapid loading of data into tables that have no indexes. In logged databases, only RAW tables can use this mode.

### Before you begin

**Warning:** Express-mode loads are not allowed for STANDARD tables in databases that support transaction logging.

### About this task

Express-mode loads use light appends, which bypass the buffer pool. Light appends eliminate the overhead associated with buffer management but do not log the data. In express mode, the database server automatically locks the table exclusively. No other users can access the table.

You can use express mode for any newly created table with no data if you define the table as type RAW and do not define any indexes until after you load the data. Choose RAW tables if you do not want to use logging in a database that supports transaction logging.

To prepare an existing table for express-mode load, drop all indexes, and make sure the table type is RAW.

Data loaded from an external table into a raw table is not logged; therefore, you must perform a level-0 backup before the database can be dropped. If you try to drop the database before you perform a level-0 backup, the database server issues ISAM error -197, as follows:

```
Partition recently appended to; can't open for write or logging
```

Consider a table with the following schema:

```
TABLE employee (
  name CHAR(18),
  hiredate DATE,
  address CHAR(40),
  empno INTEGER);
```

To use express-mode load on an existing table

1. Alter the table type to allow fast loading.

```
ALTER TABLE employee TYPE (RAW);
```

2. Create the external table description.

```
CREATE EXTERNAL TABLE emp_ext
SAMEAS employee
USING (
  FORMAT 'DELIMITED',
  DATAFILES
  ("DISK:/work2/mydir/emp.dat"),
  REJECTFILE "/work2/mydir/emp.rej",
  EXPRESS
);
```

### 3. Load the table.

```
INSERT INTO employee SELECT * FROM emp_ext;
```

If the database server chooses express mode, the load stops with an error message if the destination table contains indexes, constraints, or any other problem conditions.

### 4. Create a level-0 backup.

Because the data is not logged, you must perform a level-0 backup to allow data recovery. If a disk fails, you cannot recover the data automatically. You need to use the most recent level-0 backup files. ,

## Results

If the table type is RAW (nonlogging), omit the statements BEGIN WORK and COMMIT WORK.

**Note:** If you delete many rows from a table and then load many new rows into the table in EXPRESS mode, the table grows in size because light appends insert rows at the end of the table, and do not reuse the empty space inside the table. (Whether or not you specify EXPRESS mode, the loader might choose DELUXE mode to fill in the space if a table has many deleted rows.)

## Loading data in DELUXE mode

DELUXE mode combines fast parallel loading with evaluation of indexes and unique constraints. The database server chooses this mode for indexed target tables in all databases, and for STANDARD target tables in logged databases.

### About this task

DELUXE mode loads use regular single-row inserts, which add rows to a table that can contain indexes. The insert modifies each index for each row during the load. The insert also checks all constraints for each row. A DELUXE mode load allows you to keep the table unlocked during the load so other users can continue to use it.

You also can use DELUXE mode on tables that do not contain indexes; for instance, if you want to have complete recoverability or maintain access to tables during a load.

You can specify DELUXE mode to override the default EXPRESS load mode for RAW target tables without indexes if the database is logged.

The following steps show you how to prepare a table for DELUXE mode load, create the internal table as type STANDARD, and create the external table.

 **Tip:** The database server will automatically use DELUXE mode to load this type of table. You do not need to specify the DELUXE keyword when you define the external table. If you specify the EXPRESS keyword in the table definition, the database server will use DELUXE mode anyway and issue an informational message.

To use DELUXE-mode load on a table:

1. If you want row locking, specify row locking in the CREATE TABLE statement. (Page locking is the default.) If you want other users to be able to read the table during the load, set the lock mode to `share`. Otherwise, set it to `exclusive`.

```
BEGIN WORK;
LOCK TABLE employee IN SHARE MODE;
```

2. Define the external table.

```
CREATE EXTERNAL TABLE emp_ext
SAMEAS employee
USING (
  DATAFILES ("DISK:/work2/mydir/emp.dat"),
  REJECTFILE "/work2/mydir/emp.rej",
);
```

3. Load the table.

```
INSERT INTO employee SELECT * FROM emp_ext;
```

4. Commit the load, releasing row or page locks.

```
COMMIT WORK;
```

## Results

 **Important:** Configure logical logs to allow maximum concurrent DELUXE load transactions to complete.

## Loading from a Delimited File to a Database Table with the Same Schema

You can avoid defining the schema of an external table if it has the same schema as the database table.

### About this task

Consider loading a delimited ASCII text file into a table with the following schema:

```
TABLE employee (
  name CHAR(18) NOT NULL,
  hiredate DATE DEFAULT TODAY,
  address VARCHAR(40),
  empno INTEGER);
```

The SQL statements used to load data into the employee table would be as follows:

```
CREATE EXTERNAL TABLE emp_ext
SAMEAS employee
USING (
  DATAFILES ("DISK:/work2/mydir/emp.dat"),
```

```
REJECTFILE "/work2/mydir/emp.rej"
);
INSERT INTO employee SELECT * FROM emp_ext;
```

The external table has the same name, type, and default for each column because the CREATE statement includes the SAMEAS keyword. The default format is delimited, so no format keyword is required.

Delimited files are ASCII by default. The default row delimiter is an end-of-line character unless you use the RECORDEND keyword to specify a different delimiter when you created the external table. (The RECORDEND keyword works for delimited format only.)

## Loading from a Fixed Text File

A fixed text file is one in which data resides in fixed positions within the file.

### About this task

The following SQL statements load data from the **emp\_exp** external table to a fixed-position table (**employee**):

```
CREATE EXTERNAL TABLE emp_ext
( name CHAR(18) EXTERNAL CHAR(18),
  hiredate DATE EXTERNAL CHAR(10),
  address VARCHAR(40) EXTERNAL CHAR(40),
  empno INTEGER EXTERNAL CHAR(6) )
USING (
  FORMAT 'FIXED',
  DATAFILES ("DISK:/work2/mydir/emp.fix")
);
INSERT INTO employee SELECT * FROM emp_ext;
```

The enumerated columns use the keyword EXTERNAL to describe the format in which to store the data in the external file.

## Loading Between Tables That Have the Same Schema

You can easily move data from an external table to a database table if the tables have the same schema.

### About this task

You can load data from one table to another table that has the same schema (for example, **worldemp**) with a simple INSERT statement.

```
INSERT INTO worldemp SELECT * FROM emp_ext;
```

## Loading Values into Serial Columns

You can insert successive numbers or explicit values in a serial column.

### About this task

The database server loads serial columns with either the values from the original data file or values that the database server automatically generates.

If you want the serial column values to be the values from the data file, the INSERT statement does not require special handling. If you want the database server to generate the value automatically, omit the serial column from the INSERT statement. For example, if the first column in the table (**col1**) is the serial column and you use the following statement, the default mechanism provides the serial value:

```
INSERT INTO mytable (col2, ...) SELECT ...
```

If the table is being loaded into multiple partitions, the serial values are incremented in the same sequence as the table fragments.

## Loading Data Warehousing Tables

You can use external tables to load very large tables for data warehousing applications.

This section discusses various scenarios to load very large tables:

- Loading initially
- Refreshing periodically
- Loading of OLTP data from database servers other than Informix®.

## Loading Initially

### About this task

The following scenario creates and loads a data warehouse table with external data.

To load a table initially

1. Create the table as type RAW to take advantage of light appends and to avoid the overhead of logging during the load.

```
CREATE RAW TABLE tab1 ...
```

2. Describe the external data file to the database server with the CREATE EXTERNAL TABLE statement, specifying the EXPRESS statement in the USING clause.
3. Load the table.

```
INSERT INTO tab1 SELECT * FROM ext_tab
```

The table loads quickly, and the operation uses very little log space.

4. Verify the integrity of the data.
5. Create indexes on the table so that queries run more quickly.
6. Perform a level-0 backup so that you can restore the table later, if necessary. You do not need to perform this level-0 backup if it would be just as easy to reload the table from the original source in the case of a problem.

## Refreshing Periodically

This scenario loads new data in a data warehouse table periodically from some other source.

### About this task

The scenario assumes that the table is type STANDARD during normal operation and that the CREATE EXTERNAL TABLE statement has been previously executed and the EXPRESS keyword was specified in the USING clause.

To refresh a table periodically

1. Drop all indexes on the table.
2. Alter the table to type RAW.

```
ALTER TABLE tab1 TYPE(RAW);
```

3. Load the new data in the table.

```
INSERT INTO tab1 SELECT * FROM ext_tab
```

This insert statement quickly appends new data to the end of the table, and the operation uses very little log space.

4. Verify the integrity of the data.
5. Change the table to type STANDARD.

```
ALTER TABLE tab1 TYPE(STANDARD);
```

6. Re-create indexes on the table so that queries run more quickly.
7. Perform a level-0 backup to enable you to restore the table later, if necessary. You do not need to perform this level-0 backup if it would be just as easy to reload the table from the original source in the case of a problem.

## Initial Loading of OLTP Data from Other Database Servers

This scenario loads data into Informix® for the first time, as you might do when you migrate from a different database server.

### About this task

In this scenario, the table to load will be used for OLTP, so you need logged transactions, rollback, and recoverability.

To load OLTP data initially from a different database server using the CREATE EXTERNAL TABLE statement:

1. Create the table as type RAW to take advantage of light appends and to avoid the overhead of logging during the load.

```
CREATE RAW TABLE tab1 ...
```

2. Describe the external data file to the database server with the CREATE EXTERNAL TABLE statement.
3. Load the table.

```
INSERT INTO tab1 SELECT * FROM ext_tab
```

The table loads quickly, and the operation uses very little log space.

4. Verify the integrity of the data.

5. Perform a level-0 backup to provide a point from which to recover.
6. Change the table to type STANDARD.

```
ALTER TABLE tab1 TYPE(STANDARD);
```

7. Create indexes on the table so that queries run more quickly.
8. Enable constraints on the table to preserve the integrity of the data.

## Unloading Data to External Tables from Informix®

You unload data by creating an external table and inserting the data into it, or by selecting data from an internal table into an external file.

To unload data in parallel, initiate a query that runs in parallel and writes its output to multiple files. The unload job uses a round-robin technique to equalize the number of rows in the output files.

## Unloading to a Delimited File

### About this task

You can unload data to a delimited-ASCII text file from a table, as the following example shows:

```
CREATE EXTERNAL TABLE emp_ext
SAMEAS employee
USING (
    DATAFILES ("DISK:/work2/mydir/emp.dat")
);
INSERT INTO emp_ext SELECT * FROM employee;
```

Delimited files are ASCII by default.

## Unloading to Informix® Data Files

### About this task

To unload from the **employee** table to a table in Informix® internal format, use statements similar to the following ones:

```
SELECT * FROM employee
WHERE hiredate > "1/1/1996"
INTO EXTERNAL emp_ext
USING (
    FORMAT 'INFORMIX',
    DATAFILES ("DISK:/work2/mydir/emp.dat")
);
```

Because the output files use Informix® internal representation, you need to specify the FORMAT 'INFORMIX' option in the USING clause. (The default is delimited-ASCII format.)

## Unloading to a Fixed-Text File

You can unload data from the database into fixed format files.

### About this task

The following SQL statements unload the **employee** table in fixed text format into the **emp\_ext** external table:

```
CREATE EXTERNAL TABLE emp_ext
  ( name CHAR(18) EXTERNAL CHAR(20),
    hiredate DATE EXTERNAL CHAR(10),
    address VARCHAR(40) EXTERNAL CHAR(40),
    empno INTEGER EXTERNAL CHAR(6) )
USING (
  FORMAT 'FIXED',
  DATAFILES ("DISK:/work2/mydir/emp.fix")
);
INSERT INTO emp_ext SELECT * FROM employee;
```

These statements create a fixed-text file with 20 character positions in the first field, the next 10 character positions in the second field, and so on. Because you are choosing the rows with a SELECT statement, you can format the SELECT list in any way that you want.

## Adding an End-of-Line Character to a Fixed Text File

You can add an end-of-line character to each line of a fixed-text file to use the file for other applications.

### About this task

If you are writing text in a fixed-text format, separate lines for each record are helpful. An end-of-line character makes the data more legible and clear. If you use delimited format defaults, an end-of-line character is automatic. However, for fixed-format unloads, you need to add an end-of-line character to your records. For example, consider a table with the following schema:

```
TABLE sample (
  lastname CHAR(10),
  firstname CHAR(10),
  dateofbirth DATE);
```

This table contains the following values:

|       |      |            |
|-------|------|------------|
| Adams | Sam  | 10-02-1957 |
| Smith | John | 01-01-1920 |

Next, consider an external table with the following schema:

```
CREATE EXTERNAL TABLE sample_ext (
  lastname CHAR(10) EXTERNAL CHAR(10),
  firstname CHAR(10) EXTERNAL CHAR(10),
  dateofbirth DATE EXTERNAL CHAR(12));
```

Unloading **sample\_ext** without an end-of-line character produces the following output:

|       |     |            |       |      |            |
|-------|-----|------------|-------|------|------------|
| Adams | Sam | 10-02-1957 | Smith | John | 01-01-1920 |
|-------|-----|------------|-------|------|------------|

You can add end-of-line characters by using a program or script, or by adding a newline field in a SELECT statement.

## Using a Program or Script

To add an end-of-line character, you can write the fixed-length records to a data file and then modify the data file with a program or script.

### About this task

For example, you could use a C program to find the length of each record, locate the end of a line, and then add an end-of-line character.

## Adding a Newline Field in a SELECT Statement

You can use an external table to load the newline character in your internal table.

### About this task

To add an end-of-line character, select a final value from a table that contains a newline character, as in the following example:

1. Create a file that contains only a newline character.

```
echo "" > /tmp/cr.fixed
```

2. Create an internal table to store this newline value to use when you unload the data.

```
CREATE TABLE dummyCr (cr CHAR(1));
```

3. Create the external table to load the newline value.

```
CREATE EXTERNAL TABLE x_cr (cr CHAR(1) EXTERNAL CHAR(1))
```

```
USING (DATAFILES ('DISK:/tmp/cr.fixed'), FORMAT 'FIXED');
```

4. Load the external table in the internal **dummyCr** table.

```
INSERT INTO dummyCr SELECT * FROM x_cr;
```

### Results

The internal table, **dummyCr**, now contains an end-of-line character that you can use to unload in a SELECT statement:

1. To unload data from your internal table to an external table, create the external table with the end-of-line character as an EXTERNAL CHAR.

```
CREATE EXTERNAL TABLE sample_ext
(
  lastname CHAR(10) EXTERNAL CHAR(10),
  firstname CHAR(10) EXTERNAL CHAR(10),
  dateofbirth DATE EXTERNAL CHAR(12),
  eol CHAR(1) EXTERNAL CHAR(1)
USING (DATAFILES (...), FORMAT 'FIXED');
```

2. Select from the internal table and the **dummyCr** table to create an output file that has rows separated by end-of-line characters.

```
INSERT INTO sample_ext(lastname, firstname, dateofbirth, eol)
SELECT a.lastname, a.firstname, a.dateofbirth, b.cr
FROM mytable a, dummyCr b;
```

## Restrictions on External Tables

Certain operations on external tables are not supported or have limited scope.

[Table 1: Database Tables and External Tables on page 237](#) compares table operations that are supported for database tables and external tables.

**Table 1. Database Tables and External Tables**

| Table Operation  | Database Table | External Table   |
|--|----------------|--|
| Support for indexes and:<br><ul style="list-style-type: none"> <li>• Primary keys</li> <li>• Foreign keys</li> <li>• Unique and non-unique indexes</li> <li>• Index scans</li> <li>• Automatic index (autoindex) during query execution</li> <li>• Index join</li> </ul> | Yes            | No, sequential scans are used.   |
| Triggers are supported   | Yes            | No   |
| Table can be a target in a MERGE statement   | Yes            | No. Not allowed as target but allowed as source. See <a href="#">MERGE Example on page 239</a> |
| Table fragmentation is supported   | Yes            | No   |
| Multiple database tables are allowed in the FROM clause  | Yes            | No. See <a href="#">Query Example on page 240</a>  |

**Table 1. Database Tables and External Tables (continued)**

| <b>Table Operation</b>                                     | <b>Database Table</b> | <b>External Table</b>  |
|--|-----------------------|--|
| DB-Access LOAD FROM ... INSERT INTO statement is supported | Yes                   | No   |
| The TRUNCATE TABLE statement truncates a table             | Yes                   | No. Data in external tables is not truncated using the TRUNCATE statement. Unloading data from a database table to an external table automatically truncates the external table. |
| Table data is replicated                                   | Yes                   | No   |
| The UPDATE STATISTICS statement is supported               | Yes                   | No   |
| UPDATE and DELETE statements are supported                 | Yes                   | No   |
| The ALTER TABLE statement is supported                     | Yes                   | No   |
| LBAC is supported  | Yes                   | No   |
| Compression is supported                                   | Yes                   | No   |
| START and STOP VIOLATIONS statements supported             | Yes                   | No   |
| TEMP tables are supported                                  | Yes                   | No   |
| The EXTERNAL data type is supported for table columns      | No                    | Yes  |
| DEFAULT clause is supported                                | Yes                   | No   |

**Table 1. Database Tables and External Tables (continued)**

| Table Operation   | Database Table  | External Table   |
|---|---|--|
| PUT clause is supported for BLOB and CLOB types                               | Yes   | No. BLOBDIR and CLOBDIR can be specified using the DATAFILES clause.   |
| SERIAL, SERIAL8, and BIGSERIAL data types generate serial numbers             | Yes   | No. These data types are converted to equivalent integer types and no serial value is generated.                                 |
| Table can be replicated using Enterprise replication (ER)                     | Yes   | No   |
| Changes to tables are logged and can be replicated                            | Yes   | No. External tables are not logged and cannot be replicated; however system catalogs are replicated.                             |
| ACID (atomicity, consistency, isolation, durability) properties are supported | Yes   | No   |
| ETL (extract, transform, load) is supported                                   | SQL interface for ETL operations is not supported; however, utilities such as dbload, onload, onunload and LOAD, UNLOAD statements are supported. | Supported using a simple SQL interface using the INSERT ... SELECT statement for high performance loading and unloading of data. |

Certain high-availability cluster operations are not supported (see *External Tables in High-Availability Cluster Environments in the Informix® Administrator's Guide*).

To load BLOB or CLOB objects from an external table, you must create a temporary sbspace and create temporary smart large objects in that space to store the BLOB or CLOB data from the external table. Loading BLOB or CLOB data from a read-only secondary server is not supported, because you cannot create a temporary smart large object on a read-only secondary server.

### Example

#### MERGE Example

An external table cannot be the target of the MERGE statement. For example, if **ext** is an external table, the following MERGE statement is valid with **ext** as the source table:

```
MERGE INTO t1
  USING ext ON t1.c1 = ext.c1
```

```

WHEN MATCHED THEN UPDATE
  SET t1.c2 = ext.c2
WHEN NOT MATCHED THEN INSERT VALUES (99, '999');

```

The following statement, however, fails with **ext** as the target table:

```

MERGE INTO  ext
  USING t1 ON ext.c1 = t1.c1
  WHEN MATCHED THEN UPDATE
    SET ext.c2 = t1.c2
  WHEN NOT MATCHED THEN INSERT VALUES (99, '999');

```

## Example

### Query Example

Only the outermost query can have an external table reference. Only one external table can be specified in any query. For example, the following statement is allowed:

```
SELECT * FROM ext, t2 WHERE ext.c1 = t2.c1;
```

However, the following statements are not allowed:

- Multiple external tables cannot be specified within a query:

```
SELECT * FROM ext, ext3 WHERE ext.c1 = ext3.c1;
```

- An external table cannot be used in a subquery:

```
SELECT * FROM t1 WHERE t1.c1 IN (SELECT c1 FROM ext);
```

## CREATE FUNCTION statement

Use the CREATE FUNCTION statement to create a user-defined function, to register an external function, or to write and register an SPL function.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```

>>-CREATE-----+-----+-----+----->
      |   (1)   | | (2) |
      '-OR REPLACE---' '-DBA-----'

>--FUNCTION--++-----+---function(+-----+---+)->
      '-IF NOT EXISTS-' | | (3) |
                        '-| Routine Parameter List |-----'

>--+-----+-----+-----+----->
      | | (4) | |
      '-| REFERENCING Clause |-----FOR -+-----+---table_object-'
                                     '-|-----owner--'-'-'

      (5)

```

| Element             | Description  | Restrictions   | Syntax   |
|---------------------|--|--|--|
| <i>pathname</i>     | Pathname to a file in which compile-time warnings are stored                 | The specified pathname must exist on the computer where the database resides | The path and filename must conform to your operating-system rules. |
| <i>table_object</i> | Name or synonym of the table or view whose triggers can call <i>function</i> | Must exist in the local database   | <a href="#">Identifier on page 1456</a>                            |

**Tip:** If you are trying to create a function from text of source code that is in a separate file, use the CREATE FUNCTION FROM statement.

## Usage

HCL Informix® supports user-defined functions written in these languages:

- The HCL Informix® stored procedure language (SPL).
- One of the external languages (C or Java™) that Informix® supports (*external functions*).

When the IFX\_EXTEND\_ROLE configuration parameter is set to ON, only users to whom the DBSA grants the built-in EXTEND role can create external functions. Additional requirements for using the CREATE FUNCTION statement are identified in the topic [Privileges necessary for using CREATE FUNCTION on page 243](#).

How many values a function can return is language-dependent. Functions written in SPL can return one or more values. External functions written in the C or Java™ languages must return exactly one value. But a C function can return a collection type, and external functions in queries can return additional values indirectly from OUT parameters (and for the SPL and Java™ languages, from INOUT parameters) that Informix® can process as statement-local variables (SLVs).

Return values from OUT and INOUT parameters of an SPL function can be processed as SLVs. You can also use local variables or parameters of an SPL routine to retrieve values from SPL or C routines that have OUT or INOUT parameters.

For information about how this document uses the terms UDR, function, and procedure, as well as recommended usage, see [Relationship Between Routines, Functions, and Procedures on page 294](#) and [Using CREATE PROCEDURE Versus CREATE FUNCTION on page 294](#).

In ESQL/C, you can use a CREATE FUNCTION statement only within a PREPARE statement. If you want to create a user-defined function for which the text is known at compile time, you must put the text in a file and specify this file with the CREATE FUNCTION FROM statement.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a function of the specified name is already registered in the current database. (Because the identifier of a function can be overloaded, it might be unnecessary to include these keywords, if the database server can resolve the argument list of the new function as different from that of any other function of the same name in the current database.)

Functions use the collating order that was in effect when they were created. See [SET COLLATION statement on page 862](#) for information about using non default collation.

## Privileges necessary for using CREATE FUNCTION

You must hold the Resource privilege or the DBA privilege on a database to create a function within that database.

Before you can create a function, you must also hold the Usage privilege on the programming language in which the function is written. The GRANT USAGE ON LANGUAGE statement can specify the SPL, C, or Java™ language when it grants a language-level privilege to a user or to a role. For more information, see [Language-Level Privileges on page 607](#).

By default, Usage privilege on SPL is granted to PUBLIC.

To register functions in the C or Java™ external programming languages, you must also hold the built-in EXTEND role, unless the IFX\_EXTEND\_ROLE configuration parameter is set to `0` or to `OFF`.

## DBA keyword and Execute privilege on the created function

If you create a UDR with the DBA keyword, it is known as a DBA-privileged UDR. You need the DBA privilege to create a DBA-privileged UDR. If you omit the DBA keyword, the UDR is known as an owner-privileged UDR. Other users who have Execute privilege on the UDR run the UDR with the privileges of the user who created the UDR.

## DBA-privileged UDRs

For a DBA-privileged UDR, users who do not hold the DBA privilege can run the routine under the following conditions:

- The DBA grants the user Execute privilege on the UDR.
- The DBA grants the Execute privilege to PUBLIC so that all users can run the UDR.

When you have Execute privilege on a DBA-privileged UDR, you run the UDR with DBA privileges.

For additional information about DBA-privileged UDRs, see [Ownership of Created Database Objects on page 301](#).

## Owner-privileged UDRs

In an ANSI-compliant database, before other users can execute an owner-privileged UDR, the owner must grant the Execute privilege, either to individual users, or to roles, or to PUBLIC.

In a database that is not ANSI compliant, any user can run the UDR because PUBLIC is granted the Execute privilege by default. To restrict access to an owner-privileged UDR to specific users, the owner must revoke the Execute privilege on the UDR from PUBLIC, and then grant it to specified users or roles. However, you can prevent privileges on UDRs from being granted to PUBLIC by default. by setting the **NODEFDAC** environment variable to `yes`. Then the owner must grant the Execute privilege for the UDR to other users.

For an owner-privileged UDR, all non-qualified database objects that the UDR references are implicitly qualified by the name of the UDR owner. To allow other users to run the UDR, the owner of the UDR must be granted the necessary privileges on any underlying database objects with the WITH GRANT OPTION keyword in the GRANT statement.

The privileges of the owner determine who can run an owner-privileged UDR:

- If the owner does not have privileges on all of the objects that are referenced by the UDR, then the UDR fails regardless of whether the owner or another user runs it.
- If the owner has privileges on all referenced objects, but does not have the GRANT option, then only the owner can run the UDR. Other users cannot run the UDR, even if they have Execute privilege on the UDR.
- If the owner has privileges with the GRANT option on all referenced objects, then the owner and other users who have the Execute privilege can run the UDR. Other users who have Execute privilege run the UDR with the owner's privileges.

If an external C or Java™ language function has a negator function, you must grant the Execute privilege on both the external function and on its negator function before users can execute the external function.

---

[WITH GRANT OPTION keywords on page 613](#)

## OR REPLACE Clause

The OR REPLACE clause is used to update an existing function without changing any object privileges granted on it.

**Example**

```

create function testfunc() returning char(50);
    return "this is the original function";
end function;
Routine created.

execute function testfunc();

(expression)

this is the original function

1 row(s) retrieved.

create function testfunc() returning char(50);
    return "this is the replaced function";
end function;

673: Another routine (testfunc) with same signature already exists in database

create or replace function testfunc() returning char(50);
    return "this is the replaced function";
end function;
Routine created.

execute function testfunc();

(expression)

this is the replaced function

1 row(s) retrieved.

```

**The REFERENCING and FOR Clauses**

The REFERENCING clause can declare correlation names for the original value and for the updated value in columns of the *table\_object* that the FOR clause specifies.

REFERENCING and FOR Clauses

**REFERENCING**

<sup>115</sup>**OLD**

<sup>115</sup>**NEW**

**AS**

*correlation*

**FOR**

*'owner'.*

*table\_object*

115. Use path no more than once

| Element             | Description   | Restrictions                     | Syntax                                  |
|---------------------|---|----------------------------------|---|
| <i>correlation</i>  | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a trigger routine | Must not be <i>table_object</i>  | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>        | Owner of <i>table_object</i>  | Must own <i>table_object</i>     | <a href="#">Owner name on page 1488</a> |
| <i>table_object</i> | Name or synonym of a table or view whose triggers can call <i>function</i>  | Must exist in the local database | <a href="#">Identifier on page 1456</a> |

If you include the REFERENCING and FOR *table\_object* clauses immediately after the parameter list of the CREATE FUNCTION statement, the function that you create is known as a *trigger function* (or *trigger UDR* or *trigger routine*). The FOR clause specifies the table or view whose triggers can invoke the function from the FOR EACH ROW section of their Triggered Action list.

In the REFERENCING clause, the OLD *correlation* specifies a prefix by which the trigger routine can reference the value that a column of *table\_object* had before the trigger routine modifies that column value. The NEW *correlation* specifies a prefix for referencing the new value that the trigger routine assigns to the column. Whether the trigger routine can use correlation names to reference the OLD column value, the NEW column value, or both values depends on the type of triggering event:

- A trigger routine invoked by an Insert trigger can reference only the NEW correlation name.
- A trigger routine invoked by a Delete trigger or by a Select trigger can reference only the OLD correlation name.
- A trigger routine invoked by an Update trigger can reference both the OLD and the NEW correlation names.

For information about how to use the *correlation.column* notation in triggered actions, see [REFERENCING Clauses on page 422](#).

Besides the general requirements for any Informix® UDR that is written in the SPL language, trigger routines can support certain additional syntax features, and are subject to certain restrictions, that are not features (or that are not restrictions) for ordinary UDRs that are not trigger routines:

- A trigger routine must include the FOR *table\_object* clause that specifies the name of the table or view in the local database whose triggers can invoke this routine.
- A trigger routine can also include the REFERENCING clause to declare correlation names for OLD and NEW values that SPL statements in the UDR can reference.
- Trigger routines can be invoked only in the FOR EACH ROW section of the Triggered Action list in the trigger definition.
- Correlated variables for OLD or NEW values can appear in the IF statement of SPL and in CASE expressions.
- Correlated variables for OLD values cannot be on the left-hand side of a LET expression.
- Correlated variables for NEW values cannot be on the left-hand side of a LET expression if the FOR clause specifies a view whose INSTEAD OF trigger action list invokes the trigger routine.
- Only correlated variables for NEW values can be on the left-hand side of a LET expression that references correlated variables. In this case, however, the FOR clause must specify a table, rather than a view.
- Both OLD and NEW values can be on the right-hand side of a LET expression.

- The Boolean operators `SELECTING`, `INSERTING`, `DELETING`, and `UPDATING` are valid in trigger routines (and only in trigger routines and in other UDRs that are invoked in triggered action statements) in contexts where Boolean expressions are valid. These operators return `TRUE` ('t') if the triggering event matches the DML operation referenced by the name of the operator, and they return `FALSE` ('f') otherwise.
- If a single triggering event activates multiple triggers on the same table or view, then all of the `BEFORE` actions take place before any of the `FOR EACH ROW` actions, and all of the `AFTER` actions follow the `FOR EACH ROW` actions. The order of execution of different triggers on the same event is not guaranteed.
- Trigger routines must be written in the SPL language. They cannot be written in an external language, like the C or Java™ language, but they can include calls to external language routines, such as the **mi\_trigger** application programming interface for trigger introspection.
- Trigger functions cannot reference savepoints. Any changes to the data values or to the schema of the database by a triggered action must be committed or rolled back in their entirety. Informix® does not support the partial rollback of triggered actions.

For more information about the **mi\_trigger** API, refer to the *Informix® DataBlade® API Programmer's Guide* and to the *Informix® DataBlade® API Function Reference*.

If you include the `REFERENCING` clause but omit the `FOR` clause, or if you include the `FOR` clause but omit the `REFERENCING` clause, the `CREATE FUNCTION` statement fails with an error.

If you omit the `REFERENCING` and `FOR` clauses, the UDR cannot use the `SELECTING`, `INSERTING`, `DELETING`, and `UPDATING` operators, and cannot declare variables that can represent and manipulate column values in triggered actions on the table or view that the trigger definition specifies.

See the [REFERENCING Clauses on page 422](#) section in the `CREATE TRIGGER` statement description for the syntax of the `REFERENCING` clause for Delete, Insert, Select, and Update triggers.

## Overloading the Name of a Function

Because Informix® supports *routine overloading*, you can define more than one function with the same name, but different parameter lists. You might want to overload functions in the following situations:

- You create a user-defined function with the same name as a built-in function (such as **equal()**) to process a new user-defined data type.
- You create *type hierarchies*, in which subtypes inherit data representation and functions from supertypes.
- You create *distinct types*, which are data types that have the same internal storage representation as an existing data type, but have different names and cannot be compared to the source type without casting. Distinct types inherit support functions from their source types.

For a brief description of the routine signature that uniquely identifies each user-defined function, see [Routine Overloading and Routine Signatures on page 1454](#).

## Examples

Overloaded functions are uniquely identified by the name and the input parameter list. Instead of providing a long unique identifier, it is possible to provide specific name and use it later. The following example illustrates an overloaded function, whose identifier is `getArea`, that has the specific names `getSquareArea` and `getRectangleArea`:

```
CREATE FUNCTION getArea
  (i INT DEFAULT 0)
RETURNING INT SPECIFIC getSquareArea;
DEFINE j INT;
LET j = i * i;
RETURN j;
END FUNCTION;

CREATE FUNCTION getArea
  (i INT DEFAULT 0, j INT DEFAULT 0)
RETURNING INT SPECIFIC getRectangleArea;
DEFINE k INT;
LET k = i * j;
RETURN k;
END FUNCTION;
```

Now you can use the specific name, as in the following example:

```
GRANT EXECUTE ON SPECIFIC FUNCTION getSquareArea TO informix;
GRANT EXECUTE ON SPECIFIC FUNCTION getRectangleArea TO informix;
```

Without the specific name, you would need to issue the following:

```
GRANT EXECUTE ON FUNCTION getArea (INTEGER) TO informix;
GRANT EXECUTE ON FUNCTION getArea (INTEGER,INTEGER) TO informix;
```

---

### Related information

- [SPL statements on page 1081](#)

## Using the SPECIFIC Clause to Specify a Specific Name

You can declare a specific name, unique to the database, for a user-defined function. A specific name is useful when you are overloading a function.

## DOCUMENT Clause

The quoted string in the DOCUMENT clause provides a synopsis and description of the UDR. The string is stored in the **sysprocbody** system catalog table and is intended for the user of the UDR. Anyone with access to the database can query the **sysprocbody** system catalog table to obtain a description of one or all of the UDRs stored in the database.

For example, the following query obtains a description of the SPL function **update\_by\_pct**, that [SPL Functions on page 249](#) shows:

```
SELECT data FROM sysprocbody b, sysprocedures p
WHERE b.procid = p.procid
      --join between the two catalog tables
      AND p.procname = 'update_by_pct'
      -- look for procedure named update_by_pct
      AND b.datakey = 'D'-- want user document;
```

The preceding query returns the following text:

```
USAGE: Update a price by a percentage
Enter an integer percentage from 1 - 100
and a part id number
```

A UDR or application program can query the system catalog tables to fetch the DOCUMENT clause and display it for a user.

For C and Java™ language functions, you can include a DOCUMENT clause at the end of the CREATE FUNCTION statement, whether or not you use the END FUNCTION keywords.

## WITH LISTING IN Clause

The WITH LISTING IN clause specifies a filename where compile time warnings are sent. After you compile a UDR, this file holds one or more warning messages.

If you do not use the WITH LISTING IN clause, the compiler does not generate a list of warnings.

On UNIX™ platforms, if you specify a filename but not a directory, this listing file is created in your home directory on the computer where the database resides. If you do not have a home directory on this computer, the file is created in the root directory (the directory named /).

On Windows™ systems, if you specify a filename but not a directory, this listing file is created in your current working directory if the database is on the local computer. Otherwise, the default directory is %INFORMIXDIR%\bin.

## SPL Functions

SPL functions are UDRs written in SPL that return one or more values. To write and register an SPL function, use a CREATE FUNCTION statement. Embed appropriate SQL and SPL statements between the CREATE FUNCTION and END FUNCTION keywords. You can also follow the function with the DOCUMENT and WITH FILE IN options.

SPL functions are parsed, optimized (as far as possible), and stored in the system catalog tables in executable format. The body of an SPL function is stored in the **sysprocbody** system catalog table. Other information about the function is stored in other system catalog tables, including **sysprocedures**, **sysprocplan**, and **sysprocauth**. For more information about these system catalog tables, see the *Informix® Guide to SQL: Reference*.

The END FUNCTION keywords are required in every SPL function, and a semicolon (;) must follow the clause that immediately precedes the statement block. The following code example creates an SPL function:

```
CREATE FUNCTION update_by_pct ( pct INT, pid CHAR(10))
  RETURNING INT;
  UPDATE inventory SET price = price + price * (pct/100)
    WHERE part_id = pid;
  return (select price from inventory where part_id = pid);
END FUNCTION
  DOCUMENT "USAGE: Update a price by a percentage",
    "Enter an integer percentage from 1 - 100",
    "and a part id number"
  WITH LISTING IN '/tmp/warn_file';
```

For more information on how to write SPL functions, see the chapter about SPL routines in *Informix® Guide to SQL: Tutorial*.

See also the section [Transactions in SPL Routines on page 1527](#).

You can include valid SQL or SPL language statements in SPL functions. See, however, the following sections in [Other syntax segments on page 1433](#) that describe restrictions on SQL and SPL statements within SPL routines: [Subset of SPL Statements Valid in the Statement Block on page 1523](#); [SQL Statements Valid in SPL Statement Blocks on page 1523](#); and [Restrictions on SPL Routines in Data-Manipulation Statements on page 1525](#).

## External Functions

### About this task

*External functions* are functions you write in an external language (that is, a programming language other than SPL) that Informix® supports.

To create a C user-defined function

1. Write the C function.
2. Compile the function and store the compiled code in a shared library (the shared-object file for C).
3. Register the function in the database server with the CREATE FUNCTION statement.

### Results

To create a user-defined function written in the Java™ language

1. Write a Java™ static method, which can use the JDBC functions to interact with the database server.
2. Compile the Java™ source file and create a **.jar** file (the shared-object file for Java™).
3. Execute the **install\_jar()** procedure with the EXECUTE PROCEDURE statement to install the JAR file in the current database.
4. If the UDR uses user-defined data types, create a map between SQL data types and Java™ classes. Use the **setUDTextName()** procedure that is explained in [EXECUTE PROCEDURE statement on page 557](#).
5. Register the UDR with the CREATE FUNCTION statement.

Rather than storing the body of an external routine directly in the database, the database server stores only the pathname of the shared-object file that contains the compiled version of the routine. When it executes the external routine, the database server invokes the external object code.

The database server stores information about an external function in system catalog tables, including **sysprocbody** and **sysprocauth**. For more information on the system catalog, see the *Informix® Guide to SQL: Reference*.

## Example of Registering a C User-Defined Function

The following example registers an external C user-defined function named **equal()** in the database. This function takes two arguments of the type **basetype1** and returns a single Boolean value. The external routine reference name specifies the path to the C shared library where the function object code is actually stored. This library contains a C function **basetype1\_equal()**, which is invoked during execution of the **equal()** function.

```
CREATE FUNCTION equal ( arg1 basetype1, arg2 basetype1)
RETURNING BOOLEAN;
EXTERNAL NAME
  "/usr/lib/basetype1/lib/libbtype1.so(basetype1_equal)"
LANGUAGE C
END FUNCTION;
```

## Example of Registering a UDR Written in the Java™ Language

The following CREATE FUNCTION statement registers the user-defined function, **sql\_explosive\_reaction()**. This function is discussed in `sqlj.install_jar`.

```
CREATE FUNCTION sql_explosive_reaction(INT) RETURNS INT WITH (class="jvp")
EXTERNAL NAME "course_jar:Chemistry.explosiveReaction" LANGUAGE JAVA;
```

This function returns a single INTEGER value. The EXTERNAL NAME clause specifies that the Java™ implementation of the **sql\_explosive\_reaction()** function is a method called **explosiveReaction()**, which resides in the **Chemistry** Java™ class that resides in the **course\_jar** JAR file.

## Ownership of Created Database Objects

The user who creates an owner-privileged UDR, rather than the user who executes the UDR, owns any database objects that are created by the UDR when the UDR is executed, unless another owner is specified for the created object.

For example, assume that user **mike** creates this user-defined function:

```
CREATE FUNCTION func1 () RETURNING INT;
  CREATE TABLE tab1 (colx INT);
  RETURN 1;
END FUNCTION;
```

If user **joan** now executes function **func1**, user **mike**, not user **joan**, is the owner of the newly created table **tab1**.

In the case of a DBA-privileged UDR, however, the user who executes a UDR (rather than the UDR owner) owns any database objects created by the UDR, unless another owner is specified for the database object within the UDR.

For example, assume that user **mike** creates this user-defined function:

```
CREATE DBA FUNCTION func2 () RETURNING INT;
  CREATE TABLE tab2 (coly INT);
  RETURN 1;
END FUNCTION;
```

If user **joan** now executes function **func2**, user **joan**, not user **mike**, is the owner of the newly created table **tab2**.

See also the section [Support for roles and user identity on page 1527](#).

## CREATE FUNCTION FROM statement

Use the CREATE FUNCTION FROM statement to access a user-defined function whose CREATE FUNCTION statement resides in a separate file.

This statement is an extension to the ANSI/ISO standard for SQL. Use this statement with ESQL/C.

### Syntax

#### CREATE FUNCTION FROMIF NOT EXISTS

'file' *file\_var*

| Element         | Description   | Restrictions   | Syntax                                  |
|-----------------|---|--|---|
| <i>file</i>     | Path and filename of a file that contains the full CREATE FUNCTION statement text. Default pathname is current directory. | Must exist and contain exactly one CREATE FUNCTION statement | Must conform to operating-system rules. |
| <i>file_var</i> | Variable storing value of <i>file</i>   | Same as for <i>file</i>                                      | Language specific                       |

### Usage

Functions written in the C or Java™ language are called *external* functions. When the IFX\_EXTEND\_ROLE configuration parameter is set to ON, only users who have been granted the built-in EXTEND role can create external functions.

Informix® ESQL/C programs cannot directly create user-defined functions. That is, they cannot contain the CREATE FUNCTION statement.

To create these functions within Informix® ESQL/C programs:

1. Create a source file with the CREATE FUNCTION statement.
2. Use the CREATE FUNCTION FROM statement to send the contents of this source file to the database server for execution.

The file that you specify in the *file* parameter can contain only one CREATE FUNCTION statement.

For example, suppose that the following CREATE FUNCTION statement is in a separate file, called **del\_ord.sql**:

```
CREATE FUNCTION delete_order( p_order_num INT) RETURNING INT, INT;
  DEFINE item_count INT;
  SELECT count(*) INTO item_count FROM items
    WHERE order_num = p_order_num;
  DELETE FROM orders WHERE order_num = p_order_num;
  RETURN p_order_num, item_count;
END FUNCTION;
```

In the Informix® ESQL/C program, you can access the **delete\_order()** SPL function with the following CREATE FUNCTION FROM statement:

```
EXEC SQL create function from 'del_ord.sql';
```

If you are not sure whether the UDR in the file is a user-defined function or a user-defined procedure, use the CREATE ROUTINE FROM statement.

The filename that you provide is relative. If you provide a simple filename with no pathname (as in the preceding example), the client application looks for the file in the current directory.

**Important:** The Informix® ESQL/C preprocessor does not process the contents of the file that you specify. It only sends the contents to the database server for execution. Therefore, there is no syntactic check that the file that you specify in CREATE FUNCTION FROM actually contains a CREATE FUNCTION statement. To improve readability of the code, however, it is recommended that you match these two statements.

## CREATE INDEX statement

Use the CREATE INDEX statement to create an index for one or more columns in a table, or on values returned by a UDR that uses column values as arguments.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### CREATE

Index-Type Options<sup>116</sup>

**INDEXIF NOT EXISTS***index*

#### ON

*table synonym*

Index-Key Specs<sup>117</sup>

Index Options

Index Options

USING Access-Method Clause<sup>118</sup>

120. See [Storage options on page 271](#)

121. See [Index modes on page 277](#)

122. See [COMPRESSED option for indexes on page 271](#)

123. See [Extent Size Options on page 272](#)

124. See [HASH ON clause on page 268](#)

125. See [The ONLINE keyword of CREATE INDEX on page 279](#)

| Element | Description | Restrictions   | Syntax |
|---------|-------------|--|--------|
|         |             |  <b>Note:</b> BTS index on temp table is not supported. |        |

## Usage

When you issue the CREATE INDEX statement, the table is locked in exclusive mode. If another process is using the table, CREATE INDEX returns an error. (For an exception, however, see [The ONLINE keyword of CREATE INDEX on page 279.](#))

If the index is on a column that stores encrypted data, the database server cannot use the index.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an index of the specified name is already defined on the specified table in the current database.

Indexes use the collation that was in effect when CREATE INDEX executed.

A *secondary-access method* (sometimes referred to as an *index-access method*) is a set of database server functions that build, access, and manipulate an index structure such as a B-tree, R-tree, or an index structure that a DataBlade® module provides, in order to speed up the retrieval of data.

Neither *synonym* nor *table* can refer to a virtual table or to a table object that the CREATE EXTERNAL TABLE statement defined.

You cannot directly base a functional index on a built-in function, but you can create an SPL wrapper that calls and returns a value from a built-in function. The arguments to a user-defined function that defines a functional index cannot be the values from a column of a collection data type.

The following statistics are generated automatically by the CREATE INDEX statement, with or without the ONLINE keyword:

- Index-level statistics, equivalent to the statistics gathered in the UPDATE STATISTICS operation in LOW mode for B-tree indexes.
- Column-distribution statistics, equivalent to the distribution generated in the UPDATE STATISTICS operation in HIGH mode, for a non-opaque leading indexed column of an ordinary B-tree index.

---

## Index-type options

Use the **DISTINCT** or **UNIQUE** and **CLUSTER** options of the **CREATE INDEX** statement to specify the characteristics of the index.

### Index-Type Options

#### **DISTINCT UNIQUE**

#### **CLUSTER**

##### **DISTINCT**

Specifies that the columns on which the index is based accept only unique data.

##### **UNIQUE**

Specifies that the columns on which the index is based accept only unique data.

##### **CLUSTER**

Reorders the rows of the table in the order that the index designates.

### **UNIQUE or DISTINCT option usage**

If you do not specify the **UNIQUE** or **DISTINCT** keyword, the index allows duplicate values in the indexed column or in the set of indexed columns.

A column with a unique index can have, at most, one **NULL** value.

You cannot specify an R-tree secondary-access method for a **UNIQUE** index key.

The following example creates a unique index that prevents duplicate values in the **customer\_num** column:

```
CREATE UNIQUE INDEX c_num_ix ON customer (customer_num);
```

The **DISTINCT** and **UNIQUE** keywords are synonyms, so the following statement has the same effect as the previous example:

```
CREATE DISTINCT INDEX c_num_ix ON customer (customer_num);
```

The index in both examples is maintained in ascending order, which is the default order. The next example defines a unique descending index called **c\_num\_desc\_ix** on the same column:

```
CREATE UNIQUE INDEX c_num_desc_ix ON customer (customer_num DESC);
```

You can also prevent duplicate values in a column or in a set of columns by creating a unique constraint with the **CREATE TABLE** or **ALTER TABLE** statement and the **ADD CONSTRAINT** clause.

In an **NLSCASE INSENSITIVE** database, indexes on columns of the **NCHAR** and **NVARCHAR** data types disregard lettercase differences, so that the database server treats case variants among strings composed of the same sequence of letters as duplicate values. You cannot insert or update a row of table with an **NCHAR** or **NVARCHAR** column on which a unique

index or a unique constraint is defined, if that column value in the new row differs only by letter case from the value in the same column of any existing row of the same table. For more information about databases with the NLSCASE INSENSITIVE property, see [Duplicate rows in NLSCASE INSENSITIVE databases on page 779](#) and [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

### CLUSTER option usage

You cannot specify the CLUSTER option and the ONLINE keyword in the same statement. In addition, some secondary-access methods (such as R-tree) do not support clustering. Before you specify CLUSTER for your index, be sure that the index uses an access method that supports clustering.

The CREATE CLUSTER INDEX statement fails if a CLUSTER index already exists on the same table.

```
CREATE CLUSTER INDEX c_clust_ix ON customer (zipcode);
```

This statement creates an index on the **customer** table and physically orders the rows according to their postal code values, in (by default) ascending order.

If the CLUSTER option is specified and fragments exist on the data, values are clustered only within each fragment, and not globally across the entire table.

If the CREATE CLUSTER INDEX statement also includes the COMPRESSED keyword as a storage option, the database server issues error -26950. To create a cluster index that supports compression requires two steps:

- Use the CREATE CLUSTER INDEX statement to define a cluster index with no index compression.
- Call the SQL administration API **task()** or **admin()** function with the `'index compress'` argument to compress the existing cluster index.

You cannot use the CLUSTER option on a forest of trees index.

---

#### Related information

[Differences Between a Unique Constraint and a Unique Index on page 356](#)

## How indexes affect primary-key, unique, and referential constraints

The database server creates internal B-tree indexes for primary-key, unique, and referential constraints. If a primary-key, unique, or referential constraint is added after the table is created, any user-created indexes on the constrained columns are used, if appropriate.

An appropriate index is one that indexes the same columns that are used in the primary-key, referential, or unique constraint.

If an appropriate user-created index is not available, the database server creates a nonfragmented internal index on the constrained column or columns.

## Index-key specification

Use the Index-key specification of the CREATE INDEX statement to define the key value for the index. This can also specify the ascending or descending sort order, and the operator class.

This is the syntax of the Index-Key Specification:

```
Index-Key Specification
(
,
column
function (
, func_col
)
op_class
BSON column specification 126
ASC DESC
)
```

| Element         | Description  | Restrictions   | Syntax                                  |
|-----------------|--|--|---|
| <i>column</i>   | Column whose value is used as a key to this index                                  | See <a href="#">Restrictions on columns as index keys on page 261</a> .  | <a href="#">Identifier on page 1456</a> |
| <i>function</i> | User-defined function whose return value is used as a key to this index            | Must be a nonvariant function that does not return a large object data type. Cannot be a built-in algebraic, exponential, log, or hex function.                          | <a href="#">Identifier on page 1456</a> |
| <i>func_col</i> | Column whose value is an argument to <i>function</i>                               | Cannot be of a collection data type. See <a href="#">Using the return value of a function as an index key on page 261</a> .  | <a href="#">Identifier on page 1456</a> |
| <i>op_class</i> | Operator class associated with <i>column</i> or <i>function</i> for this index key | If the secondary-access method in the USING clause has no default operator class, you must specify one here. (See <a href="#">Using an Operator Class on page 266</a> .) | <a href="#">Identifier on page 1456</a> |

The index-key value can be one or more columns of built-in data types. If you specify multiple columns, the concatenation of values from the set of columns is treated as a single composite column for indexing.

The index-key value also can be one of the following:

- A column of type LVARCHAR(*size*), if *size* is smaller than 387 bytes
- One or more columns of user-defined data types
- One or more values that a user-defined function returns (referred to as a *functional index*), where the argument list of the UDF is one or more column values in the same row
- A combination of one or more column values and the return value from one or more user-defined functions.

126. See [Indexing a BSON field on page 259](#).

The 387-byte LVARCHAR size limit is for dbspaces of the default (2 kilobyte) page size, but dbspaces of larger page sizes can support larger index key sizes, as listed in the following table.

**Table 2. Maximum Index Key Size for Selected Page Sizes**

| Page Size    | Maximum Index Key Size |
|--------------|------------------------|
| 2 kilobytes  | 387 bytes              |
| 4 kilobytes  | 796 bytes              |
| 8 kilobytes  | 1,615 bytes            |
| 12 kilobytes | 2,435 bytes            |
| 16 kilobytes | 3,245 bytes            |

### Specifying the sort order

By default, the index is sorted in ascending order, from the lowest value to the highest, according to the collation order for the locale, or else to the collation order that was in effect when the index was created, if the SET COLLATION statement has specified a nondefault collation. You can use the DESC keyword to reverse the sort order, so that the index is sorted from the highest value to the lowest.

If you explicitly specify the ASC keyword in the Index-Key Specification, the index is sorted in ascending order.

### Specifying an operator class

If the secondary access method in the USING clause has no default operator class, the Index-Key Specification can specify an operator class for the index key.

If the secondary access method in the USING clause has a default operator class, the Index-Key Specification can specify an operator class to override the default operator class for the index.

## Indexing a BSON field

You can create an index on a field within a BSON column.

### Syntax

Use the following syntax in the index-key specification. See [Index-key specification on page 257](#).

BSON field specification

**BSON\_GET** *BSON\_value\_function*

( " *BSON\_column\_name* .

.

*BSON\_field\_name* *BSON\_array\_position*

")

**USING BSON**

| Element                    | Description  | Restrictions   | Syntax  |
|----------------------------|--|--|---|
| <i>BSON_array_position</i> | A positive integer that represents the position of a value in an array, starting with 0 for the first value. | Must be preceded by all ancestor field names.  |   |
| <i>BSON_column_name</i>    | A BSON column name   | Must be of type BSON.  | <a href="#">Expression on page 1193</a>         |
| <i>BSON_field_name</i>     | BSON field name  | Must be a literal BSON field name. Can be a multilevel field identifier, up to 32 levels. All ancestor field names must be included. | <a href="#">Column Expressions on page 1219</a> |
| <i>BSON_value_function</i> | A BSON value function for a specific data type, except the <code>BSON_VALUE_OBJECTID</code> function         | You cannot use the <code>BSON_VALUE_OBJECTID</code> function to create an index  | BSON processing functions                       |

You cannot create an index on a BSON column. You must create the index on a field within the BSON column.

The `BSON_GET` or `BSON` value function specifies which field to index. The `USING BSON` keywords are necessary to specify that the index is created on a BSON column.

### Example

#### Example: Create an index on a BSON field

The following statements create and populate a table that has a BSON column:

```
CREATE DATABASE testdb WITH LOG;
CREATE TABLE IF NOT EXISTS bson_table(bson_col BSON);

INSERT INTO bson_table VALUES(
  '{person:{givenname:"Jim",surname:"Flynn",age:29,cars:["dodge","olds"]}}'
  ::JSON::BSON);
```

The following statement creates an index on the **surname** field in the BSON column:

```
CREATE INDEX idx2 ON bson_table(
  BSON_GET(bson_col, "person.surname")) USING BSON;
```

## Restrictions on columns as index keys

Whether the database server accepts the Index Key specification as valid can depend on various factors, including attributes of the table, and the data types, the storage size, and the total number of index-key columns, as well as dependencies between index-key columns and constraints on the same table.

The following restrictions apply to any column or column list that the Index Key Specification of the CREATE INDEX statement references:

- All the columns must exist in the table on which the index is defined.
- The table must exist in the current database, and cannot be an object that the CREATE EXTERNAL TABLE statement defined.
- A column defined as an index key cannot be a complex data type (LIST, MULTISET, SET, a generic COLLECTION type, or a ROW type) or a JSON or BSON data type, with the following exceptions:
  - You can create a *functional index* on a column of a named ROW type.
  - You can create an index on a specific field of a BSON column, or create multiple indexes, each on a different field of the same BSON column. You cannot create an index on an entire BSON column.
- The maximum number of columns and the total width of all column index keys are dependent on the page size of the database server. See [Creating Composite Indexes on page 262](#).
- You cannot add an ascending index to a column list on which a unique constraint is defined. See [Using the ASC and DESC Sort-Order Options on page 263](#).
- You cannot add a unique index to a column list that has a primary-key constraint. The reason is that defining the column or column list as the primary key causes the database server to implement the constraint by creating a unique internal index on the column or column list. The CREATE INDEX statement cannot define another unique index whose key is the same column or column list.
- The number of indexes that you can define on the same list of columns is restricted. See [Restrictions on the Number of Indexes on a Set of Columns on page 265](#).

For additional index-key restrictions that apply to columns that are specified as arguments to functional indexes, see [Using the return value of a function as an index key on page 261](#).

## Using the return value of a function as an index key

A *functional index* is indexed on the value that a specified function returns from a column-value argument, rather than on the value of a column.

For example, the following statement creates a functional index on table **zones** using the value that the user-defined function **Area()** returns as the key:

```
CREATE INDEX zone_func_ind ON zones (Area(length,width));
```

You can create the function on which to define a functional index within an SPL routine. You can also create an index on a nonvariant user-defined function that does not return a large object.

The functional index can be a B-tree index, an R-tree index, or a user-defined secondary-access method.

The value returned by the function can be the index key, as in the example above, or it can be part of a composite index whose other key parts are the values of columns, the values of partial columns, or the return values of other functional indexes. (For more information, see the topic [Creating Composite Indexes on page 262](#)).

**Important:** The database server imposes the following restrictions on the user-defined routines (UDRs) on which a functional index is defined:

- The arguments cannot be the names of column of a collection data type (LIST, MULTISSET, or SET).
- The function cannot return a large object of the data types BLOB, BYTE, CLOB, and TEXT.
- The function cannot be a VARIANT function.
- The function cannot include any DML statement of SQL.
- The ONLINE keyword is not valid when you create a functional index; see [The ONLINE keyword of CREATE INDEX on page 279](#).
- The function must be a user-defined function, or, to create an index on a field in a BSON column, the BSON\_GET function or a BSON value function. You cannot create a functional index on any other built-in function of SQL.

Despite the last restriction above, however, you can create a functional index on a user-defined function that calls a non-variant built-in SQL function, so that the value returned by the built-in function is the index key of a functional index. (That is, create an SPL wrapper that calls and returns the value from a built-in function of SQL, and then define a functional index on this user-defined SPL function.)

## Creating Composite Indexes

A *simple* index lists only one *column* (or only one *function*, whose argument list must be a list of one or more columns) in its Index Key Specification. Any other index is a *composite* index. You should list the columns in a composite index in the order from most frequently used to least frequently used.

If you use SET COLLATION to specify the collating order of a nondefault locale, you can create multiple indexes on the same set of columns, using different collations. (Such indexes are useful only on NCHAR or NVARCHAR columns.)

The following example creates a composite index using the **stock\_num** and **manu\_code** columns of the **stock** table:

```
CREATE UNIQUE INDEX st_man_ix ON stock (stock_num, manu_code);
```

The UNIQUE keyword prevents any duplicates of a given combination of **stock\_num** and **manu\_code**. The index is in ascending order by default.

You can include up to 16 columns in a composite index. The total width of all indexed columns in a single composite index cannot exceed 380 bytes.

An *index key part* is either a column in a table, or the result of a user-defined function on one or more columns. A composite index can have up to 16 key parts that are columns, or up to 341 key parts that are values returned by a UDR. This limit is language-dependent and applies to UDRs written in SPL or Java™. Functional indexes based on C language UDRs can have up to 102 key parts. A composite index can include any of the following index key parts in its index key:

- One or more columns
- One or more values that a user-defined function returns (referred to as a *functional index*).

The index key parts of a composite index can be a combination of columns and user-defined functions.

For dbspaces of the default page size of 2 kilobytes, the total width of all indexed columns in a single CREATE INDEX statement cannot exceed 387 bytes, except for functional indexes of Informix®, whose language-dependent limits are described earlier in this section. For the maximum sizes in dbspaces larger than 2 kilobytes, see [Index-key specification on page 257](#).

Whether the index is based directly on column values in the table, or on functions that take column values as arguments, the maximum size of the index key depends only on page size. The maximum index key size for functional indexes in dbspaces larger than 2 kilobytes are the same as for column indexes. The only difference between limits on column indexes and functional indexes is the number of key parts. An index based on columns can have no more than 16 key parts, but a functional index has different language-dependent limits on key parts. For a given page size, the maximum index key size is the same for both column-based and functional indexes.

## Using the ASC and DESC Sort-Order Options

The ASC option specifies an index maintained in ascending order; this is the default order. The DESC option can specify an index that is maintained in descending order. These ASC and DESC options are valid with B-trees only.

## Effects of Unique Constraints on Sort Order Options

When a column or list of columns is defined as unique in a CREATE TABLE or ALTER TABLE statement, the database server implements that UNIQUE CONSTRAINT by creating a unique ascending index. Thus, you cannot use the CREATE INDEX statement to add an ascending index to a column or column list that is already defined as unique.

However, you can create a descending index on such columns, and you can include such columns in composite ascending indexes in different combinations. For example, the following sequence of statements is valid:

```
CREATE TABLE customer (
  customer_num SERIAL(101) UNIQUE,
  fname          CHAR(15),
  lname          CHAR(15),
  company        CHAR(20),
  address1       CHAR(20),
  address2       CHAR(20),
  city           CHAR(15),
  state          CHAR(2),
  zipcode        CHAR(5),
  phone         CHAR(18)
);

CREATE INDEX c_temp1 ON customer (customer_num DESC);
CREATE INDEX c_temp2 ON customer (customer_num, zipcode);
```

In this example, the **customer\_num** column has a unique constraint placed on it. The first CREATE INDEX statement places an index sorted in descending order on the **customer\_num** column. The second CREATE INDEX includes the **customer\_num** column as part of a composite index. For more information on composite indexes, see [Creating Composite Indexes on page 262](#).

## Bidirectional Traversal of Indexes

If you do not specify the ASC or DESC keywords when you create an index on a single column, key values are stored in ascending order by default; but the bidirectional-traversal capability of the database server lets you create just one index on a column and use that index for queries that specify sorting of results in either ascending or descending order of the sort column.

Because of this capability, it does not matter whether you create a single-column index as an ascending or descending index. Whichever storage order you choose for an index, the database server can traverse that index in ascending or descending order when it processes queries.

If you create a composite index on a table, however, the ASC and DESC keywords might be required. For example, if you want to enter a SELECT statement whose ORDER BY clause sorts on multiple columns and sorts each column in a different order, and you want to use an index for this query, you need to create a composite index that corresponds to the ORDER BY columns. For example, suppose that you want to enter the following query:

```
SELECT stock_num, manu_code, description, unit_price
FROM stock ORDER BY manu_code ASC, unit_price DESC;
```

This query sorts first in ascending order by the value of the **manu\_code** column and then in descending order by the value of the **unit\_price** column. To use an index for this query, you need to issue a CREATE INDEX statement that corresponds to the requirements of the ORDER BY clause. For example, you can enter either of the following statements to create the index:

```
CREATE INDEX stock_idx1 ON stock
  (manu_code ASC, unit_price DESC);
CREATE INDEX stock_idx2 ON stock
  (manu_code DESC, unit_price ASC);
```

The composite index that was used for this query (**stock\_idx1** or **stock\_idx2**) cannot be used for queries in which you specify the same sort direction for the two columns in the ORDER BY clause. For example, suppose that you want to enter the following queries:

```
SELECT stock_num, manu_code, description, unit_price
  FROM stock ORDER BY manu_code ASC, unit_price ASC;
SELECT stock_num, manu_code, description, unit_price
  FROM stock ORDER BY manu_code DESC, unit_price DESC;
```

If you want to use a composite index to improve the performance of these queries, you need to enter one of the following CREATE INDEX statements. You can use either one of the created indexes (**stock\_idx3** or **stock\_idx4**) to improve the performance of the preceding queries.

```
CREATE INDEX stock_idx3 ON stock
  (manu_code ASC, unit_price ASC);
CREATE INDEX stock_idx4 ON stock
  (manu_code DESC, unit_price DESC);
```

You can create no more than one ascending index and one descending index on a column. Because of the bidirectional-traversal capability of the database server, you only need to create one of the indexes. Creating both would achieve exactly the same results for an ascending or descending sort on the **stock\_num** column.

After INSERT or DELETE operations are performed on an indexed table, the number of index entries can vary within a page, and the number of index pages that a table requires can depend on whether the index specifies ascending or descending order. For some load and DML operations, a descending single-column or multi-column index might cause the database server to allocate more index pages than an ascending index requires.

## Restrictions on the Number of Indexes on a Set of Columns

You can create multiple indexes on a set of columns, provided that each index has a unique combination of ascending and descending columns. For example, to create all possible indexes on the **stock\_num** and **manu\_code** columns of the **stock** table, you could create four indexes:

- The **ix1** index on both columns in ascending order
- The **ix2** index on both columns in descending order
- The **ix3** index on **stock\_num** in ascending order and on **manu\_code** in descending order
- The **ix4** index on **stock\_num** in descending order and on **manu\_code** in ascending order

Because of the bidirectional-traversal capability of the database server, you do not need to create these four indexes. You only need to create two indexes:

- The **ix1** and **ix2** indexes achieve the same results for sorts in which the user specifies the same sort direction (ascending or descending) for both columns, so you only need one index of this pair.
- The **ix3** and **ix4** indexes achieve the same results for sorts in which the user specifies different sort directions for the two columns (ascending on the first column and descending on the second column or vice versa). Thus, you only need to create one index of this pair. (See also [Bidirectional Traversal of Indexes on page 264.](#))

Informix® can also support multiple indexes on the same combination of ascending and descending columns, if each index has a different collating order; see [SET COLLATION statement on page 862.](#)

## Using an Operator Class

An *operator class* is the set of operators associated with a secondary-access method for query optimization and building the index. You must specify an operator class when you create an index if either one of the following is true:

- No default operator class for the secondary-access method exists. (A user-defined access method can provide no default operator class.)
- You want to use an operator class that is different from the default operator class that the secondary-access method provides.

If you use an alternative access method, and if the access method has a default operator class, you can omit the operator class here; but if you do not specify an operator class and the secondary-access method does not have a default operator class, the database server returns an error. For more information, see [Default Operator Classes on page 290.](#) The following CREATE INDEX statement creates a B-tree index on the **cust\_tab** table that uses the **abs\_btree\_ops** operator class for the **cust\_num** key:

```
CREATE INDEX c_num1_ix ON cust_tab (cust_num abs_btree_ops);
```

## USING access-method clause

The USING clause specifies the secondary-access method for the new index.

USING Access-Method Clause

**USING***sec\_acc\_method*

```
(
,parameter = value
)
```

| Element          | Description                                      | Restrictions   | Syntax                                     |
|------------------|--|--|--|
| <i>parameter</i> | Secondary-access-method parameter for this index | See the user documentation for your user-defined access method | <a href="#">Quoted String on page 1424</a> |

| Element                     | Description                             | Restrictions   | Syntax  |
|-----------------------------|---|--|---|
| <code>sec_acc_method</code> | Secondary-access method for this index  | Method can be a B-tree, R-tree, BTS, or user-defined access method, such as one that a DataBlade® module defines | <a href="#">Identifier on page 1456</a>   |
| <code>value</code>          | Value of the specified <i>parameter</i> | Must be a valid literal value for <i>parameter</i> in this secondary-access method                               | <a href="#">Quoted String on page 1424</a> or <a href="#">Literal Number on page 1419</a> |

A *secondary-access method* is a set of routines that perform all of the operations that are needed for an index, such as create, drop, insert, delete, update, and scan.

The database server provides the following secondary-access methods:

- The generic B-tree index is the built-in secondary-access method.

A B-tree index is good for a query that retrieves a range of data values. The database server implements this secondary-access method and registers it as **btree** in the system catalog tables.

- The R-tree method is a registered secondary-access method.

An R-tree index is good for searches on multidimensional data. The database server registers this secondary-access method as **rtree** in the system catalog tables of a database. An R-tree secondary-access method is not valid for a UNIQUE index key. An R-tree index cannot be clustered. An R-tree index can be stored in a dbspace with a non-default page size. For more information about R-tree indexes, see the *Informix® R-Tree Index User's Guide*.

- The **bts** method is a registered secondary-access method.

Use the **bts** access method to perform basic text searching for words and phrases in a document repository that is stored in a column of a table. To perform basic text searches, you create an index using the **bts** access method on a text column and then use the `bts_contains()` search predicate function and other management functions. For more information about the **bts** access method, see [bts access method syntax on page](#) .

The access method that you specify must be registered in the **sysams** system catalog table. The default secondary-access method is B-tree.

If the access method is B-tree, you can create only one index for each unique combination of ascending and descending columnar or functional keys with operator classes. (This restriction does not apply to other secondary-access methods.) By default, CREATE INDEX creates a generic B-tree index. If you want to create an index with a secondary-access method other than B-tree, you must specify the name of the secondary-access method in the USING clause.

Some user-defined access methods are packaged as DataBlade® modules. Some DataBlade® modules provide indexes that require specific parameters when you create them. For more information about user-defined access methods, refer to the documentation of your secondary access-method or DataBlade® module.

The following example (for a database that implements R-tree indexes) creates an R-tree index on the **location** column that contains an opaque data type, **point**, and performs a query with a filter on the **location** column.

```
CREATE INDEX loc_ix ON TABLE emp (location) USING rtree;
SELECT name FROM emp WHERE location N_equator_equals point('500, 0');
```

The following CREATE INDEX statement creates an index that uses the **fulltext** secondary-access method, which takes two parameters: WORD\_SUPPORT and PHRASE\_SUPPORT. It indexes a table **t**, which has two columns: **i**, an integer column, and **data**, a TEXT column.

```
CREATE INDEX tx ON t(data)
  USING fulltext (WORD_SUPPORT='PATTERN',
  PHRASE_SUPPORT='MAXIMUM');
```

## HASH ON clause

Use the HASH ON clause of the CREATE INDEX statement to specify the columns and number of subtrees (buckets) for a forest of trees index.

HASH ON clause

```
HASH ON(
, column
)WITHnumberBUCKETS
```

| Element       | Description   | Restrictions   | Syntax  |
|---------------|---|--|---|
| <i>column</i> | The name of the column or columns on which you use the HASH ON clause to create a forest of trees index | The list must be a prefix list of the index columns used in the CREATE INDEX statement                                 | <a href="#">Identifier on page 1456</a>       |
| <i>number</i> | The number of subtrees (buckets) to create for a forest of trees index                                  | The number of buckets for a forest of trees index must range from 2 to the number of available index pages per dbspace | <a href="#">Integer Literals on page 1420</a> |

## Usage

Forest of trees indexes are detached indexes. They cannot be attached indexes.

You can create forest of trees indexes on columns with base data types.

You cannot:

- Create forest of trees indexes on columns with complex data types, UDTs, or functional columns.
- Use the FILLFACTOR option of the CREATE INDEX statement when you create forest of trees indexes, because the indexes are built from top to bottom.
- Create clustered forest of trees indexes.
- Run the ALTER INDEX statement on forest of trees indexes.
- Use forest of trees indexes in queries that use aggregates, including minimum and maximum range values
- Perform range scans directly on the HASH ON columns of a forest of trees index.

However, you can perform range scans on columns that are not listed in the HASH ON column list. For range scans on columns listed in HASH ON column list, you must create an additional B-tree index that contains the appropriate column list for the range scan. This additional B-tree index might have the same column list as the forest of trees index, plus or minus a column.

- Use a forest of trees index for an OR index path. The database server does not use forest of trees indexes for queries that have an OR predicate on the indexed columns.

When you create a forest of trees index, choose enough columns to create unique values.

**Tip:** Generally, the columns to choose depend on the number of duplicates for each column. For example, if the first column contains a small number of duplicates, the first two columns are sufficient for hashing if they do not contain a large number of duplicates. If the first two columns contain a majority of duplicates, then you need to also choose a third column.

The number of subtrees depends on your goal for the index. If your goal is:

- To reduce contention, initially create a forest of trees index with 2 subtrees per CPU VP. You might need more subtrees, depending on the number of rows in the table and how many duplicates exist.
- To reduce the number of levels in the B-tree:
  1. Run the oncheck -pT command.
  2. In the output, find the number of nodes at each level.
  3. Determine how many subtrees are required to achieve the desired depth for each tree in the index.

For example, suppose an index averages 100 keys per page, the index has 1M keys, and the tree looks like this:

```
Level 1 (root) 100 keys
Level 2 10K keys
Level 3 1M keys
```

To reduce the 3-level tree to 100 2-level trees, the index needs roughly 100 subtrees. To reduce the 3-level tree to 10K 1-level trees, the index needs roughly 10K subtrees.

Forest of tree pages can be sparser than traditional B-tree pages if too many or too few subtrees are used. When the pages are sparser, more pages occupy the buffer pool, and therefore, cause other tables to become less cached.

## Examples

The following command creates a forest of trees index named `idx1` with 100 subtrees on column `c1`:

```
CREATE INDEX idx1 ON tab1(c1) HASH ON (c1) with 100 buckets;
```

The following command creates a forest of trees index named `idx2`. In the command, the prefix list for the HASH ON portion of the statement is `c1` and `c2`, which is a prefix list of the `c1`, `c2`, and `c3` columns used in the CREATE INDEX portion of the statement.

```
CREATE INDEX idx2 on tab2(c1, c2, c3) HASH ON (c1, c2) with 10 buckets;
```

The following command creates a forest of trees index for equality lookups on columns `c1` and `c2`:

```
CREATE INDEX idx3 on tab3(c1, c2) HASH ON (c1, c2) with 100 buckets;
```

The following command creates a B-tree index that is similar to the previous forest of trees index. This index is for range scans on columns `c1` and `c2`:

```
CREATE INDEX idx4 on tab4(c1, c2, c3);
```

## FILLFACTOR Option

Use the FILLFACTOR option to specify the degree of index-page fullness when you want to create compacted indexes or provide information for the expansion of an index at a later date.

The FILLFACTOR option takes effect only in the following cases:

- when you build an index on a table that contains more than 5,000 rows and that uses more than 100 table pages
- when you create an index on a fragmented table
- when you create a fragmented index on a nonfragmented table.

You cannot use the FILLFACTOR option on a forest of trees index.

FILLFACTOR Option

**FILLFACTOR***percent*

| Element        | Description  | Restrictions                      | Syntax                                      |
|----------------|--|-----------------------------------|---|
| <i>percent</i> | Percentage of each index page that is filled by index data when the index is created. The default is <code>90</code> . | 1 <i>percent</i> <code>100</code> | <a href="#">Literal Number on page 1419</a> |

When the index is created, the database server initially fills only that percentage of the nodes specified with the FILLFACTOR value.

The FILLFACTOR can also be set as a parameter in the ONCONFIG file. The FILLFACTOR clause on the CREATE INDEX statement overrides the setting in the ONCONFIG file. For more information about the ONCONFIG file and the parameters you can use, see your *Informix® Administrator's Guide*.

## Providing a Low Percentage Value

If you provide a low percentage value, such as `50`, you allow room for growth in your index. The nodes of the index initially fill to a certain percentage and contain space for inserts. The amount of available space depends on the number of keys in each page as well as the percentage value.

For example, with a 50-percent FILLFACTOR value, the page would be half full and could accommodate doubling in size. A low percentage value can result in faster inserts and can be used for indexes that you expect to grow.

## Providing a High Percentage Value

If you provide a high percentage value, such as `99`, indexes are compacted, and any new index inserts result in splitting nodes. The maximum density is 100 percent. With a 100-percent FILLFACTOR value, the index has no room available for growth; any addition to the index results in splitting the nodes.

A 99-percent FILLFACTOR value allows room for at least one insertion per node. A high percentage value can result in faster queries and is appropriate for indexes that you do not expect to grow, or for mostly read-only indexes.

## Storage options

The storage options specify the distribution scheme of an index. You can use the IN clause to specify a storage space for the entire index, or you can use the FRAGMENT BY clause to fragment the index across multiple storage spaces.

### Storage Options

#### IN

*dbspace*<sup>127</sup>

*extspace*<sup>128</sup>

<sup>130</sup>**TABLE**<sup>131</sup>

FRAGMENT BY Clause for Indexes<sup>129</sup>

| Element         | Description   | Restrictions | Syntax  |
|-----------------|---|--------------|---|
| <i>dbspace</i>  | The dbspace in which to store the index   | Must exist   | <a href="#">Identifier on page 1456</a>       |
| <i>extspace</i> | Name assigned by the onspaces command to a storage area outside the database server | Must exist   | See the documentation for your access method. |

If you specify any storage option (except IN TABLE), you create a *detached index*. Detached indexes are indexes that are created with a specified distribution scheme. Even if the distribution scheme specified for the index is identical to that specified for the table, the index is still considered to be detached. If the distribution scheme of a table changes, all detached indexes continue to use the distribution scheme that the Storage Option clause specified.

If you do not include the Storage Option clause, by default an attached index is created in the same dbspaces as the corresponding table fragments. However, if automatic location is enabled, an index created on a round-robin table is detached by default in a single fragment, located in a dbspace chosen by the server. You enable automatic location by setting the AUTOLOCATE configuration parameter or session environment option to a positive integer.

#### Important:

When you are defining an index on a table that was created with AUTOLOCATE enabled, if a round-robin storage distribution scheme was automatically defined for the table, you cannot use the IN TABLE keywords to specify nonfragmented storage for the index. That storage option is valid only for B-tree indexes on nonfragmented tables.

127. See [Storing an Index in a dbspace on page 273](#)

128. See [Storing Data in an extspace on page 274](#)

129. See [FRAGMENT BY Clause for Indexes on page 275](#)

130. B-tree indexes on nonfragmented tables only

131. See [Creating an Index with the IN TABLE Keywords on page 274](#)

## COMPRESSED option for indexes

Use the COMPRESSED keyword of the CREATE INDEX statement to compress the B-tree index if the index has 2000 or more keys.

You can create a compressed index on a fragmented or non-fragmented table.

You cannot create a compressed index that is also a cluster index. However, you can compress an existing cluster index by running an SQL administration API `task()` or `admin()` function with the **index compress** argument.

To be compressed, the index or fragment within the index must have at least 2000 keys. If you use the COMPRESSED option when you create an index that does not have enough keys, the database server does not compress the index or fragment when it creates the index. The index remains uncompressed even if new keys are added to it. If you want to compress the index, run an SQL administration API `task()` or `admin()` function with the **index compress** argument.

If a table does not have enough data to provide a large enough sample of index keys, the database server does not compress the index or fragment. Even the minimum required number of new keys are added to an existing index that is not compressed, the database server does not compress the index.

However, after an index is compressed, the database server compresses and inserts any new key added to the index.

The following example creates a compressed index named **cust3\_ix** on the address column of the customer table.

```
CREATE INDEX cust3_ix ON customer (address) COMPRESSED
EXTENT SIZE 32 NEXT SIZE 32;
```

The following example creates a unique, compressed index:

```
CREATE UNIQUE INDEX cust3_ix ON customer (address) COMPRESSED ;
```

## Extent Size Options

The Extent Size options can define the size of storage extents allocated to the index.

Extent Size Options

**EXTENT SIZE***first\_kilobytes*

**NEXT SIZE***next\_kilobytes*

| Element                | Description   | Restrictions   | Syntax                                  |
|------------------------|---|--|---|
| <i>first_kilobytes</i> | Length in kilobytes of the first extent for the index | Must return a positive number; maximum is the chunk size, in kilobytes | <a href="#">Expression on page 1193</a> |
| <i>next_kilobytes</i>  | Length in kilobytes of each subsequent extent         | Same as for <i>first_kilobytes</i>                                     | <a href="#">Expression on page 1193</a> |

The minimum length of *first\_kilobytes* (and of *next\_kilobytes*) is four times the disk-page size on your system. For example, if you have a 2-kilobyte page system, the minimum length is 8 kilobytes.

If you need to revise the extent sizes of an index, you can modify the extent and next-extent sizes in the generated schema files of an unloaded table. For example, to make a database more efficient, you might drop an index, modify the extent sizes in the schema files, and then create a new index. For information about how to optimize extents, see your *Informix® Administrator's Guide*.

Only extent size values that you explicitly assign as extent sizes for the new index are stored in the system catalog. The value that you specify in the EXTENT SIZE option to the CREATE INDEX statement is stored in the **fectsize** column of the **sysindices** system catalog table, and the value that you specify in the NEXT SIZE option is stored in the **nextsize** column of the same table. If you omit these options, however, the database server stores a value of zero (0) in those system catalog columns, rather than the default value that it calculates and allocates for the first extent or the next extent of the index.

### Example of an index defined with explicit extent sizes

The following program fragment creates a new table and defines two nonfragmented indexes on the table.

```
CREATE TABLE IF NOT EXISTS t (a INT, b INT);
CREATE INDEX IF NOT EXISTS idx1 ON t(a) EXTENT SIZE 32 NEXT SIZE 32;
CREATE INDEX IF NOT EXISTS idx2 ON t(b);
```

Here the definition of **idx1** specifies 32 kilobytes as explicit extent sizes. The second index, **idx2**, has default extent sizes that the system calculates. The two CREATE INDEX statements produce system catalog descriptions of these indexes that include these extent size entries:

- The **sysindices.fextent** and **sysindices.nextent** column values are each 32 for **idx1**.
- The **sysindices.fextent** and **sysindices.nextent** column values are each 0 for **idx2**.

Here the 0 values for **idx2** indicate that no explicit extent sizes were specified (rather than indicating that no storage space was allocated).

## IN Clause

Use the IN clause to specify a storage space to hold the entire index. The storage space that you specify must already exist.

### Storing an Index in a dbspace

Use the IN *dbspace* clause to specify the dbspace where you want your index to reside. When you use this clause with any option except the TABLE keyword, you create a detached index.

The IN *dbspace* clause allows you to isolate an index. For example, if the **customer** table is created in the **custdata** dbspace, but you want to create an index in a separate dbspace called **custind**, use the following statements:

```
CREATE TABLE customer
. . .
IN custdata EXTENT SIZE 16;

CREATE INDEX idx_cust ON customer (customer_num) IN custind;
```

### Storing an Index Fragment in a Named Partition

Besides the option of storing a fragment of the index in a dbspace, Informix® supports storing named fragments of the index in one or more dbspaces. Unless you explicitly declare names for the fragments in the PARTITION BY or FRAGMENT BY

clause, each fragment, by default, has the same name as the dbspace where it resides. This includes all fragmented tables and indexes migrated from earlier releases of Informix®.

## Storing Data in an extspace

In general, use the *extspace* storage option in conjunction with the [USING access-method clause on page 266](#). For more information, refer to the user documentation for your custom-access method.

## Creating an Index with the IN TABLE Keywords

Specifying IN TABLE as the storage option creates an index where both the index and the data pages for its table are stored together in the same extents, and the dbspace distribution scheme for the index is the same as that of the table on which it was built.

Using IN TABLE as the storage option specifies the same storage design for non-fragmented B-tree indexes as enabling the **DEFAULT\_ATTACH** environment variable, but both **DEFAULT\_ATTACH** and the IN TABLE keywords are deprecated features.

The name of the **DEFAULT\_ATTACH** environment variable preserves an obsolete definition of the term *attached index*. In current Informix® nomenclature, this term now designates an index whose data pages are stored in separate tablespaces and separate extents from the data pages of the table, but the index and its table share the same dbspace distribution scheme. For more information, see the description of **DEFAULT\_ATTACH** in the *Informix® Guide to SQL: Reference*.

The following restrictions apply to the IN TABLE keywords as an index storage option:

- If the table on which you define the index is a fragmented table, Informix® issues errors -212 and -130 if you specify the IN TABLE option.
- You cannot apply the IN TABLE storage option to forest of trees indexes.
- This option does not support extensibility-related indexes, such as R-tree indexes, functional indexes, or indexes that DataBlade® modules provide.
- You cannot specify this storage option for any index that uses a collating order different from that of its table, nor different from what the **DB\_LOCALE** setting specifies. For more information about the **DB\_LOCALE** environment variable, see the *Informix® Guide to SQL: Reference*.
- You cannot apply the IN TABLE storage option to indexes on tables implicitly fragmented by the AUTOLOCATE configuration parameter or by the SET ENVIRONMENT AUTOLOCATE session environment option.

For example, suppose that automatic location is enabled for the current session when the following DDL statements are issued:

```
CREATE TABLE tab_autoloc (col1 INT);
CREATE INDEX ind_intab ON tab_autoloc (col1) IN TABLE;
```

Although no explicit storage option is specified for the **tab\_autoloc** table, it has an implicit round-robin storage distribution, based on the AUTOLOCATE setting. Consequently, the CREATE INDEX statement fails, and no **ind\_intab** index is registered in the system catalog, because in-table indexes cannot be created on fragmented tables.

 **Restriction:** When you are defining an index on a table that was created with AUTOLOCATE enabled, if a round-robin storage distribution scheme was automatically defined for the table, you cannot use the IN TABLE keywords to specify nonfragmented storage for the index. That storage option is valid only for B-tree indexes on nonfragmented tables.

does not recommend use in new applications of the IN TABLE storage option, nor of the **DEFAULT\_ATTACH** environment variable. Such indexes are a deprecated feature that might not be supported in some future release of Informix®.

## FRAGMENT BY Clause for Indexes

Use the FRAGMENT BY clause to create a detached index and to define its fragmentation strategy across dbspaces or partitions.

This closely resembles the syntax of the FRAGMENT BY clause for tables, but the ROUND ROBIN keywords are not supported for index fragmentation. The PARTITION BY keywords are a synonym for the FRAGMENT BY keywords in this context.

FRAGMENT BY Clause for Indexes

**FRAGMENT**

**PARTITION**

**BY**

**EXPRESSION** Expression Fragment Clause<sup>134</sup>

**RANGE**(*fragment\_key*)

Interval Fragment Clause<sup>132</sup>

**LIST**(*fragment\_key*) List Fragment Clause<sup>133</sup>

| Element             | Description   | Restrictions  | Syntax                                  |
|---------------------|---|---|---|
| <i>dbspace</i>      | The <i>dbspace</i> to store the index fragment  | You can specify no more than 2,048 <i>dbspaces</i> . All <i>dbspaces</i> that store the fragments must have the same page size. | <a href="#">Identifier on page 1456</a> |
| <i>fragment_key</i> | Cast, column, or function expressions on an index column.<br>Index is fragmented on the value of this expression. | Columns must be from the current table only.  | <a href="#">Expression on page 1193</a> |

Here the IN keyword introduces the name of a storage space where an index fragment is to be stored. If you list multiple *dbspace* names after the IN keyword, use parentheses to delimit the *dbspace* list. All *dbspaces* that store the fragments must have the same page size. The parentheses around the list of fragment definitions that follow the EXPRESSION keyword are optional.

132. See

133. See [List fragment clause on page 388](#)

134. See [Expression Fragment Clause on page 385](#)

For indexes that use the same RANGE interval or LIST fragmentation strategy as their table, each fragment name that you declare after the PARTITION keyword must be the same as the identifier of the corresponding table fragment.

For attached indexes that are fragmented by a RANGE interval fragmentation strategy, if no existing table fragment is in the range of a new inserted row, the database server creates a new table fragment to store the new row, and declares a system-generated name for the new table fragment. If the table is indexed, and the index is fragmented by the same RANGE interval strategy as its table, the database server also creates a new index fragment. In this case, the index fragment has the same system-generated identifier as the corresponding table fragment. For more information about system-generated RANGE interval fragments, see .

## Storing an Index Fragment in a Named Partition

Besides the option of storing a fragment of the index in a dbspace, Informix® supports storing named fragments of the index in one or more dbspaces. Unless you explicitly declare names for the fragments in the PARTITION BY or FRAGMENT BY clause, each fragment, by default, has the same name as the dbspace where it resides. This includes all fragmented tables and indexes migrated from earlier releases of Informix®.

## Restrictions on fragmentation expressions

The following restrictions apply to the expression:

- Each fragment expression can contain columns only from the current table, with data values only from a single row.
- The expression must return a BOOLEAN (true or false) value.
- No subqueries, aggregates, user-defined routines, nor references to fields of a ROW type column or sequence objects are valid.
- The built-in CURRENT, SYSDATE, TODAY, SITENAME, DBSERVERNAME, CURRENT\_USER, or USER functions are not valid.
- The DEFAULT\_ROLE and CURRENT\_ROLE operators are not valid.

The restrictions listed above also apply to indexes that use a LIST fragmentation strategy.

## Fragmentation of System Indexes

System indexes (such as those that implement referential constraints and unique constraints) utilize user-defined indexes if they exist. If no user-defined indexes can be utilized, system indexes remain nonfragmented, and are moved to the dbspace where the database was created.

To fragment a system index, create the fragmented index on the constraint columns, and then add the constraint using the ALTER TABLE statement.

## Fragmentation of Unique Indexes

You can fragment unique indexes on a table that uses a round-robin or an expression-based distribution scheme, but any columns referenced in the fragment expression must be indexed columns. If your index fragmentation strategy violates this restriction, the CREATE INDEX statement fails, and work is rolled back.

## Fragmentation of Indexes on Temporary Tables

You can fragment a unique index on a temporary table only if the underlying table uses an expression-based distribution scheme. That is, the CREATE TEMP TABLE statement that defines the temporary table must specify an explicit expression-based distribution scheme. (Fragmentation of the index by ROUND ROBIN is not supported, and fragmentation by LIST or by INTERVAL is automatic, for a unique index on a table that uses a list or interval storage partitioning strategy.)

If you try to create a fragmented, unique index on a temporary table for which you did not specify a fragmentation strategy when you created the table, the database server creates the index in the first dbspace that the **DBSPACETEMP** environment variable specifies. For more information on the **DBSPACETEMP** environment variable, see the *Informix® Guide to SQL: Reference*.

For more information on the default storage characteristics of temporary tables, see [Where temporary tables are stored on page 403](#).

---

## Index modes

Use the index mode options of the CREATE INDEX statement to specify the behavior of the index during INSERT, DELETE, MERGE, and UPDATE operations.

Index Modes

**ENABLED DISABLED**

**FILTERING**

**WITHOUT ERROR WITH ERROR**

### DISABLED

The database server does not update the index after insert, delete, and update operations that modify the base table. The optimizer does not use the index during the execution of queries.

### ENABLED

The database server updates the index after insert, delete, and update operations that modify the base table. The optimizer uses the index during query execution. If an insert or update operation causes a duplicate key value to be added to a unique index, the statement fails.

### FILTERING

The database server updates a unique index after insert, delete, and update operations that modify the base table. (This option is not available with duplicate indexes.)

The optimizer uses the index during query execution. If an insert or update operation causes a duplicate key value to be added to a unique index in filtering mode, the statement continues processing, but the bad row is written to the violations table associated with the base table. Diagnostic information about the unique-index violation is written to the diagnostics table associated with the base table.

If you specify filtering for a unique index, you can also specify one of the following error options.

**WITHOUT ERROR**

A unique-index violation during an insert or update operation returns no integrity-violation error to the user.

**WITH ERROR**

Any unique-index violation during an insert or update operation returns an integrity-violation error to the user.

For information on changing the database object mode of a unique index, see [Modes for constraints and unique indexes on page 876](#).

## Specifying Modes for Unique Indexes

You must observe the following guidelines when you specify modes for unique indexes in CREATE INDEX statements:

- You can set the mode of a unique index to enabled, disabled, or filtering.
- If you do not specify a mode, then by default the index is enabled.
- For an index set to filtering mode, if you do not specify an error option, the default is WITHOUT ERROR.
- When you add a new unique index to an existing base table and specify the disabled mode for the index, your CREATE INDEX statement succeeds even if duplicate values in the indexed column would cause a unique-index violation.
- When you add a new unique index to an existing base table and specify the enabled or filtering mode for the index, your CREATE INDEX statement succeeds provided that no duplicate values exist in the indexed column that would cause a unique-index violation. However, if any duplicate values exist in the indexed column, your CREATE INDEX statement fails and returns an error.
- When you add a new unique index to an existing base table in the enabled or filtering mode, and duplicate values exist in the indexed column, erroneous rows in the base table are not filtered to the violations table. Thus, you cannot use a violations table to detect the erroneous rows in the base table.

## Adding a Unique Index When Duplicate Values Exist in the Column

If you attempt to add a unique index in the enabled mode but receive an error message because duplicate values are in the indexed column, take the following steps to add the index successfully:

1. Add the index in the disabled mode. Issue the CREATE INDEX statement again, but this time specify the DISABLED keyword.
2. Start a violations and diagnostics table for the target table with the START VIOLATIONS TABLE statement.
3. Issue a SET Database Object Mode statement to change the mode of the index to enabled. When you issue this statement, existing rows in the target table that violate the unique-index requirement are duplicated in the violations table. You receive an integrity-violation error message, however, and the index remains disabled.
4. Issue a SELECT statement on the violations table to retrieve the nonconforming rows that are duplicated from the target table. You might need to join the violations and diagnostics tables to get all the necessary information.
5. Take corrective action on the rows in the target table that violate the unique-index requirement.
6. After you fix all the nonconforming rows in the target table, issue the SET Database Object Mode statement again to switch the disabled index to the enabled mode. This time the index is enabled, and no integrity violation error message is returned because all rows in the target table now satisfy the new unique-index requirement.

## Specifying Modes for Duplicate Indexes

You must observe the following guidelines when you specify modes for duplicate indexes in CREATE INDEX statements:

- You can set a duplicate index to enabled or disabled mode. Filtering mode is available only for unique indexes.
- If you do not specify the mode of a duplicate index, by default the index is enabled.

## How the Database Server Treats Disabled Indexes

Whether a disabled index is a unique or duplicate index, the database server effectively ignores the index during data-manipulation (DML) operations.

When an index is disabled, the database server stops updating it and stops using it during queries, but the catalog information about the disabled index is retained. You cannot create a new index on a column or set of columns if a disabled index on that column or set of columns already exists. Similarly, you cannot create an active (enabled) unique, foreign-key, or primary-key constraint on a column or on a set of columns if the indexes on which the active constraint depends are disabled.

## The ONLINE keyword of CREATE INDEX

The DBA can reduce the risk of nonexclusive access errors, and can increase the availability of the indexed table, by including the ONLINE keyword as the last specification of the CREATE INDEX statement. The ONLINE keyword instructs the database server to create the index while minimizing the duration of an exclusive lock, so that the index can be created while concurrent users are accessing the table.

By default, CREATE INDEX attempts to place an exclusive lock on the indexed table to prevent all other users from accessing the table while the index is being created. The CREATE INDEX statement fails if another user already has a lock on the table, or is currently accessing the table at the Dirty Read isolation level.

The database server builds the index, even if other users are performing Dirty Read and DML operations on the indexed table. Immediately after you issue the CREATE INDEX ONLINE statement, the new index is not yet visible to the query optimizer for use in query plans or cost estimates, and the database server does not support any other DDL operations on the indexed table, until after the specified index has been built without errors. At this time, the database server briefly locks the table while updating the system catalog with information about the new index.

The indexed table in a CREATE INDEX ONLINE statement can be permanent or temporary, logged or unlogged, and fragmented or non-fragmented. You cannot specify the ONLINE keyword, however, when you are creating an index that has any of the following attributes:

- a functional index
- a clustered index
- a virtual index
- an R-tree index

- an index that is partitioned by an interval fragmentation strategy
- an index on a table that is partitioned by an interval fragmentation strategy.

In addition, if a primary key constraint is defined on the table, a CREATE INDEX ONLINE operation can generate error -710 if one or more concurrent sessions are performing DML operations on a child table that has a foreign key constraint referencing that primary key. Before the index can be created ONLINE, you must wait until all the user sessions with those child tables have completed.

The following statement instructs the database server to create a unique online index called **idx\_1** on the **lname** column of the **customer** table:

```
CREATE UNIQUE INDEX IF NOT EXISTS idx_1 ON customer(lname) ONLINE;
```

If, while this index is being constructed, other users insert into the **customer** table new rows in which **lname** is not unique, the database server issues an error after it has created the new **idx\_1** index and registered it in the system catalog.

The term *online index* refers to the locking strategy that the database follows in creating or dropping an index with the ONLINE keyword, rather than to properties of the index that persist after its creation (or its destruction) has completed. This term appears in some error messages, however, and in recovery or restore operations, the database server re-creates as an online index any index that you created as an online index.

No more than one CREATE INDEX ONLINE or DROP INDEX ONLINE statement can concurrently reference online indexes on the same table, or online indexes that have the same identifier.

For indexes defined with the IN TABLE keyword option, however, the indexed table remains locked for the duration of the CREATE INDEX ONLINE operation. While the in-table index is being created, attempted access by other sessions to the locked table would fail with these errors:

```
107: ISAM error: record is locked.
211: Cannot read system catalog (systables).
710: Table (table.tix) has been dropped, altered or renamed.
```

## Automatic Calculation of Distribution Statistics

When the CREATE INDEX statement runs successfully, with or without the ONLINE keyword, Informix® automatically gathers statistics for the newly created index, and updates the **sysdistrib** system catalog table with values that are equivalent to an UPDATE STATISTICS operation in a mode that depends on the type of index:

- Index level statistics, equivalent to the statistics gathered by UPDATE STATISTICS in the LOW mode, are calculated for most types of indexes, including B-tree, Virtual Index Interface, and functional indexes.
- Column distribution statistics, equivalent to the distribution generated in the HIGH mode, for a non-opaque leading indexed column of an ordinary B-tree index. The resolution percentage is 1.0 if the table has fewer than a million rows, and 0.5 for larger table sizes.

These distribution statistics are available to the query optimizer when it designs query plans for the table on which the new index was created.

For composite key indexes, only distributions of the leading column are created implicitly by the CREATE INDEX statement.

The implicit creation of distribution statistics is not supported for the following types of indexes:

- Indexes on columns of user-defined data types
- Indexes on columns of the built-in opaque data types (including BOOLEAN and LVARCHAR)
- R-tree indexes
- Attached indexes.

If the calculation of distribution statistics fails during the CREATE INDEX operation, the database server reports that failure in the error log, but continues to create the index.

When distributions are successfully created by an explicit or implicit CREATE INDEX operation, explain information (similar to one generated by UPDATE STATISTICS) such as following is generated if the SET EXPLAIN facility is set to ON.

```
Index:          idx_01 on nita.foo
STATISTICS CREATED AUTOMATICALLY:
Column Distribution for:          nita.foo.a
Mode:          MEDIUM
Number of Bins:    101 Bin size:  100.0
Sort data:        0.3 MB
Completed building distribution in:  0 minutes 33 seconds
```

See the description of the [UPDATE STATISTICS statement on page 1054](#) for information about distribution statistics and about the difference between LOW mode and MEDIUM mode distributions.

## CREATE OPAQUE TYPE statement

Use the CREATE OPAQUE TYPE statement to create an opaque data type.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```
CREATE OPAQUE TYPE IF NOT EXISTS type
(INTERNALLENGTH =
length VARIABLE
,
, Opaque-Type Modifier135
)
```

| Element       | Description   | Restrictions   | Syntax                                      |
|---------------|---|--|---|
| <i>length</i> | Number of bytes needed to store a value of this data type | Positive integer returned when <code>sizeof( )</code> directive is applied to the type structure | <a href="#">Literal Number on page 1419</a> |
| <i>type</i>   | Name that you declare here for the new opaque data type   | Must be unique among data type names in the database   | <a href="#">Identifier on page 1456</a>     |

135. See [Opaque-Type Modifier on page 283](#)

## Usage

The CREATE OPAQUE TYPE statement registers a new opaque data type in the **sysxdtypes** system catalog table.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an OPAQUE data type of the specified name is already registered in the current database.

To create an opaque type, you must have the Resource privilege on the database. When you create the opaque type, only you, the owner, have the Usage privilege on the new opaque data type. You can use the GRANT or REVOKE statements to grant or revoke the Usage privilege of other users of the database.

To view the privileges on a data type, check the **sysxdtypes** system catalog table for the owner name, and check the **sysxdtpeauth** system catalog table for additional type privileges that might have been granted.

For details of system catalog tables, see the *Informix® Guide to SQL: Reference*.

The DB-Access utility can also display privileges on opaque data types.

---

## Declaring a Name for an Opaque Type

The name that you declare for an opaque data type is an SQL identifier. When you create an opaque type in a database that is not ANSI-compliant, the name must be unique among the names of data types within the database.

When you create an opaque type in an ANSI-compliant database, *owner.type* combination must be unique within the database. The owner name is case sensitive. If you do not put quotation marks around the owner name, the name of the opaque-type *owner* is stored in uppercase letters.

## INTERNALLENGTH Modifier

The INTERNALLENGTH modifier specifies the storage size that is required for the opaque data type as fixed length or varying length.

## Fixed-Length Opaque Types

A fixed-length opaque type has an internal structure of fixed size. To create a fixed-length opaque type, specify the size of the internal structure, in bytes, for the `INTERNALLENGTH` modifier. The next example creates a fixed-length opaque type called `fixlen_typ` and allocates 8 bytes for storing this data type.

```
CREATE OPAQUE TYPE fixlen_typ(INTERNALLENGTH=8, CANNOTHASH)
```

## Varying-Length Opaque Types

A varying-length opaque type has an internal structure whose size might vary from one value to another. For example, the internal structure of an opaque data type might hold the actual value of a string up to a certain size, but beyond this size it might use an LO-pointer to a CLOB to hold the value.

To create a varying-length opaque data type, use the `VARIABLE` keyword with the `INTERNALLENGTH` modifier. The following statement creates a variable-length opaque data type called `varlen_typ`:

```
CREATE OPAQUE TYPE varlen_typ
(INTERNALLENGTH=VARIABLE, MAXLEN=1024)
```

## Opaque-Type Modifier

Opaque-Type Modifier

**MAXLEN**=*length*

**CANNOTHASH PASSEDBYVALUE**

**ALIGNMENT**=*align\_value*

| Element            | Description  | Restrictions   | Syntax   |
|--------------------|--|--|--|
| <i>align_value</i> | Byte boundary on which to align an opaque type that is passed to a user-defined routine. Default is 4 bytes. | Must be 1, 2, 4, or 8, depending on the C definition of the opaque data type and hardware and compiler used to build the object file for the data type | <a href="#">Literal</a><br><a href="#">Number on page 1419</a> |
| <i>length</i>      | Maximum length to allocate for instances of varying-length opaque types. Default is 2 kilobytes.             | Must be a positive integer 32 kilobytes. Do not specify for fixed-length data types. Values that exceed this length return errors.                     | <a href="#">Literal</a><br><a href="#">Number on page 1419</a> |

Modifiers can specify the following optional information for opaque types:

- `MAXLEN` specifies the maximum length for varying-length types.
- `CANNOTHASH` specifies that the database server cannot use the built-in hash function on the opaque type.
- `ALIGNMENT` specifies the byte boundary on which the database server aligns the opaque type.
- `PASSEDBYVALUE` specifies that an opaque type that requires 4 bytes or fewer of storage is passed by value.

By default, opaque types are passed to user-defined routines by reference.

## Defining an Opaque Type

To define a new opaque data type to the database server, you must provide the following information in the C or Java™ language.

### About this task

- A data structure that serves as the internal storage of the opaque data type

The internal storage details of the type are hidden, or opaque. Once you define a new opaque data type, the database server can manipulate it without knowledge of the C or Java™ structure in which it is stored.

- Support functions that allow the database server to interact with this internal structure.

The support functions tell the database server how to interact with the internal structure of the data type. These support functions must be written in the C or Java™ programming language.

- Additional user-defined functions that other support functions or end users can invoke to operate on the opaque type (optional)

Possible support functions include operator functions and cast functions. Before you can use these functions in SQL statements, they must be registered with the appropriate CREATE CAST, CREATE PROCEDURE, or CREATE FUNCTION statement.

The following table summarizes the support functions for an opaque data type.

| Function          | Description   | Invoked   |
|-------------------|---|---|
| <b>input( )</b>   | Converts the opaque type from its external LVARCHAR representation to its internal representation   | When a client application sends a character representation of the opaque type in an INSERT, UPDATE, or LOAD statement   |
| <b>output( )</b>  | Converts the opaque type from its internal representation to its external LVARCHAR representation   | When the database server sends a character representation of the opaque type as a result of a SELECT or FETCH statement |
| <b>receive( )</b> | Converts the opaque type from its internal representation on the client computer to its internal representation on the server computer Provides platform-independent results regardless of differences between client and server computer types | When a client application sends an internal representation of the opaque type in an INSERT, UPDATE, or LOAD statement   |
| <b>send( )</b>    | Converts the opaque type from its internal representation on the server computer to its internal representation on the client computer Provides platform-independent  | When the database server sends an internal representation of the opaque type as a result of a SELECT or FETCH statement |

| Function                 | Description  | Invoked  |
|--------------------------|--|--|
|                          | results regardless of differences between client and database server computer types  |  |
| <b>db_receive( )</b>     | Converts the opaque type from its internal representation on the local database to the <b>dbsendrecv</b> type for transfer to an external database on the local server                         | When a local database receives a <b>dbsendrecv</b> type from an external database on the local database server |
| <b>db_send( )</b>        | Converts the opaque type from its internal representation on the local database to the <b>dbsendrecv</b> type for transfer to an external database on the local server                         | When a local database sends a <b>dbsendrecv</b> type to an external database on the local database server      |
| <b>server_receive( )</b> | Converts the opaque type from its internal representation on the local server computer to the <b>srvsendrecv</b> type for transfer to a remote database server Use any name for this function. | When the local database server receives a <b>srvsendrecv</b> type from a remote database server                |
| <b>server_send( )</b>    | Converts the opaque type from its internal representation on the local server computer to the <b>srvsendrecv</b> type for transfer to a remote database server Use any name for this function. | When the local database server sends a <b>srvsendrecv</b> type to a remote database server                     |
| <b>import( )</b>         | Performs any tasks needed to convert from the external (character) representation of an opaque type to the internal format for a bulk copy   | When DB-Access (LOAD) initiates a bulk copy from a text file to a database                                     |
| <b>export( )</b>         | Performs any tasks needed to convert from the internal representation of an opaque type to the external (character) format for a bulk copy   | When DB-Access (UNLOAD) initiates a bulk copy from a database to a text file                                   |
| <b>importbinary( )</b>   | Performs any tasks needed to convert from the internal representation of an opaque type on the client computer to the internal representation on the server computer for a bulk copy           | When DB-Access (LOAD) or the High Performance Loader initiates a bulk copy from a binary file to a database    |
| <b>exportbinary( )</b>   | Performs any tasks needed to convert from the internal representation of an opaque type on the server computer to the internal representation on the client computer for a bulk copy           | When DB-Access (UNLOAD) or the High Performance Loader initiates a bulk copy from a database to a binary file  |
| <b>assign( )</b>         | Performs any processing required before storing the opaque type to disk This support function must be named <b>assign( )</b> .   | When the database server executes INSERT, UPDATE, or LOAD, before it stores the opaque type to disk            |
| <b>destroy( )</b>        | Performs any processing necessary before removing a row that contains the opaque type This support function must be named <b>destroy( )</b> .  | When the database server executes the DELETE or DROP TABLE, before it removes the opaque type from disk        |

| Function            | Description  | Invoked   |
|---------------------|--|---|
| <b>lohandles( )</b> | Returns a list of the LO-pointer structures (pointers to smart large objects) in an opaque type  | When the database server must search opaque types for references to smart large objects; when <b>oncheck</b> runs, or an archive is performed         |
| <b>compare( )</b>   | Compares two values of the opaque type and returns an integer value to indicate whether the first value is less than, equal to, or greater than the second value | When the database server encounters an ORDER BY, UNIQUE, DISTINCT, or UNION clause in a SELECT statement, or when CREATE INDEX creates a B-tree index |

After you write the necessary support functions for the opaque type, use the CREATE FUNCTION statement to register these support functions in the same database as the opaque type. Certain support functions convert other data types to or from the new opaque type. After you create and register these support functions, use the CREATE CAST statement to associate each function with a particular cast. The cast must be registered in the same database as the support function.

After you have written the necessary C language or Java™ language source code to define an opaque data type, you then use the CREATE OPAQUE TYPE statement to register the opaque data type in the database.

## CREATE OPCLASS statement

Use the CREATE OPCLASS statement to create an *operator class* for a *secondary-access method*.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```
CREATE OPCLASSIF NOT EXISTS opclass
FOR sec_acc_method
STRATEGIES(
, Strategy Specification136
)
SUPPORT(
, support_function
)
```

| Element               | Description   | Restrictions   | Syntax                                  |
|-----------------------|---|--|---|
| <i>opclass</i>        | Name that you declare here for a new operator class                     | Must be unique among operator classes within the database            | <a href="#">Identifier on page 1456</a> |
| <i>sec_acc_method</i> | Secondary-access method with which the new operator class is associated | Must already exist and must be registered in the <b>sysams</b> table | <a href="#">Identifier on page 1456</a> |

136. See [CREATE OPCLASS statement on page 286](#)

| Element                 | Description  | Restrictions  | Syntax                                  |
|-------------------------|--|---|---|
| <i>support_function</i> | Support function that the secondary-access method requires | Must be listed in the order expected by the access method | <a href="#">Identifier on page 1456</a> |

## Usage

An *operator class* is the set of operators that support a secondary-access method for query optimization and building the index. A *secondary-access method* (sometimes referred to as an *index access method*) is a set of database server functions that build, access, and manipulate an index structure such as a B-tree, R-tree, or an index structure that a DataBlade® module provides.

The database server provides the B-tree and R-tree secondary-access methods. For more information on the **btree** secondary-access method, see [Default Operator Classes on page 290](#).

Define a new operator class when you want one of the following:

- An index to use a different order for the data than the sequence that the default operator class provides
- A set of operators that is different from any existing operator classes that are associated with a particular secondary-access method

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an operator class of the specified name is already registered in the current database.

You must have the Resource privilege or be the DBA to create an operator class. The actual name of an operator class is an SQL identifier. When you create an operator class, the *opclass* name must be unique within the database.

When you create an operator class in an ANSI-compliant database, the *owner.opclass* combination must be unique within the database. The owner name is case sensitive. If you do not put quotation marks around the *owner* name (or else set the **ANSIOWNER** environment variable), the name of the operator-class owner is stored in uppercase letters.

The following CREATE OPCLASS statement creates a new operator class called **abs\_btree\_ops** for the **btree** secondary-access method:

```
CREATE OPCLASS abs_btree_ops FOR btree
  STRATEGIES (abs_lt, abs_lte, abs_eq, abs_gte, abs_gt)
  SUPPORT (abs_cmp);
```

An operator class has two kinds of operator-class functions:

- Strategy functions

Specify strategy functions of an operator class in the STRATEGY clause of the CREATE OPCLASS statement. In the preceding CREATE OPCLASS code example, the **abs\_btree\_ops** operator class has five strategy functions.

- Support functions

Specify support functions of an operator class in the SUPPORT clause. In the preceding CREATE OPCLASS code example, the **abs\_btree\_ops** operator class has one support function.

**Related reference**[CREATE INDEX statement on page 253](#)[CREATE SCHEMA statement on page 313](#)[CREATE FUNCTION statement on page 240](#)[DROP OPCLASS statement on page 517](#)[Purpose Options on page 1493](#)

## STRATEGIES Clause

*Strategy functions* are functions that users can invoke within a DML statement to operate on a specific data type. The query optimizer uses the strategy functions to determine whether a given index can be used to process a query.

If a query includes a UDF or a column on which an index exists, and if the qualifying operator in the query matches any function in the STRATEGIES clause, then the query optimizer considers using the index for the query. For more information on query plans, see your *Informix® Performance Guide*.

When you create a new operator class, the STRATEGIES clause identifies the strategy functions for the secondary-access method. Each strategy specification lists the name of a strategy function (and optionally, the data types of its parameters). You must list these functions in the order that the secondary-access method expects. For the specific order of strategy operators for the default operator classes for a B-tree index and for an R-tree index, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Strategy Specification

The STRATEGIES keyword introduces a comma-separated list of function names or function signatures for the new operator class. Each element of this list is called a *strategy specification* and has the following syntax:

Strategy Specification

*strategy\_function*

```
(
,
,output_type
)
```

| Element           | Description   | Restrictions   | Syntax                                 |
|-------------------|---|--|--|
| <i>input_type</i> | Data type of an input parameter to the strategy function for which you intend to use a specific secondary-access method | A <i>strategy function</i> accepts two input parameters and can have one optional output parameter | <a href="#">Data Type on page 1163</a> |

| Element                  | Description   | Restrictions   | Syntax                                  |
|--------------------------|---|--|---|
| <i>output_type</i>       | Data type of the optional output parameter of the strategy function | Optional output parameter for side-effect indexes                              | <a href="#">Data Type on page 1163</a>  |
| <i>strategy_function</i> | Strategy function to associate with the specified operator class    | Must be listed in the order that the specified secondary-access method expects | <a href="#">Identifier on page 1456</a> |

Each *strategy\_function* is an external function. The CREATE OPCLASS statement does not verify that a user-defined function of the name you specify exists. However, for the secondary-access method to use the strategy function, the external function must be:

- Compiled in a shared library
- Registered in the database with the CREATE FUNCTION statement

Optionally, you can specify the signature of a strategy function in addition to its name. A strategy function requires two input parameters and an optional output parameter. To specify the function signature, specify:

- An *input data type* for each of the two input parameters of the strategy function, in the order that the strategy function uses them
- Optionally, one *output data type* for an output parameter of the strategy function

You can specify UDTs as well as built-in data types. If you do not specify the function signature, the database server assumes that each strategy function takes two arguments of the same data type and returns a BOOLEAN value.

## Indexes on Side-Effect Data

*Side-effect* data are additional values that a strategy function returns after a query that contains the strategy function. For example, an image DataBlade® module might use a *fuzzy* index to search image data. The index ranks the images according to how closely they match the search criteria. The database server returns the rank values as side-effect data with the qualifying images.

## SUPPORT Clause

*Support functions* are functions that the secondary-access method uses internally to build and search the index. Specify these functions for the secondary-access method in the SUPPORT clause of the CREATE OPCLASS statement.

You must list the names of the support functions in the order that the secondary-access method expects. For the specific order of support operators for the default operator classes for a B-tree index and an R-tree index, refer to [Default Operator Classes on page 290](#).

The support function is an external function. CREATE OPCLASS does not verify that a specified support function exists. For the secondary-access method to use a support function, however, the support function must meet these criteria:

- Be compiled in a shared library
- Be registered in the database with the CREATE FUNCTION statement

## Default Operator Classes

Each secondary-access method has a default operator class that is associated with it. By default, the CREATE INDEX statement associates the default operator class with an index.

For example, the following CREATE INDEX statement creates a B-tree index on the **zipcode** column and automatically associates the default B-tree operator class with this column:

```
CREATE INDEX zip_ix ON customer(zipcode)
```

For each of the secondary-access methods that Informix® provides, it provides a default operator class, as follows:

- The default B-tree operator class is a built-in operator class.

The database server implements the operator-class functions for this operator class and registers it as **btree\_ops** in the system catalog tables of a database.

- The default R-tree operator class is a registered operator class.

The database server registers this operator class as **rtree\_ops** in the system catalog tables. The database server does *not* implement the operator-class functions for the default R-tree operator class.

**Important:** To use an R-tree index, you must install a spatial DataBlade® module, such as a third-party DataBlade® module that implements the R-tree index. These implement the R-tree operator-class functions.

DataBlade® modules can provide other types of secondary-access methods. If a DataBlade® module provides a secondary-access method, it might also provide a default operator class. For more information, refer to your DataBlade® module user's guide.

## CREATE PROCEDURE statement

Use the CREATE PROCEDURE statement to create a user-defined procedure. (To create a procedure from text of source code that is in a separate file, use the CREATE PROCEDURE FROM statement.)

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```
>>-CREATE-----+-----+-----+-----PROCEDURE-----+----->
      |   (1)   | | (2) |           '-IF NOT EXISTS-'
      '-OR REPLACE---' '-DBA-----'

>--+procedure-----+----->
```

```

| (3) |
'-----function-'

>--(-----)----->
| (4) |
'| Routine Parameter List |-----'

>+-----+>
| (5) |
'| REFERENCING Clause |-----FOR +-----+---table_object-'
'|-----owner--'.'-'

>+-----+>

10. External routines only

11. See [External Routine Reference on page 1454](#)
12. See [Quoted String on page 1424](#)

| Element                               | Description   | Restrictions  | Syntax                                  |
|---------------------------------------|---|---|---|
| <i>function</i> ,<br><i>procedure</i> | Name declared here for a new SPL routine                            | See <a href="#">Procedure names in Informix on page 298</a> . | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>                          | Owner of <i>table_object</i>  | Must own <i>table_object</i>                                  | <a href="#">Owner name on page 1488</a> |
| <i>pathname</i>                       | File to store compile-time warnings                                 | Must exist on the computer where the database resides         | Operating system specific               |
| <i>table_object</i>                   | Name or synonym of a table or view whose triggers can call this UDR | Must exist in the local database                              | <a href="#">Identifier on page 1456</a> |

## Usage

In Informix® ESQL/C, you can use CREATE PROCEDURE only as text within a PREPARE statement. If you want to create a procedure for which the text is known at compile time, you must use a CREATE PROCEDURE FROM statement.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a procedure of the specified name is already registered in the current database. (Because the identifier of a procedure can be overloaded, it might be unnecessary to include these keywords, if the database server can resolve the argument list of the new procedure as different from that of any other procedure of the same name in the current database.)

Routines use the collating order that was in effect when they were created. See [SET COLLATION statement on page 862](#) statement of Informix® for information about using non-default collation.

## Example

For this example, assume that you have two overloaded procedures that are defined as follows:

```
CREATE PROCEDURE raise_prices ( per_cent INT)
  UPDATE stock SET unit_price = unit_price + (unit_price * (per_cent/100) );
END PROCEDURE

CREATE PROCEDURE raise_prices ( per_cent INT, selected_unit CHAR )
  UPDATE stock SET unit_price = unit_price + (unit_price * (per_cent/100) )
  where unit=selected_unit;
END PROCEDURE
```

In order to refer to the above procedures, you would need to provide the procedure name followed by the parameter list, as in the following examples:

```
DROP PROCEDURE raise_prices(INT);
DROP PROCEDURE raise_prices(INT, CHAR);
```

A more convenient way is to use the specific name to identify each of them. The following example will create the procedure using the specific name:

```

CREATE PROCEDURE raise_prices ( per_cent INT ) SPECIFIC
  raise_prices_all
UPDATE stock SET unit_price = unit_price + (unit_price * (per_cent/100) );
END PROCEDURE

DROP SPECIFIC PROCEDURE raise_prices_all;

CREATE PROCEDURE raise_prices ( per_cent INT, selected_unit CHAR )
  SPECIFIC raise_prices_by_unit
UPDATE stock SET unit_price = unit_price + (unit_price * (per_cent/100) )
  where unit=selected_unit;
END PROCEDURE

```

We can simply drop them using their specific names:

```

DROP SPECIFIC PROCEDURE raise_prices_by_all;
DROP SPECIFIC PROCEDURE raise_prices_by_unit;

```

---

[Overloading the Name of a Function on page 247](#)  
[INSTEAD OF Triggers on Views on page 439](#)

## Using CREATE PROCEDURE Versus CREATE FUNCTION

Although you can use CREATE PROCEDURE to write and register an SPL routine that returns one or more values (that is, an SPL function) in Informix®, it is recommended that you use CREATE FUNCTION instead. To register an external function, you must use CREATE FUNCTION.

Use the CREATE PROCEDURE statement to write and register an SPL procedure or to register an external procedure.

For information on how terms such as user-defined procedures and user-defined functions are used in this document, see [Relationship Between Routines, Functions, and Procedures on page 294](#).

## Relationship Between Routines, Functions, and Procedures

A *procedure* is a routine that can accept arguments but does not return any values. A *function* is a routine that can accept arguments and returns one or more values. *User-defined routine* (UDR) is a generic term that includes both user-defined procedures and user-defined functions. For information about named and unnamed returned values, see [Return Clause on page 1499](#).

You can write a UDR in SPL (a SPL *routine*) or in an external language (an *external routine*) that the database server supports. Where the term UDR appears in this document, it can refer to both SPL routines and external routines.

The term *user-defined procedure* refers to SPL procedures and external procedures. *User-defined function* refers to SPL functions and external functions.

In the documentation of earlier releases, the term *stored procedure* was used for both SPL procedures and SPL functions. In this document, the term *SPL routine* replaces the term stored procedure. When it is necessary to distinguish between an SPL function and an SPL procedure, this document does so.

The term *external routine* applies to an external procedure or an external function, both constructs designating UDRs that are written in a programming language other than SPL. When it is necessary to distinguish between an external function and an external procedure, this document does so.

## Privileges Necessary for Using CREATE PROCEDURE

You must have the Resource privilege on a database to create a user-defined procedure within that database.

Before you can create an SPL procedure, you must also have the Usage privilege on the SPL, C, or Java™ language in which the procedure is written. For more information, see [Language-Level Privileges on page 607](#).

By default, the Usage privilege on SPL is granted to PUBLIC. You must also have at least the Resource privilege on a database to create an SPL procedure within that database.

## OR REPLACE Clause

The OR REPLACE clause is used to update an existing procedure without changing any object privileges granted on it.

**Example**

```

create procedure testproc() returning char(50);
    return "this is the original procedure";
end procedure;
Routine created.

call testproc();

(expression)

this is the original procedure

1 row(s) retrieved.

create procedure testproc() returning char(50);
    return "this is the replaced procedure";
end procedure;
673: Another routine (testproc) with same signature already exists in database

create or replace procedure testproc() returning char(50);
    return "this is the replaced procedure";
end procedure;
Routine created.

call testproc();

(expression)

this is the replaced procedure

1 row(s) retrieved.

```

**DBA Keyword and Privileges on the Procedure**

If you create a UDR with the DBA keyword, it is known as a DBA-privileged UDR. You need the DBA privilege to create a DBA-privileged UDR. If you omit the DBA keyword, the UDR is known as an owner-privileged UDR. Other users who have Execute privilege on the UDR run the UDR with the privileges of the user who created the UDR.

**DBA-privileged UDRs**

For a DBA-privileged UDR, users who do not hold the DBA privilege can run the routine under the following conditions:

- The DBA grants the user Execute privilege on the UDR.
- The DBA grants the Execute privilege to PUBLIC so that all users can run the UDR.

When you have Execute privilege on a DBA-privileged UDR, you run the UDR with DBA privileges.

For additional information about DBA-privileged UDRs, see [Ownership of Created Database Objects on page 301](#).

## Owner-privileged UDRs

In an ANSI-compliant database, before other users can execute an owner-privileged UDR, the owner must grant the Execute privilege, either to individual users, or to roles, or to PUBLIC.

In a database that is not ANSI compliant, any user can run the UDR because PUBLIC is granted the Execute privilege by default. To restrict access to an owner-privileged UDR to specific users, the owner must revoke the Execute privilege on the UDR from PUBLIC, and then grant it to specified users or roles. However, you can prevent privileges on UDRs from being granted to PUBLIC by default, by setting the **NODEFDAC** environment variable to `yes`. Then the owner must grant the Execute privilege for the UDR to other users.

For an owner-privileged UDR, all non-qualified database objects that the UDR references are implicitly qualified by the name of the UDR owner. To allow other users to run the UDR, the owner of the UDR must be granted the necessary privileges on any underlying database objects with the WITH GRANT OPTION keyword in the GRANT statement.

The privileges of the owner determine who can run an owner-privileged UDR:

- If the owner does not have privileges on all of the objects that are referenced by the UDR, then the UDR fails regardless of whether the owner or another user runs it.
- If the owner has privileges on all referenced objects, but does not have the GRANT option, then only the owner can run the UDR. Other users cannot run the UDR, even if they have Execute privilege on the UDR.
- If the owner has privileges with the GRANT option on all referenced objects, then the owner and other users who have the Execute privilege can run the UDR. Other users who have Execute privilege run the UDR with the owner's privileges.

[WITH GRANT OPTION keywords on page 613](#)

## The REFERENCING and FOR Clauses

The REFERENCING clause can declare correlation names for the original value and for the updated value in columns of the *table\_object* that the FOR clause specifies

REFERENCING and FOR Clauses

### REFERENCING

<sup>137</sup>**OLD**

<sup>137</sup>**NEW**

### AS

*correlation*

### FOR

*'owner'*.

*table\_object*

137. Use path no more than once

| Element             | Description   | Restrictions                     | Syntax                                  |
|---------------------|---|----------------------------------|---|
| <i>correlation</i>  | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a trigger routine | Must not be <i>table_object</i>  | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>        | Owner of <i>table_object</i>  | Must own <i>table_object</i>     | <a href="#">Owner name on page 1488</a> |
| <i>table_object</i> | Name or synonym for the table or view whose triggers can call this procedure  | Must exist in the local database | <a href="#">Identifier on page 1456</a> |

If you include the REFERENCING and FOR *table\_object* clauses immediately after the parameter list of the CREATE PROCEDURE statement, the routine that you create is known as a *trigger procedure* (or *trigger UDR* or *trigger routine*). The FOR clause specifies the table or view whose triggers can invoke the routine from the FOR EACH ROW section of their Triggered Action list.

In the REFERENCING clause, the OLD *correlation* specifies a prefix by which the trigger routine can reference the value that a column of *table\_object* had before the trigger routine modifies that column value. The NEW *correlation* specifies a prefix for referencing the new value that the trigger routine assigns to the column. Whether the trigger routine can use correlation names to reference the OLD column value, the NEW column value, or both values depends on the type of triggering event:

- A trigger routine invoked by an Insert trigger can reference only the NEW correlation name.
- A trigger routine invoked by a Delete trigger or by a Select trigger can reference only the OLD correlation name.
- A trigger routine invoked by an Update trigger can reference both the OLD and the NEW correlation names.

For information about how to use the *correlation.column* notation in triggered actions, see [REFERENCING Clauses on page 422](#).

Besides the general requirements for any Informix® UDR that is written in the SPL language, trigger routines can support certain additional syntax features, and are subject to certain restrictions, that are not features (or that are not restrictions) for ordinary UDRs that are not trigger routines:

- A trigger routine must include the FOR *table\_object* clause that specifies the name of the table or view in the local database whose triggers can invoke this routine.
- A trigger routine can also include the REFERENCING clause to declare correlation names for OLD and NEW values that SPL statements in the UDR can reference.
- Trigger routines can be invoked only in the FOR EACH ROW section of the Triggered Action list in the trigger definition.
- Correlated variables for OLD or NEW values can appear in the IF statement of SPL and in CASE expressions.
- Correlated variables for OLD values cannot be on the left-hand side of a LET expression
- Correlated variables for NEW values cannot be on the left-hand side of a LET expression if the FOR clause specifies a view whose INSTEAD OF trigger action list invokes the trigger routine.

- Only correlated variables for NEW values can be on the left-hand side of a LET expression that references correlated variables. In this case, the FOR clause must specify a table, rather than a view, and the trigger whose action invokes the SPL routine cannot be an INSTEAD OF trigger.
- Both OLD and NEW values can be on the right-hand side of a LET expression.
- The Boolean operators SELECTING, INSERTING, DELETING, and UPDATING are valid in trigger routines (and only in trigger routines and in other UDRs that are invoked in triggered action statements) in contexts where Boolean expressions are valid. These operators return TRUE ('t') if the triggering event matches the DML operation referenced by the name of the operator, and they return FALSE ('f') otherwise.
- If a single triggering event activates multiple triggers on the same table or view, then all of the BEFORE actions take place before any of the FOR EACH ROW actions, and all of the AFTER actions follow the FOR EACH ROW actions. The order of execution of different triggers on the same event is not guaranteed.
- Trigger routines must be written in the SPL language. They cannot be written in an external language, like the C or Java™ language, but they can include calls to external language routines, such as the **mi\_trigger** application programming interface for trigger introspection.
- Trigger routines cannot reference savepoints. Any changes to the data values or to the schema of the database by a triggered action must be committed or rolled back in their entirety. Partial rollback of a triggered action is not supported.

For more information about the **mi\_trigger** API, refer to the *Informix® DataBlade® API Programmer's Guide* and to the *Informix® DataBlade® API Function Reference*.

If you include the REFERENCING clause but omit the FOR clause, or if you include the FOR clause but omit the REFERENCING clause, the CREATE PROCEDURE statement fails with an error.

If you omit the REFERENCING and FOR clauses, the UDR cannot use the SELECTING, INSERTING, DELETING, and UPDATING operators, and cannot declare variables that can represent and manipulate column values in triggered actions on the table or view that the trigger definition specifies.

See the [REFERENCING Clauses on page 422](#) section in the CREATE TRIGGER statement description for the syntax of the REFERENCING clause for Delete, Insert, Select, and Update triggers on tables, and for Delete, Insert, and Update INSTEAD OF triggers on views.

## Procedure names in Informix®

Because HCL Informix® offers *routine overloading*, you can define more than one user-defined routine (UDR) with the same name, but different parameter lists. You might want to overload UDRs in the following situations:

- You create a UDR with the same name as a built-in routine (such as **equal( )**) to process a new user-defined data type.
- You create *type hierarchies* in which subtypes inherit data representation and UDRs from supertypes.
- You create *distinct types*, which are data types that have the same internal storage representation as an existing data type, but have different names and cannot be compared to the source type without casting. Distinct types inherit UDRs from their source types.

For a brief description of the routine signature that uniquely identifies each UDR, see [Routine Overloading and Routine Signatures on page 1454](#).

## Using the SPECIFIC Clause to Specify a Specific Name

You can declare a *specific name* that is unique in the database for a user-defined procedure. A specific name is useful when you are overloading a procedure.

## DOCUMENT Clause

The quoted string in the DOCUMENT clause provides a synopsis and description of a UDR. The string is stored in the **sysprocbody** system catalog table and is intended for the user of the UDR.

Anyone with access to the database can query the **sysprocbody** system catalog table to obtain a description of one or all the UDRs stored in the database. A UDR or application program can query the system catalog tables to fetch the DOCUMENT clause and display it for a user.

For example, to find the description of the SPL procedure **raise\_prices**, shown in [SPL Procedures on page 299](#), enter a query such as this example:

```
SELECT data FROM sysprocbody b, sysprocedures p
WHERE b.procid = p.procid
      --join between the two catalog tables
      AND p.procname = 'raise_prices'
      -- look for procedure named raise_prices
      AND b.datakey = 'D';-- want user document
```

The preceding query returns the following text:

```
USAGE: EXECUTE PROCEDURE raise_prices( xxx )
xxx = percentage from 1 - 100
```

For external procedures, you can use a DOCUMENT clause at the end of the CREATE PROCEDURE statement, whether or not you use the END PROCEDURE keywords.

## Using the WITH LISTING IN Option

The WITH LISTING IN clause specifies a filename where compile time warnings are sent. After you compile a UDR, this file holds one or more warning messages. This listing file is created on the computer where the database resides.

If you do not use the WITH LISTING IN clause, the compiler does not generate a list of warnings.

On UNIX™, if you specify a filename but not a directory, this listing file is created in your home directory on the computer where the database resides. If you do not have a home directory on this computer, the file is created in the root directory (the directory named /).

On Windows™, if you specify a filename but not a directory, this listing file is created in your current working directory if the database is on the local computer. Otherwise, the default directory is **%INFORMIXDIR%\bin**.

## SPL Procedures

SPL procedures are UDRs written in Stored Procedure Language (SPL) that do not return a value. To write and register an SPL routine, use the CREATE PROCEDURE statement. Embed appropriate SQL and SPL statements between the CREATE PROCEDURE and END PROCEDURE keywords. You can also follow the UDR definition with the DOCUMENT and WITH FILE IN options.

SPL routines are parsed, optimized (as far as possible), and stored in the system catalog tables in executable format. The body of an SPL routine is stored in the **sysprocbody** system catalog table. Other information about the routine is stored in other system catalog tables, including **sysprocedures**, **sysprocplan**, and **sysprocauth**.

If the Statement Block portion of the CREATE PROCEDURE statement is empty, no operation takes place when you call the procedure. You might use such a "placeholder" procedure in the development stage when you intend to establish the existence of a procedure but have not yet coded it.

If you specify an optional clause after the parameter list, you must place a semicolon after the clause that immediately precedes the Statement Block.

The following example creates an SPL procedure:

```
CREATE PROCEDURE raise_prices ( per_cent INT )
  UPDATE stock SET unit_price =
    unit_price + (unit_price * (per_cent/100));
END PROCEDURE
DOCUMENT "USAGE: EXECUTE PROCEDURE raise_prices( xxx )",
"xxx = percentage from 1 - 100 "
WITH LISTING IN '/tmp/warn_file';
```

## External Procedures

### About this task

*External procedures* are procedures you write in an external programming language that the database server supports. (Procedures written in the SPL language are not external procedures.)

To create a C user-defined procedure

1. Write a C function that does not return a value.
2. Compile the C function and store the compiled code in a shared library (the shared-object file for C).
3. Register the C function in the database server with the CREATE PROCEDURE statement.

### Results

To create a user-defined procedure written in the Java™ language:

1. Write a Java™ static method, which can use the JDBC functions to interact with the database server.
2. Compile the Java™ source and create a JAR file (the shared-object file).
3. Execute the **install\_jar()** procedure with the EXECUTE PROCEDURE statement to install the JAR file in the current database.

4. If the UDR uses user-defined types, create a mapping between SQL data types and Java™ classes, using the **setUDTextName()** procedure that is explained in [EXECUTE PROCEDURE statement on page 557](#).
5. Register the UDR with the CREATE PROCEDURE statement. (If an external routine returns a value, you must register it with the CREATE FUNCTION statement, rather than with CREATE PROCEDURE.)

Rather than storing the body of an external routine directly in the database, the database server stores only the pathname of the shared-object file that contains the compiled version of the routine. The database server executes an external routine by invoking the external object code.

You must also hold either the Resource privilege or the DBA privilege on the database in which the external procedure will be registered, as well as the Usage privilege on the programming language in which the routine is written. (For the syntax of granting Usage privileges on the C language or on the Java™ language to a user, or to a role, or to the PUBLIC group, see [Language-Level Privileges on page 607](#).)

When the IFX\_EXTEND\_ROLE configuration parameter is set to **1** or to **ON**, only users who have the built-in EXTEND role can create external procedures.

## Registering a User-Defined Procedure

### About this task

This example registers a C user-defined procedure named **check\_owner()** that takes one argument of the type LVARCHAR. The external routine reference specifies the path to the C shared library where the procedure object code is stored. This library contains a C function **unix\_owner()**, which is invoked during execution of the **check\_owner()** procedure.

```
CREATE PROCEDURE check_owner ( owner lvarchar )
  EXTERNAL NAME "/usr/lib/ext_lib/genlib.so(unix_owner)"
  LANGUAGE C
END PROCEDURE;
```

This example registers a user-defined procedure named **showusers()** that is written in the Java™ language:

```
CREATE PROCEDURE showusers()
  WITH (CLASS = "jvp") EXTERNAL NAME 'admin_jar:admin.showusers'
  LANGUAGE JAVA;
```

The EXTERNAL NAME clause specifies that the Java™ implementation of the **showusers()** procedure is a method called **showusers()**, which resides in the **admin** Java™ class that resides in the **admin\_jar** JAR file.

## Ownership of Created Database Objects

The user who creates an owner-privileged UDR owns any database objects that the UDR creates when it executes, unless some other *owner* is specified for the object. In other words, the UDR owner, not the user who executes the owner-privileged UDR, is the owner of any database objects created by the UDR unless another owner is specified in the DDL statement that creates the database object.

In the case of a DBA-privileged UDR, however, the user who executes the UDR, not the UDR owner, owns any database objects that the UDR creates, unless some other owner is specified for the database object within the UDR.

For examples, see [Ownership of Created Database Objects on page 251](#) in the description of the CREATE FUNCTION statement.

## CREATE PROCEDURE FROM statement

Use the CREATE PROCEDURE FROM statement to access a user-defined procedure. The actual text of the CREATE PROCEDURE statement resides in a separate file.

This statement is an extension to the ANSI/ISO standard for SQL. You can use this statement with Informix® ESQL/C.

### Syntax

#### CREATE PROCEDURE FROMIF NOT EXISTS

'file' file\_var

| Element         | Description   | Restrictions  | Syntax                    |
|-----------------|---|---|---------------------------|
| <i>file</i>     | Pathname and filename of file that contains full text of a CREATE PROCEDURE statement. Default pathname is the current directory. | Must exist, and can contain only one CREATE PROCEDURE statement. See also <a href="#">Default Directory That Holds the File on page 303</a> . | Operating-system specific |
| <i>file_var</i> | Name of a program variable that contains <i>file</i> specification  | Must be of a character data type; its contents have same restrictions as <i>file</i>  | Language specific         |

### Usage

You cannot create a user-defined procedure directly in Informix® ESQL/C programs. That is, the program cannot contain the CREATE PROCEDURE statement.

To use a user-defined procedure in an ESQL/C program:

1. Create a source file with the CREATE PROCEDURE statement.
2. Use the CREATE PROCEDURE FROM statement to send the contents of this source file to the database server for execution.

The file can contain only one CREATE PROCEDURE statement.

For example, suppose that the following CREATE PROCEDURE statement is in a separate file, called **raise\_pr.sql**:

```
CREATE PROCEDURE raise_prices( per_cent INT )
  UPDATE stock -- increase by percentage;
  SET unit_price = unit_price +
    ( unit_price * (per_cent / 100) );
END PROCEDURE;
```

In the Informix® ESQL/C program, you can access the **raise\_prices()** SPL procedure with the following CREATE PROCEDURE FROM statement:

```
EXEC SQL create procedure from 'raise_pr.sql';
```

If you are not sure whether the UDR in the file returns a value, use the CREATE ROUTINE FROM statement.

When the IFX\_EXTEND\_ROLE configuration parameter is set to ON, only users who have the built-in EXTEND role can create external routines.

When the IFX\_EXTEND\_ROLE configuration parameter is set to 1 or to ON, only users to whom the Database Server Administrator (DBSA) has granted the built-in EXTEND role can create external routines. In addition, you must hold at least the Resource access privilege on the database in which the routine will be registered. You must also hold the Usage privilege on the programming language in which the routine is written. (For the syntax of granting Usage privileges on the C language to a user or to a role, see [Language-Level Privileges on page 607](#).)

User-defined procedures, like user-defined functions, use the collating order that was in effect when they were created. See [SET COLLATION statement on page 862](#) for information about using non-default collation.

[Arguments on page 1433](#)

## Default Directory That Holds the File

The database server treats the specified filename (and any pathname) as relative.

On UNIX™, if you specify a simple filename instead of a full pathname as the *file* parameter, the client application looks for the file in your home directory on the computer where the database resides. If you do not have a home directory on this computer, the default directory is the root directory.

On Windows™, if you specify a filename but no directory as the *file* parameter, the client application looks for the file in your current working directory if the database is on the local computer. Otherwise, the default directory is %INFORMIXDIR%\bin.

**Important:** The Informix® ESQL/C preprocessor does not process the contents of the file that you specify. It only sends the contents to the database server for execution. Therefore, there is no syntactic check that the file that you specify in CREATE PROCEDURE FROM actually contains a CREATE PROCEDURE statement. To improve readability of the code, however, it is recommended that you match these two statements.

## CREATE ROLE statement

Use the CREATE ROLE statement to declare and register a new role.

This statement is an extension to the ANSI/ISO standard for SQL.

## Syntax

### CREATE ROLE IF NOT EXISTS

*role* 'role'

| Element     | Description  | Restrictions  | Syntax                                  |
|-------------|--|---|---|
| <i>role</i> | Name declared here for a role that the DBA creates | Must be unique among <i>role</i> and user names in the database. Maximum number of bytes is 32. | <a href="#">Owner name on page 1488</a> |

## Usage

CREATE ROLE declares a new role and registers it in the system catalog. A role can associate a set of authorization identifiers with a set of access privileges on database objects. The system catalog maintains information about the roles (and their corresponding privileges) that are granted to users or to other roles.

Only the database administrator (DBA) can use CREATE ROLE to create a new role. The DBA can assign the privileges required for some work task to a role, such as **engineer**, and then use the GRANT statement to assign that role to specific users, instead of granting that set of privileges to each user individually.

The *role* name is an *authorization identifier*. It cannot be a user name that is known to the database server or to the operating system of the database server. The *role* name cannot already be listed in the **username** column of the **sysusers** system catalog table, nor in the **grantor** or **grantee** columns of the **sysstabauth**, **syscolauth**, **sysfragauth**, **sysprocauth**, or **sysroleauth** system catalog tables.

The *role* name also cannot match the name of any user or role that is already listed in the **grantor** or **grantee** columns of the **sysxtdtypeauth** system catalog table, nor any built-in role, such as EXTEND or DBSECADM.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a role of the specified name is already registered in the current database.

After a role is created, the DBA can use the GRANT statement to assign the role to PUBLIC, to users, or to other roles, and to grant specific privileges to the role. (A role cannot, however, hold database-level privileges.) After a role is granted successfully to a user or to PUBLIC, the user must use the SET ROLE statement to enable the role. Only then can the user exercise the privileges of the role.

To create the role **engineer**, for example, enter the following statement:

```
CREATE ROLE engineer;
```

To grant access privileges to the role **engineer**, the DBA can issue GRANT statements that include **engineer** in the list of grantees:

```
GRANT USAGE ON LANGUAGE SPL TO engineer;
```

To assign the role **engineer** to user **kaycee**, the DBA could issue this statement:

```
GRANT engineer TO kaycee;
```

To activate the role **engineer**, user **kaycee** must issue the following statement:

```
SET ROLE engineer;
```

If this SET ROLE statement is successful, user **kaycee** acquires whatever privileges have been granted to the role **engineer**, in addition to any other privileges that **kaycee** already holds as an individual or as PUBLIC.

A user can be granted several roles, but no more than one non-default role, as specified by SET ROLE, can be enabled for any user at a given time.

An exception to requiring SET ROLE to explicitly enable a role is any default role that the DBA specifies in the GRANT DEFAULT ROLE *role* TO *user* statement. If that statement succeeds, the default *role* is automatically enabled when *user* connects to the database. Any role can be a default role. (Similarly, users to whom the Informix® DBSA grants the EXTEND role need not execute SET ROLE before they can create and drop external routines and shared libraries.)

CREATE ROLE, when used with the GRANT and SET ROLE statements, enables a DBA to create one set of privileges for a role and then grant the role to many users, instead of granting the same set of privileges individually to many users.

With the GRANT DEFAULT ROLE and SET ROLE DEFAULT statements, *default roles* enable a DBA to assign privileges to a role that is activated automatically when any user who holds that default role connects to the database. This feature is useful when an application performs operations that require specific access privileges, but the application does not include SET ROLE statements.

The REVOKE statement can cancel access privileges of a role, remove users from a role, or cancel the default status of a role for one or more users. A role exists until either the DBA or a user to whom the role was granted with the WITH GRANT OPTION keywords uses the DROP ROLE statement to drop the role.

**Important:** The scope of a user-defined role (and of discretionary access privileges that the GRANT statement assigns to the role) is the current database. When the GRANT DEFAULT ROLE or SET ROLE statement activates a role, the role and its privileges take effect in the current database only. As a security precaution, discretionary access privileges that a user receives only from a role cannot provide access to tables outside the current database through a view or through a trigger action.

## CREATE ROUTINE FROM statement

Use the CREATE ROUTINE FROM statement to register a UDR by referencing the text of a CREATE FUNCTION statement or CREATE PROCEDURE statement that resides in a separate file.

This statement is an extension to the ANSI/ISO standard for SQL.

You can use this statement with ESQL/C.

## Syntax

### CREATE ROUTINE FROM IF NOT EXISTS

'file' *file\_var*

| Element         | Description   | Restrictions   | Syntax                     |
|-----------------|---|--|----------------------------|
| <i>file</i>     | Pathname and filename for the text of a CREATE PROCEDURE or CREATE FUNCTION statement. Default path is the current directory. | Must exist and can contain only one CREATE FUNCTION or CREATE PROCEDURE statement. | Operating-system dependent |
| <i>file_var</i> | Name of a program variable that contains <i>file</i> specification  | Must be a character data type; contents must satisfy <i>file</i> restrictions      | Language specific          |

## Usage

ESQL/C programs cannot use the CREATE FUNCTION or CREATE PROCEDURE statement directly to define a UDR. You must instead do this:

1. Create a source file with the CREATE FUNCTION or CREATE PROCEDURE statement.
2. Execute the CREATE ROUTINE FROM statement from an ESQL/C program to send the contents of this source file to the database server for execution. The file that you specify can contain only one CREATE FUNCTION or CREATE PROCEDURE statement.

The file specification that you provide is relative. If you include no pathname, the client application looks for the file in the current directory.

If you do not know at compile time whether the UDR in the file is a function or a procedure, use the CREATE ROUTINE FROM statement in the Informix® ESQL/C program. If you know whether the UDR is a function or a procedure, you can improve the readability of your code by using the matching SQL statement to access the source file:

- To access user-defined functions, use CREATE FUNCTION FROM.
- To access user-defined procedures, use CREATE PROCEDURE FROM.

When the IFX\_EXTEND\_ROLE configuration parameter is set to `1` or to `ON`, only users to whom the Database Server Administrator (DBSA) has granted the built-in EXTEND role can create external routines. In addition, you must hold at least the Resource access privilege on the database in which the routine will be registered. You must also hold the Usage privilege on the programming language in which the routine is written. (For the syntax of granting Usage privileges on the C language to a user or to a role, see [Language-Level Privileges on page 607](#).)

Routines use the collating order that was in effect when they were created. See [SET COLLATION statement on page 862](#) for information about using non-default collation.

## Examples

The following statement registers a UDR by referencing the text in the `del_ord.sql` file.

```
EXEC SQL CREATE ROUTINE FROM 'del_ord.sql';
```

ESQL/C source code example:

```

#include <stdio.h>

main()
{

    printf( "CREATE ROUTINE FROM ESQL Program running.\n\n");
    EXEC SQL WHENEVER ERROR STOP;
    EXEC SQL connect to 'stores_demo';

    EXEC SQL CREATE ROUTINE FROM 'del_ord.sql';

    EXEC SQL disconnect current;
    printf("\nCREATE ROUTINE Sample Program over.\n\n");

    exit(0);
}

del_ord.sql

CREATE FUNCTION delete_order( p_order_num int) RETURNING int, int;
    DEFINE item_count int;
    SELECT count(*) INTO item_count FROM items
        WHERE order_num = p_order_num;
    DELETE FROM orders WHERE order_num = p_order_num;
    RETURN p_order_num, item_count;
END FUNCTION;

```

**Related reference**[CREATE FUNCTION statement on page 240](#)[CREATE FUNCTION FROM statement on page 252](#)[CREATE PROCEDURE statement on page 290](#)[CREATE PROCEDURE FROM statement on page 302](#)

## CREATE ROW TYPE statement

Use the CREATE ROW TYPE statement to create a named ROW type.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****CREATE ROW TYPE IF NOT EXISTS** *owner* .*row\_type*

Named ROW type with no parent Named child ROW type

Named ROW type with no parent

```
(
, Field Definition
)
```

Named child ROW type

```
(
, Field Definition
)
```

**UNDER** *supertype*

Field Definition

*field**data\_type***NOT NULL**

| Element          | Description   | Restrictions   | Syntax                                  |
|------------------|---|--|---|
| <i>data_type</i> | Data type of the <i>field</i>   | See <a href="#">Restrictions on Serial and Simple-Large-Object Data Types on page 312</a> .  | <a href="#">Identifier on page 1456</a> |
| <i>field</i>     | Name of a field in <i>row_type</i>  | Must be unique among field names of this ROW type and of its supertype   | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>     | Authorization identifier of the owner of this ROW type                            | In an ANSI-compliant database, the combination <i>owner.row_type</i> must be unique among data-type objects                        | <a href="#">Owner name on page 1488</a> |
| <i>row_type</i>  | Name declared here for a new named ROW data type                                  | See <a href="#">Procedure for Creating a Subtype on page 312</a> . Must be unique among data type names in the database.           | <a href="#">Identifier on page 1456</a> |
| <i>supertype</i> | Name of the supertype of <i>row_type</i> within a data-type inheritance hierarchy | To create a child ROW type, this must exist in the database as a named ROW type, all of whose fields this <i>row_type</i> inherits | <a href="#">Data Type on page 1163</a>  |

**Usage**

You must hold the Resource privilege to use this statement. If the UNDER clause declares the new ROW type as a subtype of an existing named ROW type, you must also hold the UNDER privilege for that named ROW type. You are, by default, the owner of the named ROW types that you create, but a DBA who issues the CREATE ROW TYPE statement can designate another user as *owner*.

The CREATE ROW TYPE statement declares a named ROW data type and registers it in the **sysxdtypes** system catalog table. You can assign a named ROW data type to a table or view to create a *typed table* or *typed view*. You can also define a column as a named ROW type.

The following example creates a named ROW type called **people\_t** with four fields:

```
CREATE ROW TYPE people_t
(
  name      VARCHAR(40) NOT NULL,
  address   VARCHAR(35),
  city      VARCHAR(25),
  bdate     DATE
);
```

In some SQL code examples in this document, the SQL identifiers of named ROW types have **\_t** as the last two characters. This suffix is only a documentation convention, and not a requirement of the database server.

Although you can assign a ROW type to a table to define the schema of the table, ROW data types are not the same as table rows. Table rows consist of one or more *columns*; ROW data types consist of one or more *fields*, defined using the Field Definition syntax.

A named ROW data type is valid in most contexts where you can specify a data type.

The following CREATE TABLE statement defines a typed table whose only column is of the **people\_t** ROW type:

```
CREATE TABLE birthdays OF TYPE people_t
  LOCK MODE ROW;
```

Named ROW types are said to be *strongly typed*. No two named ROW types are equivalent, even if they are structurally equivalent. To compare values of a named ROW type with values of another named ROW type, or with values of an unnamed ROW type, you must use an explicit cast, so that both rows are of the same data type.

ROW types without identifiers are called *unnamed ROW types*. Any two unnamed ROW types are considered equivalent if they are structurally equivalent. For more information, see [ROW Data Types on page 1187](#).

Discretionary access privileges on the fields of named ROW types are the same as privileges on columns. For more information, see [Table-Level Privileges on page 597](#). (To see what privileges you have on a column, check the **syscolauth** system catalog table, which is described in the *Informix® Guide to SQL: Reference*.)

If you include the optional **IF NOT EXISTS** keywords, the database server takes no action, rather than sending an exception to the application, if a named ROW of the specified name is already registered in the current database. In this case, the CREATE ROW TYPE statement has no effect, and does not register a new named ROW type in the **sysxdtypes** system catalog table.

If no field is of the SERIAL, BIGSERIAL, or SERIAL8 data type, named ROW data types that the CREATE ROW TYPE statement defines can be the source type for DISTINCT ROW data types that the CREATE DISTINCT TYPE statement can define.

### Important:

You cannot use the CREATE ROW TYPE statement to create an unnamed ROW type. Unnamed ROW types are created in the CREATE TABLE statement or in the ALTER TABLE statement by including the ROW constructor syntax segment in the definition of a column. This can be an unnamed ROW type column that you declare in the CREATE TABLE statement, or an unnamed ROW type that you add to the schema of an existing table by using the ALTER TABLE statement.

## Field definition

When you define a new named ROW type with no UNDER clause, the Field Definition clause defines an ordered list of the data types and NOT NULL constraints of one or more fields in the new named ROW type.

If the UNDER clause identifies a *supertype*, however, the Field Definition clause can append one or more fields to the ordered list of fields that the new child ROW type inherits from its parent supertype within a named ROW type hierarchy.

If you omit the Field definition, the new subtype has only the fields that it inherits from the parent supertype that the UNDER clause specifies.

The NOT NULL constraint on the named ROW type field applies to the corresponding columns when a typed table of the named ROW type is created. If you omit the `NOT NULL` keywords, then by default, the field accepts NULL values.

The NOT NULL constraint is the only constraint that the CREATE ROW TYPE statement can define for a field of a named ROW type. To define any other constraints on the fields of a column of a named ROW type, you must use the CREATE TABLE statement, or in the ALTER TABLE statement.

The Informix® implementation of the SQL language supports no ALTER ROW TYPE statement for changing the definition of an existing named ROW type. For named ROW types that are not currently instantiated by any existing table, column, view, or named ROW type hierarchy in the database, you can use the DROP ROW TYPE statement to remove an existing named ROW type from the system catalog. You can then use the CREATE ROW TYPE statement to define a replacement named ROW type.

See, however, the [DROP ROW TYPE statement on page 524](#) for restrictions on dropping an existing named ROW type.

---

## Privileges on named ROW data types

The discretionary access privileges required for operations on a typed table (a table that is assigned a named ROW data type) are the same as privileges on any table. For more information, see [Table-Level Privileges on page 597](#). The following table shows which access privileges you need to create a named ROW type.

| Task   | Privileges Required   |
|--|---|
| Create a named ROW type                                | Resource privilege on the database                                  |
| Create a named ROW type as a subtype under a supertype | Under privilege on the supertype, as well as the Resource privilege |

For information about Resource and Under privileges and the ALL keyword in the context of privileges, see the [GRANT statement on page 592](#).

o find out what privileges exist on a ROW type, check the **sysxdtypes** system catalog table for the *owner* name and the **sysxdtpeauth** system catalog table for privileges on the ROW type that might have been granted to users or to roles.

To find out what privileges you have on a given table, check the **sysstabauth** system catalog table. For more information on system catalog tables, see the *Informix® Guide to SQL: Reference*.

## Inheritance and Named ROW Types

A named ROW type can belong to an inheritance hierarchy, as either a subtype or a supertype. Use the UNDER clause in the CREATE ROW TYPE statement to create a named ROW data type as a subtype of an existing ROW data type.

The supertype must also be a named ROW data type. If you create a named ROW data type under an existing supertype, then the new type name *row\_type* becomes the name of the subtype.

When you create a named ROW type as a subtype, the subtype inherits all fields of the supertype. In addition, you can add new fields to the subtype when you create it. The new fields are specific to the subtype alone.

You cannot substitute a ROW type in an inheritance hierarchy for its supertype or for its subtype. For example, consider a type hierarchy in which **person\_t** is the supertype and **employee\_t** is the subtype. If a column is of type **person\_t**, the column can only contain **person\_t** data. It cannot contain **employee\_t** data. Likewise, if a column is of type **employee\_t**, the column can only contain **employee\_t** data. It cannot contain **person\_t** data.

## Creating a Subtype

In most cases, you add new fields when you create a named ROW type as a subtype of another named ROW type (its supertype). To create the fields of a named ROW type, use the field definition clause, as described in [CREATE ROW TYPE statement on page 307](#). When you create a subtype, you must use the UNDER keyword to associate the supertype with the named ROW type that you want to create. The next example creates the **employee\_t** type under the **person\_t** type:

```
CREATE ROW TYPE employee_t (salary NUMERIC(10,2),
    bonus NUMERIC(10,2)) UNDER person_t;
```

The **employee\_t** type inherits all the fields of **person\_t** and has two additional fields: **salary** and **bonus**; but the **person\_t** type is not altered.

## Type Hierarchies

When you create a subtype, you create a *type hierarchy*. In a type hierarchy, each subtype that you create inherits its properties from a single supertype. If you create a named ROW type **customer\_t** under **person\_t**, **customer\_t** inherits all the fields of **person\_t**. If you create another named ROW type, **salesrep\_t** under **customer\_t**, **salesrep\_t** inherits all the fields of **customer\_t**.

Thus, **salesrep\_t** inherits all the fields that **customer\_t** inherited from **person\_t** as well as all the fields defined specifically for **customer\_t**. For a discussion of type inheritance, refer to the *Informix® Guide to SQL: Tutorial*.

## Procedure for Creating a Subtype

Before you create a named ROW type as a subtype in an inheritance hierarchy, check the following information:

- Verify that you are authorized to create new data types. You must have the Resource privilege on the database. You can find this information in the **sysusers** system catalog table.
- Verify that the supertype exists. You can find this information in the **sysxdtypes** system catalog table.
- Verify that you are authorized to create subtypes to that supertype. You must have the Under privilege on the supertype. You can find this information in the **sysusers** system catalog table.
- Verify that the name that you declare for the named ROW type is unique. In an ANSI-compliant database, the *owner.type* combination must be unique within the database. In a database that is not ANSI-compliant, the name must be unique among data type names in the database. To verify whether the name for a new data type is unique, check the **sysxdtypes** system catalog table. The name must not be the name of an existing data type.
- If you are defining fields for the ROW type, check that no duplicate field names exist in both new and inherited fields.

**Important:** When you create a subtype, you cannot redefine fields that it inherited for its supertype. If you attempt to redefine these fields, the database server returns an error.

You cannot apply constraints to named ROW data types, but you can specify constraints when you create or alter a table that uses the named ROW types. You can also specify NOT NULL constraints on individual fields of a ROW type.

## Restrictions on Serial and Simple-Large-Object Data Types

Serial and simple-large-object data types cannot be nested within a table. Therefore, if a ROW type contains a BYTE, TEXT, SERIAL, BIGSERIAL, or SERIAL8 field, you cannot use the ROW type to define a column in a table that is not based on a ROW type. For example, the following code example produces an error:

```
CREATE ROW TYPE serialtype (s serial, s8 serial8);
CREATE TABLE tab1 (col1 serialtype); --INVALID CODE
```

You cannot create a ROW type that has a BYTE or TEXT value that is stored in a separate storage space. That is, you cannot use the IN clause to specify the storage location. For example, the following example produces an error:

```
CREATE ROW TYPE row1 (field1 byte IN blobspace1); --INVALID CODE
```

A table hierarchy can include no more than one SERIAL, BIGSERIAL, or SERIAL8 column. If a supertable has a SERIAL column, none of its subtables can contain a SERIAL column (but a subtable can have a BIGSERIAL or SERIAL8 column if no other subtable contains a BIGSERIAL or SERIAL8 column, respectively). Consequently, when you create the named ROW types on which the table hierarchy is to be based, they can contain at most one SERIAL and one BIGSERIAL or SERIAL8 field among them.

You cannot set the starting SERIAL, BIGSERIAL, or SERIAL8 value in the CREATE ROW TYPE statement. To modify the value for a serial field, you must use either the MODIFY clause of the ALTER TABLE statement, or else use the INSERT statement to insert a value that is larger than the current maximum (or default) serial value.

Serial fields in ROW types have performance implications across a table hierarchy. To insert data into a subtable whose supertable (or its supertable) contains the serial counter, the database server must also open the supertable, update the serial value, and close the supertable, thus adding extra overhead.

In contexts where these restrictions or performance issues for SERIAL, BIGSERIAL, or SERIAL8 data types conflict with your design goals, you might consider using sequence objects to emulate the functionality of serial fields or serial columns.

---

## CREATE SCHEMA statement

Use the CREATE SCHEMA statement to issue a block of data definition language (DDL) and GRANT statements as a unit.

Use this statement with DB-Access.

**Syntax****CREATE SCHEMA AUTHORIZATION***user*CREATE TABLE Statement<sup>138</sup>CREATE VIEW Statement<sup>139</sup>GRANT Statement<sup>140</sup>

141

CREATE INDEX Statement<sup>142</sup>CREATE SYNONYM Statement<sup>143</sup>CREATE TRIGGER Statement<sup>144</sup>CREATE SEQUENCE Statement<sup>149</sup>CREATE ROW TYPE Statement<sup>145</sup>CREATE OPAQUE TYPE Statement<sup>146</sup>CREATE DISTINCT TYPE Statement<sup>147</sup>CREATE CAST Statement<sup>148</sup>

;

| Element     | Description  | Restrictions  | Syntax                                  |
|-------------|--|---|---|
| <i>user</i> | User who owns the database objects that this statement creates | If you have DBA privileges, you can specify the name of any user. Otherwise, you must have the Resource privilege, and you must specify your own user name. | <a href="#">Owner name on page 1488</a> |

**Usage**

The CREATE SCHEMA statement allows the DBA to specify an owner for all database objects that the CREATE SCHEMA statement creates. You cannot issue CREATE SCHEMA until you have created the database that stores the objects.

Users with the Resource privilege can create a schema for themselves. In this case, *user* must be the name of the person with the Resource privilege who is running the CREATE SCHEMA statement. Anyone with the DBA privilege can also create a schema for someone else. In this case, *user* can specify a user other than the person who is running the CREATE SCHEMA statement.

138. See [CREATE TABLE statement on page 335](#)

139. See [CREATE VIEW statement on page 452](#)

140. See [GRANT statement on page 592](#)

141. Informix® extension

142. See [CREATE INDEX statement on page 253](#)

143. See [CREATE SYNONYM statement on page 330](#)

144. See [CREATE TRIGGER statement on page 405](#)

145. See [CREATE ROW TYPE statement on page 307](#)

146. See [CREATE OPAQUE TYPE statement on page 281](#)

147. See [CREATE DISTINCT TYPE statement on page 210](#)

148. See [CREATE CAST statement on page 198](#)

149. See [CREATE SEQUENCE statement on page 326](#)

You can put CREATE and GRANT statements in any logical order, as the following example shows. Statements are considered part of the CREATE SCHEMA statement until a semicolon (;) or an end-of-file symbol is reached.

```
CREATE SCHEMA AUTHORIZATION sarah
  CREATE TABLE mytable (mytime DATE, mytext TEXT)
  GRANT SELECT, UPDATE, DELETE ON mytable TO rick
  CREATE VIEW myview AS
    SELECT * FROM mytable WHERE mytime > '12/31/2004'
  CREATE INDEX idxtime ON mytable (mytime);
```

[CREATE SYNONYM statement on page 330](#)

[CREATE TABLE statement on page 335](#)

[CREATE VIEW statement on page 452](#)

[GRANT statement on page 592](#)

## Creating Database Objects Within CREATE SCHEMA

All database objects that a CREATE SCHEMA statement creates are owned by *user*, even if you do not explicitly name each database object. If you are the DBA, you can create database objects for another user. If you are not the DBA, specifying an owner other than yourself results in an error message.

Suppose that user **oswald** holds the DBA access privilege and issues the following CREATE SCHEMA statement:

```
CREATE SCHEMA AUTHORIZATION hilda
  CREATE ROW TYPE IF NOT EXISTS
    hildago (field1 INT,
            field2 CHAR(18) NOT NULL,
            field3 DATE);
```

The owner of this named ROW type is the user whose authorization identifier is **hilda**, rather than user **oswald** who issued the CREATE ROW TYPE statement. This example would fail if user **oswald** does not hold the DBA privilege.

You can only grant access privileges with the CREATE SCHEMA statement; you cannot use CREATE SCHEMA to revoke or to drop access privileges.

If you create a database object or use the GRANT statement outside a CREATE SCHEMA statement, you receive warnings if you use the **-ansi** flag or set **DBANSIWARN**.

## CREATE SECURITY LABEL statement

Use the CREATE SECURITY LABEL statement to define a new security label for a specified security policy in the current database and to identify its components and the elements of its components.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```
CREATE SECURITY LABEL IF NOT EXISTS policy. label
, COMPONENT component
, element
```

| Element          | Description                                  | Restrictions  | Syntax                                     |
|------------------|--|---|--|
| <i>component</i> | A security label component                   | Must already exist in the database as a component of the specified <i>policy</i> , and be unique among names of components of this <i>label</i> .                 | <a href="#">Identifier on page 1456</a>    |
| <i>label</i>     | Name you declare here for this label         | Must be unique among security label names for this security <i>policy</i>   | <a href="#">Identifier on page 1456</a>    |
| <i>element</i>   | An element of the specified <i>component</i> | Must have been defined when its <i>component</i> was defined or was last altered. If <i>component</i> is an array, only a single <i>element</i> can be specified. | <a href="#">Quoted String on page 1424</a> |
| <i>policy</i>    | The security policy of this <i>label</i>     | Must already exist in the database  | <a href="#">Identifier on page 1456</a>    |

### Usage

A *security label* is a named database object that supports a specified security policy. A security label can be applied to a user, or to a row or to a column (or to both a row and a column) of a table in the database. When a user who holds a security label attempts to access data that has a security label, the database server takes into account the security label of the column or row and the security label of the user in determining whether to allow the user to access the data.

Every security label stores the following categories of information:

- It identifies an existing security policy that the label supports.
- It identifies at least one, but no more than 16 existing components of the security policy that the label supports.
- It identifies one or more existing elements of each component of the security label. (Only security label components of type SET or TREE can include more than one element in the same security label.)

Only DBSECADM can issue this statement. When the CREATE SECURITY LABEL statement executes successfully, it registers the specified *label* name, the numeric identifier of the associated security *policy*, and the cardinality of its security label *components* in the **sysseclabels** system catalog table.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a security label of the specified name is already registered in the current database.

## Components and Elements of a Security Label

Like a security policy, a security label must have at least one component, but no more than 16. The CREATE SECURITY LABEL statement cannot list security label components that are not components of the specified security policy. The same *component* name cannot be specified more than once in the same CREATE SECURITY LABEL statement. These components must already exist in the database, where DBSECADM can register them with the CREATE SECURITY LABEL COMPONENT statement.

Security label components can be of type ARRAY, SET, or TREE, as described in CREATE SECURITY LABEL COMPONENT. For a *component* of type ARRAY, the *element* list can identify only a single element. For components of type SET or TREE, the *element* list can identify multiple component elements that were defined when the component was created (or when it was last altered). See the CREATE SECURITY LABEL COMPONENT statement for more information about the structure and semantics of security label components.

The following example creates a security label called **label1** for a security policy called **MegaCorp**. The label uses two security label components, called **levels** and **compartments**, each with one element, called **VP** and **Marketing** respectively:

```
CREATE SECURITY LABEL MegaCorp.label1
  COMPONENT levels 'VP',
  COMPONENT compartments 'Marketing';
```

For this example to be valid, the **levels** and **compartments** components, and their security label components, **VP** and **Marketing** elements, must have been defined in previously executed CREATE SECURITY LABEL COMPONENT statements.

In the next example, DBSECADM creates a security label called **label2** for the same **MegaCorp** security policy. This label uses three security label components, called **levels**, **compartments**, and **groups**, where two of these components have one element, and another has two:

```
CREATE SECURITY LABEL MegaCorp.label2
  COMPONENT level 'Director',
  COMPONENT compartments 'HR', 'Finance',
  COMPONENT groups 'EntireRegion';
```

These examples illustrate that the components of a security label can be a subset of the components of the security policy that the label supports, and that more than one security label can support the same security policy.

## CREATE SECURITY LABEL COMPONENT statement

Use the CREATE SECURITY LABEL COMPONENT statement to define a new security label component in the current database and to define the elements the component.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**CREATE SECURITY LABEL COMPONENT** **IF NOT EXISTS** *component*

**ARRAY**[

, *element*

]

**SET**{

, *element*

}

**TREE**( *element* **ROOT**

, *element* **UNDER** *element*

)

| Element          | Description                            | Restrictions   | Syntax                                     |
|------------------|--|--|--|
| <i>component</i> | Name declared here for this component  | Must be unique among the names of security label components in the database.   | <a href="#">Identifier on page 1456</a>    |
| <i>element</i>   | Component element that is defined here | Must be unique among elements of this <i>component</i> , and no longer than 32 bytes. The left ( ( ) ) and right ( ) ) parentheses, comma ( , ), and colon ( : ) symbols are not valid characters. | <a href="#">Quoted String on page 1424</a> |

### Usage

Only the DBSECADM can issue the CREATE SECURITY LABEL COMPONENT statement, which defines a *security label component*. This is a database object that defines one or more logical categories whose values can be used in a security policy to determine whether a user's request to read or write data is accepted or rejected. The set of all the valid individual values that the security component can have is defined by the set of *security label elements* that this statement specifies for the component.

The logical categories that security label components implement are identified by DBSECADM in the process of designing a *security policy*, which is the core construct of label-based access control (LBAC). To implement this security feature in the database, however, DBSECADM must create security objects in the following sequence:

1. A set of one or more *security components*, each of which can be defined by the CREATE SECURITY LABEL COMPONENT statement. This statement specifies the name of a security component, the structure of its range of values, and the possible values for this component that can be assigned to a security label that applies a security policy to data or to a user.
2. One or more *security policies*, each of which can be defined by the CREATE SECURITY POLICY statement, which specifies a list of one or more components and a set of rules that the security policy applies to data and to users who attempt read or write operations on data that the security policy protects in the database. A security policy always includes all the elements of a component that CREATE SECURITY POLICY specifies.
3. A *security label* can be defined by the CREATE SECURITY LABEL statement, which specifies one or more values for each of one or more components of the security policy that the label supports. The security label can be applied to data and to users. All the components of a security label must be components of the same security policy, but multiple security policies and multiple security labels can share the same component. A security label typically includes only a subset of the elements of a security component that CREATE SECURITY LABEL COMPONENT defines.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a security label component of the specified name is already registered in the current database.

See the GRANT Security and REVOKE Security statements for information on how security labels and exemptions from the rules of a security policy define the LBAC credentials of a user or of a role.

See the CREATE TABLE and ALTER TABLE statements for information on how security labels can be associated with a database table or with an individual data row in a table.

## Types and Elements of Security Label Components

A security label component itself consists of one or more *elements* that the CREATE SECURITY LABEL COMPONENT statement declares as string constants. These elements define the set of values that are valid for the component. When the CREATE SECURITY LABEL statement executes successfully, Informix® updates the system catalog of the database with the following new entries:

- It creates a new row in the **sysseclabelcomponents** table to register the new component.
- For each *element* of the new component, it creates a new row in the **sysseclabelcomponentelements** table.

The security label component must be defined as one of the three component types. The ARRAY, SET, or TREE keyword that immediately follows the declaration of the *component* name specifies the component type, which must be followed by a list of the *elements* of the security component. These elements define the set of values that the component can have within a security policy. For all three types of security label components, the set of elements is under the following restrictions:

- The security component can have no more than 64 elements.
- Each element of a security component is a quoted string constant of no more than 32 bytes.
- Characters in the quoted string constant cannot include the left ( `(` ) or right ( `)` ) parentheses, comma ( `,` ), or colon ( `:` ) symbols, but other symbols that the **DB\_LOCALE** setting supports are valid, including the blank space (ASCII 32) character.
- Each element must be unique among elements of the same security label component, but the same quoted string constant value can also be an element of other security label components.

The definition of each element within the component implies a level of data sensitivity that a security label associates with a database table or with an individual data row, and also affects the security credentials of users who hold a security label to read or write data that is protected by the same label or by a different label that specifies one or more elements of the component.

Like other database Data Definition Language statements of SQL that can define database objects, CREATE SECURITY LABEL COMPONENT must specify a literal value for each component element, rather than a placeholder. To change the definition of an existing security label component, DBSECADM can use the ALTER SECURITY LABEL COMPONENT to insert a new element into an ARRAY, SET, or TREE component. To drop or rename one or more individual elements of a component, however, DBSECADM must use the DROP SECURITY LABEL COMPONENT statement to destroy the existing component, and then reissue the CREATE SECURITY LABEL COMPONENT statement to create a new component that defines the required set of element values within an ARRAY, SET, or TREE component structure.

## ARRAY Components

A security label component of type ARRAY is an ordered set of no more than 64 elements. Each element defines a value that is valid for that component within a security policy. The order in which elements are declared is significant, because it defines a descending order of data sensitivity, with each successive element ranking lower in data sensitivity than the preceding

element. The set of label elements of the array and their comma separators must be enclosed between a pair of bracket ( `[ ... ]` ) symbols.

When an ARRAY component is specified in the definition of a security label, the label can specify no more than one element of that component as the value of the component.

The following example defines a security label component of type ARRAY called **aquilae** that is an ordered set of five elements called **imperator**, **tribunus**, **centurio**, **miles**, and **asinus**:

```
CREATE SECURITY LABEL COMPONENT aquilae
  ARRAY [ "imperator", "tribunus", "centurio", "miles", "asinus" ];
```

Here the component element with the highest data sensitivity is **imperator** and **asinus** has the lowest data sensitivity, with the data sensitivity of **tribunus** ranking above that of **centurio** but below that of **imperator**.

A component of type ARRAY can be appropriate in contexts where some dimension of a multidimensional security policy can be mapped onto a single scale that is monotonically descending.

## SET Components

A security label component of type SET is an unordered set of no more than 64 elements. Each element of the SET is a string constant of no more than 32 bytes, and must be unique within the component, but the same value can be used in other components. The order in which the elements of a SET component are declared is not significant in regard to the data sensitivity of the categories that these elements identify. The elements and their comma separators must be enclosed between a pair of braces ( `{ ... }` ) symbols.

When a SET component is specified in the definition of a security label, the label can specify one or multiple elements of that component as valid values for the component.

In the following example, DBSECADM defines a security label component called **departments** that is an unordered set of three elements, called **Marketing**, **HR**, and **finance**:

```
CREATE SECURITY LABEL COMPONENT departments
  SET { 'Marketing', 'HR', 'Finance' };
```

Like all components of type SET, the order in which these elements are declared implies no relative rank in data sensitivity.

A component of type SET can be appropriate in contexts where some dimension of a multidimensional security policy can be represented as nominal categories, without any logical basis for ordering them on a monotonic scale, nor for arranging them in a hierarchy.

## TREE Components

A security label component of type TREE has the logical topology of a hierarchy (that is, a simple graph with no loops) that has a single root node and no more than 63 additional nodes. The string constant for the root node must be listed first and must be followed by the ROOT keyword. The string constant for each subsequently declared node must be followed by the keyword UNDER and by the string constant for some previously declared node. The set of elements of the TREE component, including their ROOT and UNDER keywords and comma separators, must be enclosed between a pair of parenthesis ( `( ... )` ) symbols.

The label element specified after the UNDER keyword is called the *parent* of the label element that precedes the same UNDER keyword (which is called the *child* of that parent element). The CREATE SECURITY LABEL COMPONENT statement fails with an error if a node name that follows the UNDER keyword has not already been declared in the same statement.

The string constant that designates the root node of a tree component has the highest data sensitivity. For a user to read or write protected data, each tree component of the user security label must include at least one of the elements in the tree component of the data row security label, or the ancestor of one such element. For example, if "**Beta**" is declared UNDER "**Alpha**" and "**Gamma**" is declared UNDER "**Beta**" then "**Gamma**" also ranks below "**Alpha**" in data sensitivity. Only elements that are in the same chain of parent-child relationships can be compared in their data sensitivity.

The next example defines a security label component called **Oakland** as a tree structure with six nodes:

```
CREATE SECURITY LABEL COMPONENT Oakland
TREE ( 'Port' ROOT,
      'Downtown' UNDER 'Port',
      'Airport' UNDER 'Port',
      'Estuary' UNDER 'Airport',
      'Avenues' UNDER 'Downtown',
      'Hills' UNDER 'Avenues');
```

Here the root node is **Port**, which has the highest data sensitivity. Within this hierarchy, the **Downtown**, **Avenues**, and **Hills** elements represent descending levels of data sensitivity, and the **Airport** element has a higher data sensitivity than the **Estuary** element. In this example, the four component elements that the UNDER keyword designates as parent nodes are each declared before being included in UNDER specifications. A modified version of this example would also be valid if the **Avenues** node declaration preceded the **Airport** node declaration, but an error would result if the **Hills** node declaration had preceded the **Avenues** node declaration.

A component of type TREE can be appropriate in contexts where some dimension of a multidimensional security policy can be mapped to a single logical hierarchy, or to a group of hierarchies that share a common root.

## CREATE SECURITY POLICY statement

Use the CREATE SECURITY POLICY statement to define a new security policy in the current database and to identify its security label components and access rules.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

**CREATE SECURITY POLICY** **IF NOT EXISTS** *policy* **COMPONENTS**

*, component* <sup>150</sup>

**WITH IDSLBACRULES**

**RESTRICT NOT AUTHORIZED WRITE SECURITY LABEL OVERRIDE NOT AUTHORIZED WRITE SECURITY LABEL**

150. You can specify no more than 16 components.

| Element          | Description                              | Restrictions   | Syntax                                  |
|------------------|--|--|---|
| <i>component</i> | A security label component               | Must already exist in the database, and be unique among the names of components for this <i>policy</i> | <a href="#">Identifier on page 1456</a> |
| <i>policy</i>    | Name declared here for a security policy | Must be unique among the names of security policies in the database                                    | <a href="#">Identifier on page 1456</a> |

## Usage

A *security policy* is a named database object that stores the following information:

- It defines a set of security label components that comprise a security label.
- It associates that security label with a set of access rules.

For tables that are protected by a security policy, the access rules enable Informix® to compare the security credentials of a user with the security label of a row or column. The security policy is applied to determine whether a user who holds a given security label can read or write data in a row or column that is labeled with a security label. A security policy has no effect on data that has no security label.

No more than one security policy can be attached to a table at any point in time, and a security policy can include no more than 16 security label components.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a security policy of the specified name is already registered in the current database. In this case, no new security policy is created, and the CREATE SECURITY POLICY statement has no effect on the existing security policy that it referenced.

Only DBSECADM can issue this statement. When the CREATE SECURITY POLICY statement executes successfully, Informix® makes the following updates to the system catalog of the current database:

- Registers the specified *policy* name and the cardinality of its security label components in the **syssecpolicies** table
- Creates for each *component* a new row in the **syssecpolicycomponentrules** table.

## Example of creating a new security policy

This is the sequence in which LBAC security objects associated with a specific security label must be created:

- Security label components
- Security policy
- Security label

For example, the following CREATE SECURITY LABEL COMPONENT statement registers a security label component named **Departments** of type **SET** in the **sysseclabelcomponents** system catalog table of the database:

```
CREATE SECURITY LABEL COMPONENT departments
SET { 'Sales', 'Legal', 'IT', 'CanineResources' };
```

The same statement also registers the four elements of the **departments** component, namely **'Sales'**, **'Legal'**, **'IT'**, and **'CanineResources'** in the **sysseclabelcomponentelements** system catalog table.

Note that this example of a security label component definition specifies no security policy, because only the `CREATE SECURITY POLICY` statement can associate a component with a security policy.

For more information about security label components, see [Types and Elements of Security Label Components on page 320](#) and [CREATE SECURITY LABEL COMPONENT statement on page 318](#).

The following SQL statement registers a new security policy called **WatchDog** in the current database:

```
CREATE SECURITY POLICY WatchDog
  COMPONENTS departments
  WITH IDSLBACRULES;
```

Here the security label component **departments** must already exist in the database, and the name **WatchDog** must be unique among the identifiers of existing security policies in the database. For an explanation of the `WITH IDSLBACRULES` keywords, see [Rules Associated with a Security Policy on page 325](#), which also provides a more general example of defining a security policy with multiple components.

Note that the definition of the **WatchDog** security policy includes no explicit references to security labels. Any security labels that the `CREATE SECURITY LABEL` statement associates with the **WatchDog** security policy must reference **departments** as their *component*, because this security policy has no other component. The following example illustrates this requirement for **WatchDog** labels:

```
CREATE SECURITY LABEL WatchDog.label9
  COMPONENT departments 'Sales','CanineResources';
```

This statement declares **label9** as the name of a new label of the **WatchDog** security policy. It also registers the following information in the **sysseclabels** system catalog table:

- this label name,
- and the numeric identifier of the associated **WatchDog** security policy,
- and the cardinality of its two (2) security label components.

The `COMPONENT` clause in the same example specifies that the **label9** label is valid for both the **'Sales'** and for the **'CanineResources'** elements of the **departments** component of the **WatchDog** security policy.

For more information about security labels, see [Components and Elements of a Security Label on page 317](#) and [CREATE SECURITY LABEL statement on page 316](#).

For information on protecting a new table by attaching a security policy when the table is being created, see the [SECURITY POLICY Clause on page 375](#) of the `CREATE TABLE` statement.

For the syntax to attach or to drop a security policy for an existing table, see [SECURITY POLICY Clause on page 160](#) of the `ALTER TABLE` statement.

## Security Label Components of a Security Policy

The CREATE SECURITY POLICY statement must specify at least one (but no more than 16) security label components. These components must already exist in the database, where DBSECADM can register them with the CREATE SECURITY LABEL COMPONENT statement. The same *component* name cannot be specified more than once in the same CREATE SECURITY POLICY statement.

See the section CREATE SECURITY LABEL COMPONENT for more information about the structure and semantics of security label components.

## Rules Associated with a Security Policy

The WITH IDSLBACRULES keywords specify the read access rules and write access rules that the new security policy enforces. If you do not specify them, these keywords are in effect by default, because the **IDSLBACRULES** access rules are the only access rules that the a security policy can support.

The following **IDSLBACRULES** access rules for read access, called **IDSLBACREAD**, apply when data values are read from labeled rows or columns in SELECT, UPDATE, or DELETE operations:

- **IDSLBACREADARRAY**: Each array component of the user security label must be greater than or equal to the array component of the data row security label. That is, only data at or below the level of the user can be read.
- **IDSLBACREADTREE**: Each tree component of the user security label must include at least one of the elements in the tree component of the data row security label (or the ancestor of one such element).
- **IDSLBACREADSET**: Each set component of the user security label must include the set component of the data row security label.

The following **IDSLBACRULES** access rules for write access, called **IDSLBACWRITE**, apply when data values are written to labeled rows or columns in INSERT, UPDATE, or DELETE operations:

- **IDSLBACWRITEARRAY**: Each array component of the user security label must be equal to the array component of the data row security label. That is, only data at the same level as the user can be written.
- **IDSLBACWRITETREE**: Each tree component of the user security label must include at least one of the elements in the tree component of the data row security label (or the ancestor of one such element).
- **IDSLBACWRITESET**: Each set component of the user security label must include the set component of the data row security label.

If DBSECADM omits the WITH IDSLBACRULES keywords, then those rules are in effect by default. If any specification except IDSLBACRULES follows the WITH keyword, however, the CREATE SECURITY POLICY statement fails with an error, and no security policy is created.

Besides the explicit or default WITH IDSLBACRULES keywords, the CREATE SECURITY POLICY statement must also specify the write access rule to enforce when a user is not authorized to write the explicitly specified security label provided in the DELETE, INSERT, or UPDATE statement for a table protected with this security policy. The security label of the user and the exemption credentials that the user holds determine whether the user has write access to an explicitly provided security label.

- If the CREATE SECURITY POLICY statement specifies **OVERRIDE NOT AUTHORIZED WRITE SECURITY LABEL**, then Informix® uses the value of the user security label, rather than the security label that is explicitly specified in the DELETE, INSERT, or UPDATE statement, to determine whether the user has write-access to data values that are protected by a security label in the DELETE, INSERT, or UPDATE operation.
- The default is **RESTRICT NOT AUTHORIZED WRITE SECURITY LABEL**. If you specify these keywords explicitly, or if they are in effect by default, then DELETE, INSERT, or UPDATE statements fail with an error if the user is not authorized to write data in a row or column that has the explicitly specified security label.

The following example creates a security policy called **MegaCorp** that uses three security label components, with no **OVERRIDE** provision for the user security label to provide write access in DELETE, INSERT, or UPDATE operations on data whose explicitly specified security label does not authorize write access for that user:

```
CREATE SECURITY POLICY MegaCorp
  COMPONENTS levels, compartments, groups
  WITH IDSLBACRULES;
```

For this example to be valid, the **levels**, **compartments**, and **groups** security label components (or components that have been renamed to these identifiers) must have been previously defined by the CREATE SECURITY LABEL COMPONENT statement.

## CREATE SEQUENCE statement

Use the CREATE SEQUENCE statement to create a sequence database object from which multiple users can generate unique integers.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****CREATE SEQUENCEIF NOT EXISTS***owner.**sequence***INCREMENTBY***step***STARTWITH** *origin***MAXVALUE***max***NOMAXVALUE****MINVALUE***min***NOMINVALUE****NOCYCLE CYCLE****CACHE***size***NOCACHE****NOORDER ORDER**

151

| Element         | Description                                      | Restrictions   | Syntax                                      |
|-----------------|--|--|---|
| <i>max</i>      | Upper limit of values                            | Must be an integer > <i>origin</i>   | <a href="#">Literal Number on page 1419</a> |
| <i>min</i>      | Lower limit of values                            | Must be an integer less than <i>origin</i>   | <a href="#">Literal Number on page 1419</a> |
| <i>origin</i>   | First number in the sequence                     | Must be an integer in INT8 or BIGINT range   | <a href="#">Literal Number on page 1419</a> |
| <i>owner</i>    | Owner of <i>sequence</i>                         | Must be an authorization identifier  | <a href="#">Owner name on page 1488</a>     |
| <i>sequence</i> | Name that you declare here for the new sequence  | Must be unique among sequence, table, view, and synonym names                        | <a href="#">Identifier on page 1456</a>     |
| <i>size</i>     | Number of values that are preallocated in memory | Integer > 1, but < cardinality of a cycle ( $= \lfloor (max - min) / step \rfloor$ ) | <a href="#">Literal Number on page 1419</a> |
| <i>step</i>     | Interval between successive values               | Nonzero integer in INT range   | <a href="#">Literal Number on page 1419</a> |

**Usage**

A sequence (sometimes called a *sequence generator* or *sequence object*) returns a monotonically ascending or descending series of unique integers, one at a time. The CREATE SEQUENCE statement defines a new sequence object, declares its identifier, and registers it in the **syssequences** system catalog table.

Authorized users of a sequence can request a new value by including the *sequence*.**NEXTVAL** expression in DML statements. The *sequence*.**CURRVAL** expression returns the current value of the specified *sequence*. **NEXTVAL** and **CURRVAL**

151. Each keyword option can appear no more than once.

expressions are valid only within SELECT, DELETE, INSERT, and UPDATE statements; Informix® returns an error if you attempt to invoke the built-in **NEXTVAL** or **CURRVAL** functions in any other context.

Generated values logically resemble the BIGSERIAL or SERIAL8 data type, but can be negative, and are unique within the sequence. Because the database server generates the values, sequences support a much higher level of concurrency than a serial column can. The values are independent of transactions; a generated value cannot be rolled back, even if the transaction in which it was generated fails.

You can use a sequence to generate primary key values automatically, using one sequence for many tables, or each table can have its own sequence.

CREATE SEQUENCE can specify the following characteristics of a sequence:

- Initial value
- Size and sign of the increment between values
- Maximum and minimum values
- Whether the sequence recycles values after reaching its limit
- How many values are preallocated in memory for rapid access.

A database can support multiple sequences concurrently, but the name of a sequence (or in an ANSI-compliant database, the *owner.sequence* combination) must be unique within the current database among the names of tables, temporary tables, views, synonyms, and sequences.

An error occurs if you include contradictory options, such as specifying both the MINVALUE and NOMINVALUE options, or both CACHE and NOCACHE.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a sequence object of the specified name is already registered in the current database, or if the specified name is the identifier of a table, view, or synonym in the current database.

## Example

The following example creates a sequence, inserts values from the sequence into the table, and selects all rows and columns from the table.

```
CREATE SEQUENCE seq_2
  INCREMENT BY 1 START WITH 1
  MAXVALUE 30 MINVALUE 0
  NOCYCLE CACHE 10 ORDER;

CREATE TABLE tab1 (col1 int, col2 int);
INSERT INTO tab1 VALUES (0, 0);

INSERT INTO tab1 (col1, col2) VALUES (seq_2.NEXTVAL, seq_2.NEXTVAL)

SELECT * FROM tab1;
```

| col1 | col2 |
|------|------|
| 0    | 0    |
| 1    | 1    |

---

[GRANT statement on page 592](#)

[REVOKE statement on page 727](#)

[NEXTVAL and CURRVAL Operators on page 1243](#)

[CREATE SCHEMA statement on page 313](#)

## INCREMENT BY Option

Use the INCREMENT BY option to specify the interval between successive numbers in the sequence. The BY keyword is optional. The interval, or *step* value, can be a positive whole number (for an *ascending* sequence) or a negative whole number (for a *descending* sequence) in the INT8 range. If you do not specify any *step* value, the default interval between successive generated values is `1`, and the sequence is an ascending sequence.

## START WITH Option

Use the START WITH option to specify the first number of the sequence. This *origin* value must be an integer within the INT8 range that is greater than or equal to the *min* value (for an ascending sequence) or that is less than or equal to the *max* value (for a descending sequence), if *min* or *max* is specified in the CREATE SEQUENCE statement. The WITH keyword is optional.

If you do not specify an *origin* value, the default initial value is *min* for an ascending sequence or *max* for a descending sequence. (The [MAXVALUE or NOMAXVALUE Option on page 329](#) and [MINVALUE or NOMINVALUE Option on page 329](#) sections that follow describe the *max* and *min* specifications respectively.)

## MAXVALUE or NOMAXVALUE Option

Use the MAXVALUE option to specify the upper limit of values in a sequence. The maximum value, or *max*, must be an integer in the INT8 range that is greater than the value of the *origin*.

If you do not specify a *max* value, the default is NOMAXVALUE. This default setting supports values that are less than or equal to `2e64` for ascending sequences, or less than or equal to `-1` for descending sequences.

## MINVALUE or NOMINVALUE Option

Use the MINVALUE option to specify the lower limit of values, or *min*. This integer must be in the INT8 range and be less than the value of *origin*.

If you do not specify a *min* value, the default is NOMINVALUE. This default setting supports values that are greater than or equal to 1 for ascending sequences, or greater than or equal to  $-(2^{64})$  for descending sequences.

## CYCLE or NOCYCLE Option

Use the CYCLE option to continue generating sequence values after the sequence reaches the maximum (ascending) or minimum (descending) limit. After an ascending sequence reaches the *max* value, it generates the *min* value for the next sequence value. After a descending sequence reaches the *min* value, it generates the *max* value for the next sequence value.

The default is NOCYCLE. At this default setting, the sequence cannot generate more values after reaching the declared limit. Once the sequence reaches the limit, the next reference to *sequence*.NEXTVAL returns an error.

## CACHE or NOCACHE Option

Use the CACHE option to specify the number of new sequence values that are preallocated in memory for rapid access. This option can enhance the performance of a sequence that grows quickly.

The cache *size* must be a positive whole number in the INT range. If you specify the CYCLE option, then *size* must be less than the number of values in a cycle (or less than  $|(max - min)/step|$ ). The minimum is 2 preallocated values. The default is 20 preallocated values.

The NOCACHE keyword specifies that no generated values (that is, zero) are preallocated in memory for this sequence object.

## ORDER or NOORDER Option

These keywords have no effect on the behavior of the sequence. The sequence always issues values to users in the order of their requests, as if the ORDER keyword were always specified. The ORDER and NOORDER keywords are accepted by the CREATE SEQUENCE statement for compatibility with implementations of sequence objects in other dialects of SQL.

## CREATE SYNONYM statement

Use the CREATE SYNONYM statement to declare and register an alternative name for an existing table, view, or sequence object.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****CREATE**<sup>152</sup>**PUBLIC**<sup>152</sup>**PRIVATE****SYNONYM** **IF NOT EXISTS** *synonym* **FOR***table view**sequence*

| Element            | Description   | Restrictions  | Syntax  |
|--------------------|---|---|---|
| <i>sequence</i>    | Name of a local sequence  | Must exist in the current database  | <a href="#">Identifier on page 1456</a>           |
| <i>table, view</i> | Name of database table, external table, or view for which <i>synonym</i> is being created | Must be registered in the current database, or in a database specified in a qualifier | <a href="#">Database Object Name on page 1450</a> |
| <i>synonym</i>     | Synonym declared here for the name of <i>table, view, or sequence</i>                     | Must be unique among table object names in the database; see also <b>Usage</b> notes. | <a href="#">Database Object Name on page 1450</a> |

**Usage**

Users have the same privileges for a synonym that they have for the database object that the synonym references. The **sysstemplate** and **sysstables** system catalog tables maintain information about synonyms.

You cannot create a synonym for a synonym in the same database.

The identifier of the synonym must be unique among the names of tables, temporary tables, external tables, views, and sequence objects in the same database. (See, however, the section [Synonyms with the Same Name on page 334](#).)

If you include the optional **IF NOT EXISTS** keywords, the database server takes no action (rather than sending an exception to the application) if a synonym of the specified name is already registered in the current database, or if the specified name is the identifier of a table, view, or sequence object in the current database.

Once a synonym is created, it persists until the owner executes the **DROP SYNONYM** statement. (This persistence distinguishes a synonym from an alias that you can declare in the **FROM** clause of a **SELECT** statement. The alias is in scope only while that **SELECT** statement is executing.)

If a synonym refers to a table, view, or sequence in the same database, however, the synonym is automatically dropped if the referenced table, view, or sequence object is dropped. For additional information, see the section [Synonyms for objects outside the current database on page 332](#).

**Related reference**

[ALTER SEQUENCE statement on page 95](#)

[CREATE SEQUENCE statement on page 326](#)

152. This keyword is valid only in databases that are not ANSI/ISO-compliant.

[CREATE SCHEMA statement on page 313](#)

[DROP SYNONYM statement on page 530](#)

[RENAME SEQUENCE statement on page 716](#)

## Synonyms for objects outside the current database

A synonym can be created for any table or view in any database of the database server to which your session is currently connected.

This example declares a synonym for a table outside your current database, in the **payables** database of your current database server.

```
CREATE SYNONYM mysum FOR payables:jean.summary;
```

You can also create a synonym for an external table that the CREATE EXTERNAL TABLE statement registered in the current database. (The external table is registered in the system catalog of the database where it was created, but it is not stored in any database.)

You can also create a synonym for a table or view that exists in a database of a database server that is not your current database server. Both database servers must be online when you create the synonym. In a network, the remote database server verifies that the table or view referenced by the synonym exists when you create the synonym. The next example creates a synonym for a table in a database of a remote database server:

```
CREATE SYNONYM mysum FOR payables@phoenix:jean.summary;
```

The identifier **mysum** now refers to the table **jean.summary**, which is in the **payables** database on the **phoenix** database server. If the **summary** table is dropped from the **payables** database, the **mysum** synonym is left intact. Subsequent attempts to use **mysum** return the error: `Table not found`.

Informix®, however, does not support synonyms for these table objects :

- Typed tables (including any table that is part of a table hierarchy)
- Tables or views with columns of any extended data types
- Sequence objects outside the local database

## PUBLIC and PRIVATE Synonyms

If you use the **PRIVATE** keyword to declare a synonym in a database that is not ANSI-compliant, the unqualified synonym can be used by its owner. Other users must qualify the synonym with the name of the owner.

If you use the **PUBLIC** keyword (or no keyword at all), anyone who has access to the database can use your synonym. If the database is not ANSI-compliant, a user does not need to know the name of the owner of a public synonym.

In an ANSI-compliant database, all synonyms are private. If you use the **PUBLIC** or **PRIVATE** keywords, the database server issues a syntax error.

### Examples of PRIVATE and PUBLIC synonyms

Suppose that in a database that is not ANSI-compliant, user **primus** issues the following SQL statements:

```
CREATE SEQUENCE IF NOT EXISTS MySequence
  INCREMENT BY 1 START WITH 1
  MAXVALUE 8000 MINVALUE 0
  NOCYCLE CACHE 20 ORDER;

CREATE PRIVATE SYNONYM IF NOT EXISTS anaphora FOR MySequence;
```

Now user **primus** is the owner of two new objects in the current database:

- a sequence object called **MySequence**,
- and a private synonym called **anaphora** for the **MySequence** sequence.

Suppose that in the same database, user **primus** also issues the following SQL statements

- to create a permanent table called **twoSmall**,
- and to declare **litotes** as a private synonym for the **twoSmall** table:

```
CREATE TABLE IF NOT EXISTS twoSmall (c1 SMALLINT, c2 SMALLINT);
INSERT INTO twoSmall VALUES (0, 0);

CREATE PRIVATE SYNONYM litotes FOR twoSmall;
```

In the same database that is not ANSI-compliant, another user could reference both the **litotes** and **anaphora** synonyms in the following INSERT statement, where **twoSmall** is the target table:

```
INSERT INTO primus.litotes (col1, col2)
  VALUES (primus.anaphora.NEXTVAL, primus.anaphora.NEXTVAL);
```

Although both synonyms in the INSERT statement were created as **PRIVATE**, the user can access the objects that those synonyms reference by qualifying the synonym names with the authorization identifier of **primus**, who is the owner of those synonyms.

If instead of creating the private synonyms in the previous examples, user **primus** had implicitly or explicitly created both **anaphora** and **litotes** as **PUBLIC** synonyms, any other user who held sufficient access privileges could omit the authorization identifier of **primus** in the previous INSERT statement:

```
INSERT INTO litotes (col1, col2)
  VALUES (anaphora.NEXTVAL, anaphora.NEXTVAL);
```

In a database that was not created as **MODE ANSI**, the following example shows the syntax for user **primus** to create **synecdoche** as a **PUBLIC** synonym for the **MySequence** object:

```
CREATE SYNONYM IF NOT EXISTS synecdoche FOR MySequence;
```

In the example above, **synecdoche** is a public synonym by default, because neither the **PUBLIC** nor **PRIVATE** keyword was specified.

In the same database, the next statement creates **zeugma** as an explicit **PUBLIC** synonym:

```
CREATE PUBLIC SYNONYM IF NOT EXISTS zeugma FOR MySequence;
```

In the same database, the next statement creates **pleonasm** as a **PRIVATE** synonym for the same sequence object:

```
CREATE PRIVATE SYNONYM IF NOT EXISTS pleonasm FOR MySequence;
```

In a database created as **MODE ANSI**, the next statement creates **asyndeton** as a **PRIVATE** synonym, because ANSI-compliant databases do not support **PUBLIC** synonyms:

```
CREATE SYNONYM asyndeton FOR MySequence;
```

In a database created as `MODE ANSI`, the next statement fails with a syntax error, because the `CREATE SYNONYM` statement does not support the `PRIVATE` or `PUBLIC` keywords in ANSI-compliant databases:

```
CREATE PRIVATE SYNONYM litotes FOR MySequence;
```

For information about the scope of reference of the identifiers of public and private synonyms in databases that are not ANSI-compliant, see the topic [Synonyms with the Same Name on page 334](#).

## Synonyms with the Same Name

In an ANSI-compliant database, the *owner.synonym* combination must be unique among all synonyms, tables, views, and sequences. You must specify *owner* when you refer to a synonym that you do not own, as in this example:

```
CREATE SYNONYM emp FOR accting.employee
```

In a database that is not ANSI-compliant, no two public synonyms can have the same identifier, and the identifier of a synonym must also be unique among the names of tables, views, and sequences in the same database.

The *owner.synonym* combination of a private synonym must be unique among all the synonyms in the database. That is, more than one private synonym with the same name can exist in the same database, but a different user must own each of these synonyms. The same user cannot create both a private and a public synonym that have the same name. For example, the following code generates an error:

```
CREATE SYNONYM our_custs FOR customer;
CREATE PRIVATE SYNONYM our_custs FOR cust_calls;-- ERROR!!!
```

A private synonym can be declared with the same name as a public synonym only if the two synonyms have different owners. If you own a private synonym, and a public synonym exists with the same name, the database server resolves the unqualified name as the private synonym. (In this case, you must specify *owner.synonym* to reference the public synonym.) If you use `DROP SYNONYM` with the unqualified synonym identifier when your private synonym and the public synonym of another user both have the same identifier, only your private synonym is dropped. If you repeat the same `DROP SYNONYM` statement, the database server drops the public synonym.

## Chaining Synonyms

### About this task

If you create a synonym for a table or view that is not in the current database, and this table or view is dropped, the synonym remains registered in the system catalog. You can create a new synonym whose identifier is the name of the dropped table or view, but that points to a table or view in the current database (or in another database).

In this way, after you rename a table, or after you move a table or view to another database location, you can chain synonyms together so that the original synonym remains valid in existing applications. You can chain up to 16 synonyms in this manner.

Chaining synonyms to reference a relocated table object is possible for tables or views, but this is not valid for synonyms that point to a sequence object, because `CREATE SYNONYM` can define synonyms only for sequences that are registered in the current database.

The following steps chain two synonyms together for the **customer** table, which will ultimately reside on the **zoo** database server. Here ellipses ( . . . ) mark CREATE TABLE statements that are not complete:

1. In the **stores\_demo** database on the database server that is called **training**, issue the following statement:

```
CREATE TABLE customer (lname CHAR(15)...);
```

2. On the database server called **acctng**, issue the following statement:

```
CREATE SYNONYM cust FOR stores_demo@training:customer;
```

3. On the database server called **zoo**, issue the following statement:

```
CREATE TABLE customer (lname CHAR(15)...);
```

4. On the database server called **training**, issue the following statement:

```
DROP TABLE customer;
CREATE SYNONYM customer FOR stores_demo@zoo:customer;
```

The synonym **cust** on the **acctng** database server now points to the **customer** table on the **zoo** database server.

The following steps show an example of chaining two synonyms together and changing the table to which a synonym points:

1. On the database server called **training**, issue the following statement:

```
CREATE TABLE customer (lname CHAR(15)...);
```

2. On the database server called **acctng**, issue the following statement:

```
CREATE SYNONYM cust FOR stores_demo@training:customer;
```

3. On the database server called **training**, issue the following statement:

```
DROP TABLE customer;
CREATE TABLE customer (lastname CHAR(20)...);
```

The synonym **cust** on the **acctng** database server now points to a new version of the **customer** table on the **training** database server.

## CREATE TABLE statement

Use the CREATE TABLE statement to create a new permanent table in the current database.

You can use the CREATE TABLE statement to create relational-database tables or to create typed tables (object-relational tables). For information about how to create temporary tables, see [CREATE TEMP TABLE statement on page 397](#). For information about how to create external table objects that are not stored in the database, see [CREATE EXTERNAL TABLE Statement on page 213](#).

See [Logging Options on page 346](#)

## Usage

When you create a table, you must declare its name and define its schema and its logging status. You can optionally specify additional attributes, as identified in topics that follow. The syntax diagram shows the sequence of required or optional specifications. These syntax segments of the CREATE TABLE statement, and some of their components, are identified in the five lists that follow.

The following keywords and clauses define column attributes of a new table:

**Table 3. Defining the name, data-type, default value, and security label for a column**

| Specification       | Topic  | What the keyword or clause defines  |
|---------------------|--|---|
| Column Definition   | <a href="#">Column definition on page 346</a>                | Column name and attributes, including data type, constraints, default value |
| DEFAULT             | <a href="#">DEFAULT clause of CREATE TABLE on page 350</a>   | Default value for a column  |
| COLUMN SECURED WITH | <a href="#">Column SECURED WITH label clause on page 348</a> | An LBAC label for a protected column  |

The following keywords and clauses define constraints on the new table:

**Table 4. Defining constraints on one or more columns of the table**

| Specification            | Topic  | What the keyword or clause defines   |
|--------------------------|--|--|
| Single-Column Constraint | <a href="#">Single-Column Constraint Format on page 353</a>      | Data-integrity, referential, or other constraints on an individual column    |
| Constraint Definition    | <a href="#">Constraint Definition on page 361</a>                | Name, attributes, and enabled or disables status of constraints on the table |
| NULL                     | <a href="#">Using the NULL Constraint on page 354</a>            | Column allows NULL values  |
| NOT NULL                 | <a href="#">Using the NOT NULL Constraint on page 354</a>        | Column does not allow NULL values  |
| UNIQUE or DISTINCT       | <a href="#">Using UNIQUE or DISTINCT Constraints on page 355</a> | Column does not allow duplicate values                                       |
| CHECK                    | <a href="#">CHECK Clause on page 360</a>                         | Check constraints with other columns   |
| PRIMARY KEY              | <a href="#">Using the PRIMARY KEY Constraint on page 356</a>     | Contains a non-NULL unique value for each row in a table                     |
| FOREIGN KEY              | <a href="#">Using the FOREIGN KEY Constraint on page 366</a>     | Establishes dependencies between tables                                      |
| REFERENCES               | <a href="#">REFERENCES Clause on page 356</a>                    | Referential-integrity constraints with other columns                         |

| STATCHANGE, STATLEVEL                | <a href="#">Statistics options of the CREATE TABLE statement on page 395</a> | Change threshold and granularity of data distribution statistics |
| AS SELECT                            | <a href="#">AS SELECT clause on page 341</a>                                 | Creates and populates a query result table                       |

## Uniqueness rules for table names and column names

When you create a new table, every column must have a data type associated with it. The names of columns must be unique among the column in the same table. (The OF TYPE option specifies an existing named ROW type, whose fields provide column names and column data types for the typed table that you are creating.)

If the database was not created as MODE ANSI, the *table* name must be unique among all the identifiers of tables, views, sequence objects, and synonyms within the same database.

In an ANSI-compliant database, the combination *owner.table* must be unique among all the tables, synonyms, views, and sequence objects in the same database. Table objects qualified with different *owner* names can have the same identifier.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a table of the specified name is already registered in the current database.

## Additional syntax notes for CREATE TABLE

For the restricted syntax options of CREATE TABLE statements that store the result set of a query in a new permanent table, see the [AS SELECT clause on page 341](#).

In DB-Access, using CREATE TABLE outside the CREATE SCHEMA statement generates warnings if you use the **-ansi** flag or if the **DBANSIWARN** environment variable is set.

## The order of table options

The syntax diagram shows the order of table options in CREATE TABLE statements that include more than one of the following options:

- WITH options for specialized columns
- SECURITY POLICY options
- Storage options
- LOCK MODE options
- USING Access-Method clause
- Statistics options

For example, the following two CREATE TABLE statements are equivalent:

```
CREATE STANDARD TABLE IF NOT EXISTS myShadowy_tab(co1A INT, co1B CHAR)
  WITH ERRKEY, WITH CRCOLS, WITH AUDIT LOCK MODE ROW;

CREATE STANDARD TABLE IF NOT EXISTS myShadowy_tab(co1A INT, co1B CHAR)
  WITH AUDIT, WITH ERRKEY, WITH CRCOLS LOCK MODE ROW;
```

If you issue both statements consecutively in the same database, the second statement fails, because the table called **myShadowy\_tab** that the first statement created already exists in the database. Because of the `IF NOT EXISTS` keywords, the redundant second statement returns no error, but it creates no new table.

The following example fails with an error, because no other Options clause can precede a WITH clause:

```
CREATE TABLE shadow_columns (co1A INT, co1B CHAR)
  LOCK MODE ROW WITH AUDIT, WITH ERRKEY, WITH CRCOLS; --incorrect options order
```

The next CREATE TABLE example also fails, because the Statistics option cannot precede the LOCK MODE option within the same Options clause:

```
CREATE TABLE shadow_columns (colA INT, colB CHAR)
  STATCHANGE 25 STATLEVEL TABLE LOCK MODE PAGE; --bad options order
```

---

## AS SELECT clause

Use the AS SELECT clause of the CREATE TABLE statement to create a new table and to insert into it the data rows that are the result set of a specified query.

This syntax closely resembles in its functionality the [INTO STANDARD and INTO RAW Clauses on page 856](#) of the SELECT statement.

Only the following subset of the CREATE TABLE statement syntax is valid when you include the AS SELECT clause to create a new query result table, and to populate that table with the qualifying rows that the specified query returns:

**CREATE**

**STANDARD RAW**

**TABLEIF NOT EXISTS**

*owner.*

*table*

(

,

*column column\_alias*

*column::target\_data\_type*

)

<sup>164</sup> Storage Options<sup>165</sup>

| <i>target_data_type</i> | Data type that is returned by an explicit cast. This will be the data type of a column in the result table. | See <a href="#">Rules for the Target Data Type on page 1218</a> | <a href="#">Data Type on page 1163</a> |

## Usage

When using the CREATE TABLE . . . AS SELECT statement to create a new permanent table to store the result of a query, you can specify the logging mode of the table as STANDARD or RAW. If you omit both of these keywords, the default is STANDARD.

You can also optionally specify the following attributes for the query result table:

- A single storage location, or a distributed storage scheme
- The storage sizes of its first extent and next extent
- Its PAGE or ROW locking granularity

If you omit a storage or locking specification, the database server uses the default value.

If an error occurs while the database server is populating the new table with qualifying rows from the query in the AS SELECT clause, the operation is rolled back, and no new table is created or populated.

The columns that appear in the Projection list of the AS SELECT clause can be from any local table, or view, or from a remote database (which must be referenced in the qualified table name), but the new table must be created in the local database.

In a grid environment, if the tables in the FROM clause of the AS SELECT clause have the same schema in all the participating database servers of the specified grid or region, you can include the AS SELECT clause to create a result table from a grid query.

## Supported data types

The CREATE TABLE . . . AS SELECT statement supports user-defined data types and all the built-in Informix® data types.

No more than one serial column, however, is allowed in the new result table. After the first column of type SERIAL, SERIAL8, or BIGSERIAL is included, any subsequent SERIAL, SERIAL8, or BIGSERIAL column is created as an INTEGER, INTEGER8, or BIGINTEGER column.

## Column names in the result table

By default, the column names in the new permanent table are the names that are specified in the SELECT list of the Projection clause. If an asterisk ( \* ) is the SELECT list of the Projection clause, the asterisk is expanded to all the column names in the corresponding tables or views in the FROM clause of the SELECT statement. Any explicit or implicit shadow columns in table objects specified by the FROM clause are not expanded by the asterisk specification.

On systems that implement Enterprise Replication, you can use the ADD CRCOLS, ADD REPLCHECK, and ADD ERKEY options to the ALTER TABLE statement to add the corresponding shadow columns to a result table that the AS SELECT clause creates.

All expressions in the SELECT list of the Projection clause, other than simple column expressions, must have a display label (also called a *column alias*). This is used as the identifier of the corresponding column in the new query result table. If a column expression has no display label, the result table uses the column name from the source table in the FROM clause of the query.

In the CREATE TABLE . . . AS SELECT statement, a column alias can be specified in either of two ways:

- As a comma-separated list of aliases, immediately following the TABLE keyword, similar to the syntax of the INSERT INTO . . . SELECT FROM statement
- As a part of the SELECT list in the Projection clause, just as in result tables that the SELECT . . . INTO STANDARD or SELECT . . . INTO RAW statements can create.

If both the SELECT list of the Projection clause and the comma-separated list of aliases that follows the TABLE keyword are present in the CREATE TABLE . . . AS SELECT statement, the comma-separated list of column aliases takes precedence. In this case, any column alias that you declare in the AS SELECT clause is ignored.

The CREATE TABLE . . . AS SELECT statement fails with an error in the following cases:

- If no display label or column alias is declared for a nontrivial column expression.
- If a display label or column alias has the same name as another column in the new result table.
- Except for storage options and LOCK MODE properties, the CREATE TABLE . . . AS SELECT statement cannot define constraints or any other special properties for columns of the new table.
- If a comma-separated list of aliases follows the TABLE keyword, but that list has fewer aliases than the number of expressions in the SELECT list of the Projection clause.

But if the column alias list that follows the TABLE keyword has more items than the SELECT list of the Projection clause, in this case the database server ignores the excess column aliases, and no exception occurs.

The AS SELECT clause can include a column in its ORDER BY clause that is not in the SELECT list of its Projection clause.

### Restrictions on result tables

Besides restrictions that the section above identifies for display labels or column aliases and for unsupported column properties in result tables, the SELECT INTO . . . TABLE syntax of the SELECT statement is not valid as a part of a subquery.

As with most DDL statements, attempts to create the new result table in another database using the fully qualified table name fail with a syntax error. It is similarly an error to create a result table with the same name as an existing table, unless the AS SELECT clause includes the `IF NOT EXISTS` keywords, as described below.

### IF NOT EXISTS keywords

If the name that you declare for the query result table in the AS SELECT clause is unique among the names of permanent tables, synonyms, views, and sequences in the database, the database server creates a query result table and populates it with all the qualifying rows that the query returns, whether or not the AS SELECT clause includes the `IF NOT EXISTS` keywords. (If the query returns no rows, the result table is empty, but its schema is registered in the system catalog of the database as a new permanent table.)

If the AS SELECT clause includes the `IF NOT EXISTS` keywords, and the name that you declare for the query result table is not unique among the names of permanent table objects in the database, the query that the AS SELECT clause defines is not executed, no result table is created, and the database server returns the message

```
0 row(s) retrieved into table.
```

If the AS SELECT clause omits the `IF NOT EXISTS` keywords, and the name that you declare for the query result table is not unique among the names of permanent table objects in the database, no result table is created, and the database server returns an error.

## Examples of creating and populating result tables

The following example creates a new raw table called **rtab1** to store the results of a join query:

```
CREATE RAW TABLE IF NOT EXISTS rtab1
AS
SELECT t1col1, t1col2, t2col1
FROM tab1, tab2
WHERE t1col1 < 100 and t2col1 > 5;
```

In the example above, the new query result table **rtab1** would contain the columns **t1col1**, **t1col2** and **t2col1**.

The next example fails with error -249, because it declares no display label for the `col1+5` column expression:

```
CREATE TABLE IF NOT EXISTS qtab1
AS
SELECT col1+5, col2
FROM tab1;
```

By declaring the column alias **qcol1** for the column expression in the Projection clause that includes the + operator, the following revised query avoids the -249 error that the previous example returns:

```
CREATE TABLE IF NOT EXISTS qtab1 (qcol1, col2)
AS
SELECT col1+5, col2
FROM tab1;
```

The corrected example above creates the standard **qtab1** table to store the AS SELECT clause query results.

The next example uses different but equivalent aliasing syntax to declare the same **qcol1** alias in the AS SELECT clause, rather than in the list of column aliases:

```
CREATE TABLE IF NOT EXISTS qtab1
AS
SELECT col1+5 qcol1, col2
FROM tab1;
```

The CREATE TABLE statement above similarly avoids the -249 error, and creates a result table that is identical in schema and in data content to the **qtab1** table in the previous example. In both of these examples, the result table has two columns, **qcol1** and **col2**. If **col1** is of type INTEGER, then **qcol1** would be type DECIMAL, the return data type from the expression `col1+5`.

As the syntax diagram indicates, the Storage and Lock Mode options to the CREATE TABLE statement are valid with the AS SELECT clause. The following example uses the `FRAGMENT BY EXPRESSION` keywords to define distributed storage for the query result table, where the **fcol1** column alias is the fragment key, and ROW is the locking granularity:

```
CREATE TABLE IF NOT EXISTS permstab (fcol1, col2)
FRAGMENT BY EXPRESSION
```

```

fcol1 < 300 IN dbs1,
fcol1 >=300 IN dbs2
LOCK MODE ROW
AS SELECT col1::FLOAT, col2
FROM tab1;

```

Any rows with **fcol1** values below 300 are inserted into dbspace **dbs1**. Rows with larger **fcol1** values are stored in the **dbs2** dbspace.

## Logging Options

Use the Logging Type options to specify logging characteristics that can improve performance in various bulk operations on the table.

Other than the default option (STANDARD) that is used for OLTP databases, these logging options are used primarily to improve performance in data warehousing databases.

A permanent table can have either of the following logging characteristics.

### Logging Type

#### Effect

#### STANDARD

Logging tables that allow rollback, recovery, and restoration from archives. This type is the default. Use this type of table for all the recovery and constraints functionality that OLTP databases require.

#### RAW

Nonlogging tables that do not support primary key constraints or unique constraints, but that support referential constraints, and can be indexed and updated. Use this type of table for quickly loading data.

**Warning:** Use raw tables for fast loading of data, but set the logging type to STANDARD and perform a level-0 backup before you use the table in a transaction or modify the data within the table. If you must use a raw table within a transaction, either set the isolation level to Repeatable Read or lock the table in exclusive mode to prevent concurrency problems.

The CREATE RAW TABLE statement is not supported on secondary servers within a high-availability cluster.

For more information on these logging types of tables, refer to your *Informix® Administrator's Guide*.

## Column definition

Use the column definition segment of the CREATE TABLE statement to declare the name and data type (and optionally the default value and the constraints or the security label) of a single column of the new table.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

## Column Definition

*column*Data Type <sup>168</sup>DEFAULT Clause <sup>169</sup>Single-Column Constraint Format <sup>170</sup>Single-Column Constraint Format <sup>170</sup>DEFAULT Clause <sup>169</sup>Column SECURED WITH label clause <sup>171</sup>

| Element       | Description  | Restrictions                 | Syntax                                  |
|---------------|--|------------------------------|---|
| <i>column</i> | Name that you declare here for a column in the table | Must be unique in this table | <a href="#">Identifier on page 1456</a> |

**Usage**

Because the maximum row size is 32,767 bytes, no more than approximately 97 columns can be of COLLECTION data types (SET, LIST, and MULTiset). No more than approximately 195 columns in the table can be of the data types BYTE, TEXT, ROW, LVARCHAR, NVARCHAR, VARCHAR, and varying-length UDTs. (Here 195 columns is an approximate lower limit that applies to platforms with a 2 KB base page size. For platforms with a base page size of 4 KB, such as Windows™ and AIX® systems, the upper limit is approximately 450 columns of these data types.)

The upper limit on the number of columns of these data types also depends on other data that describes the table that the database server stores in the same partition. For some tables, the maximum number of columns might be lower, if the aggregate length of all the SQL identifiers (including the database name, table names, and index names) that are compressed and stored on the disk reduces the free space that is available for the columns.

**Character column size semantics**

Any explicit or default storage size specifications for columns of built-in character types, such as CHAR, LVARCHAR, NCHAR, NVARCHAR, or VARCHAR, are interpreted in units of bytes, unless the SQL\_LOGICAL\_CHAR configuration parameter is set to enable logical character semantics in data type declarations.

Interpreting size declarations as logical character semantics reduces the risk of insufficient storage for column values in INSERT and UPDATE operations. When the data length exceeds the maximum size of the column, then the result depends on the ANSI-compliance status of the database:

- If the database is not ANSI-compliant, HCL Informix® truncates the value. No warning is generated when this truncation occurs.
- If the database is ANSI-compliant, then the INSERT or UPDATE operation fails and this error is returned:

```
-1279: Value exceeds string column length.
```

168. See [Data Type on page 1163](#)

169. See [DEFAULT clause of CREATE TABLE on page 350](#)

170. See [Single-Column Constraint Format on page 353](#)

171. See [Column SECURED WITH label clause on page 348](#)

See the description of the `SQL_LOGICAL_CHAR` configuration parameter for more information about the effect of its setting in locales that support a multibyte code set, such as **UTF-8**, where a single logical character can require more than one byte of storage.

### Restrictions on `IDSSECURITYLABEL` columns

The following restrictions affect the use of the Column Definition clause to specify a column of the `IDSSECURITYLABEL` data type to support label-based access control (LBAC):

- If the table has no security policy, a user who holds the `DBSECADM` role must also include the `SECURITY POLICY` clause to specify a security policy.
- Only a user who holds the `DBSECADM` role can specify a column of type `IDSSECURITYLABEL`.
- A table can have at most one column of type `IDSSECURITYLABEL`.
- The `IDSSECURITYLABEL` column cannot have column protection.
- The `IDSSECURITYLABEL` column has an implicit `NOT NULL` constraint by default. If no *label* name for the default security label is specified in the `DEFAULT` clause, the default value for this column is the security label for write access that is held by the user.
- The `IDSSECURITY LABEL` column cannot have any explicit single-column constraints, and it cannot be part of multiple-column referential or check constraints.
- The `IDSSECURITYLABEL` column cannot be encrypted.
- If the table is secured with both row-level and column-level protection, the default or explicit security label of the `IDSSECURITYLABEL` column must have the same security policy as any labels that the `COLUMN SECURED WITH` clause references.

As with any SQL identifier, syntactic ambiguities (and sometimes error messages or unexpected behavior) can occur if the *column* name is a keyword, or if it is the same as the *table* name, or the name of another table that you later join with the *table*). For information about the keywords of Informix®, see [Keywords of SQL for HCL Informix on page 1527](#).

If you define a column of a table as a named ROW type, the table does not adopt any constraints of the named ROW.

---

## Column `SECURED WITH` label clause

Use the `COLUMN SECURED WITH` label clause to provide label-based column-level security protection for a table by attaching a security label to the column. The label must be part of a security policy that the `SECURITY POLICY` clause attaches to the table.

This syntax fragment is part of the [Column definition on page 346](#).

Column `SECURED WITH` label clause

**COLUMN**

**SECURED WITH***label*

| Element      | Description              | Restrictions   | Syntax                                  |
|--------------|--------------------------|--|---|
| <i>label</i> | Name of a security label | Must exist and must belong to the security policy that protects the table. | <a href="#">Identifier on page 1456</a> |

## Usage

The Column security clause can add label-based column-level protection. This clause is valid only for tables that are protected by a security policy. For the CREATE TABLE syntax to associate a label-based security policy with a table, see [SECURITY POLICY Clause on page 375](#).

The user who includes the Column SECURED WITH label clause in the CREATE TABLE statement must hold the DBSECADAM role.

The security label can be the same label that protects other rows or columns of the table, or it can be a different label of the same security policy. The following restrictions apply to the `SECURED WITH` clause:

- The column cannot be of data type `IDSSECURITYLABEL`.
- You must specify the label without the policy qualifier, rather than as *policy.label*.
- The label must be a label of the security policy that secures the table.

## Example of creating a table with column-level protection

The following CREATE TABLE statement defines a protected table called **Rigel** with the following schema:

```
CREATE TABLE Rigel IF NOT EXISTS Rigel
  (Col1 NCHAR(134) COLUMN SECURED WITH LabelRW,
   Col2 DATE,
   Col3 CHAR(20),
   SECURITY POLICY company;
```

The column security clause for column **Col1** provides column-level protection for the data stored in that column of the **Rigel** table by associating the security label **LabelRW** with column **Col1**. The SECURITY POLICY clause specifies the **company** security policy.

The CREATE TABLE statement in this example would fail if no security policy called **company** is defined in the database, or if the **company** policy exists, but no security label **LabelRW** is a component of the **company** security policy.

## Example of creating a table with column-level and row-level protection

The following CREATE TABLE statement defines a protected table called **Vega** with the following schema:

```
CREATE TABLE Vega IF NOT EXISTS Vega
  (Col1 NCHAR(134) COLUMN SECURED WITH LabelRW,
   Col2 DATE,
   Col3 CHAR(20),
   Col4 IDSSECURITYLABEL DEFAULT LabelRW)
  SECURITY POLICY company;
```

The column security clause for column **Col1** provides column-level protection for the data stored in that column of the **Vega** table by associating the security label **LabelRW** with column **Col1**.

The table also has row-level protection from the **company** security policy, whose label **LabelRW** is the default value of the `IDSSECURITYLABEL` data type of **Col4**. In this example, label **LabelRW** provides row-level protection in **Col4**, and column-level protection in **Col1**.

The label stored in column **Col4** and the label securing column **Col1** could be different security labels, but both must be labels of the same **company** security policy.

The `CREATE TABLE` statement in this example would fail if no security policy called **company** is defined in the database, or if the **company** policy exists, but no security label **LabelRW** is a component of the **company** security policy.

## DEFAULT clause of CREATE TABLE

Use the `DEFAULT` clause in the `CREATE TABLE` statement to specify the default value for the database server to insert into a column when no explicit value for the column is specified.

This syntax fragment is part of the [Column definition on page 346](#).

DEFAULT Clause

### DEFAULT

**NULL** *label literal* **USER CURRENT\_USER**

172

### CURRENT SYSDATE

DATETIME Field Qualifier <sup>173</sup>

### TODAY SITENAME DBSERVERNAME

| Element        | Description                                | Restrictions  | Syntax                                  |
|----------------|--|---|---|
| <i>label</i>   | Name of a security label                   | Must exist and must belong to the security policy that protects the table. The column must be of type <code>IDSSECURITYLABEL</code> . | <a href="#">Identifier on page 1456</a> |
| <i>literal</i> | String of alphabetic or numeric characters | Must be an appropriate data type for the column. See <a href="#">Using a Literal as a Default Value on page 351</a> .                 | <a href="#">Expression on page 1193</a> |

You cannot specify default values for `SERIAL`, `BIGSERIAL`, or `SERIAL8` columns.

## Using NULL as a default value

If you specify no default value for a column, the default is `NULL` unless you place a `NOT NULL` constraint on the column. In this case, no default value exists.

If you specify `NULL` as the default value for a column, you cannot specify a `NOT NULL` constraint as part of the column definition. (For details of `NOT NULL` constraints, see [Using the NOT NULL Constraint on page 354](#).)

`NULL` is not a valid default value for a column that is part of a primary key.

172. Informix® extension

173. See [DATETIME Field Qualifier on page 1191](#)

For columns of large-object data types like BYTE, TEXT, BLOB, or CLOB, or of field-value pair data types like BSON or JSON, the only valid default value is `NULL`.

### Example of setting the default value of a BSON column

The following CREATE TABLE statement fails with an exception, because the BSON data type of the **data** column requires `NULL` as its default, rather than the specified field-value pair:

```
CREATE TABLE tab1
(
  id VARCHAR(128) NOT NULL,
  data "informix".BSON DEFAULT '{"id:1}":JSON',
  modcount BIGINT,
  flags INTEGER DEFAULT 12,
  PRIMARY KEY (data)
);

(U0001) - bson_to_char: unhandled storage type '98'
Error in line 8
```

The following successful statement replaces the non-NULL default value for **data** with the only valid default for BSON columns, and drops the PRIMARY KEY constraint on the **data** column.

```
CREATE TABLE tab1
(
  id VARCHAR(128) NOT NULL,
  data "informix".BSON DEFAULT NULL,
  modcount BIGINT,
  flags INTEGER DEFAULT 12
);
```

If this successful revision of the first example had defined a the PRIMARY KEY constraint on the **data** column, however, as in the first example, the CREATE TABLE statement would have failed with a different error, because for any data type, a column that has `NULL` as its default value cannot be part of a primary key.

### Using a Literal as a Default Value

You can designate a literal value as a default value. A literal value is a string of alphabetic or numeric characters. To use a literal value as a default value, you must adhere to the syntax restrictions in the following table.

| For Columns of Data Type  | Format of Default Value  |
|---|--|
| BOOLEAN   | Use <code>'t'</code> or <code>'f'</code> (respectively for <i>true</i> or <i>false</i> ) as a <a href="#">Quoted String on page 1424</a> .   |
| CHAR, CHARACTER VARYING, DATE, VARCHAR, NCHAR, NVARCHAR, LVARCHAR | <a href="#">Quoted String on page 1424</a> .<br>DATE literals must be of the format that the <b>DBDATE</b> (or else <b>GL_DATE</b> ) environment variable specifies. In the default locale, if neither <b>DBDATE</b> nor <b>GL_DATE</b> is set, date literals must be of the <i>mm/dd/yyyy</i> format. |
| DATETIME  | <a href="#">Literal DATETIME on page 1414</a>  |

| For Columns of Data Type   | Format of Default Value   |
|--|---|
| BIGINT, DECIMAL, FLOAT, INT8, INTEGER, MONEY, SMALLFLOAT, SMALLINT | <a href="#">Literal Number on page 1419</a>   |
| INTERVAL   | <a href="#">Literal INTERVAL on page 1418</a>   |
| Opaque data types  | <a href="#">Quoted String on page 1424</a> in format of <a href="#">Single-Column Constraint Format on page 353</a> |

For example, the following statement includes a column definition with a literal DATETIME:

```
CREATE TABLE tabl
(
  id VARCHAR(128) NOT NULL,
  date DATETIME YEAR TO FRACTION(3) DEFAULT DATETIME(1971-01-01 00:00:00.000)
    YEAR TO FRACTION(3),
  modcount BIGINT,
  flags INTEGER DEFAULT 12
);
```

### Using a Constant Expression as a Default Value

You can specify a constant expression as the default column value.

The following table lists constant expressions that you can specify, the data type requirements, and the recommended size (in bytes) for their corresponding columns.

**Table 8. Constant expressions as default values**

| Constant Expression    | Data Type Requirement                                       | Recommended Size  |
|------------------------|---|---|
| CURRENT, SYSDATE       | DATETIME column with matching qualifier                     | Enough bytes to store the longest DATETIME value for the locale |
| DBSERVERNAME, SITENAME | CHAR, VARCHAR, NCHAR, NVARCHAR, or CHARACTER VARYING column | 128 bytes   |
| TODAY                  | DATE column   | Enough bytes to store the longest DATE value for the locale     |
| USER, CURRENT_USER     | CHAR, VARCHAR, NCHAR, NVARCHAR, or CHARACTER VARYING column | 32 bytes  |

These column sizes are recommended because, if the column length is too small to store the default value during INSERT or ALTER TABLE operations, the database server returns an error.

You cannot designate a constant expression that behaves like a variant function (that is, CURRENT, SYSDATE, USER, TODAY, SITENAME, or DBSERVERNAME) as the default value for a column that holds an OPAQUE or DISTINCT data type. In addition, larger column sizes are required if the data values are encrypted, or if they are encoded in the Unicode character set of the **UTF-8** locale. (See the description of the SET ENCRYPTION statement later in this chapter for more information about storage size requirements for encrypted data.)

For descriptions of these functions, see [Constant Expressions on page 1235](#).

The following example creates a table with columns that have literal default values. The **acc\_id** column value defaults to the authorization identifier of the current user.

```
CREATE TABLE accounts (
  acc_num INTEGER DEFAULT 1,
  acc_type CHAR(1) DEFAULT 'A',
  acc_descr CHAR(20) DEFAULT 'New Account',
  acc_date DATETIME YEAR TO DAY DEFAULT SYSDATE DATETIME YEAR TO DAY,
  acc_id CHAR(32) DEFAULT CURRENT_USER);
```

## Single-Column Constraint Format

Use the Single-Column Constraint format to define and declare the name of at least one constraint on a single column, and to specify the mode of each constraint.

The Single-Column Constraint format can associate one or more constraints with a column, in order to perform any of the following tasks:

- Create one or more data-integrity constraints for a column.
- Specify a meaningful name for a constraint.
- Specify the constraint-mode that controls the behavior of a constraint during insert, delete, and update operations.

This syntax fragment is part of the [Column definition on page 346](#).

Single-Column Constraint Format

**NULL NOT NULL**

<sup>174</sup> **DISTINCT**

**UNIQUE PRIMARY KEY**

REFERENCES Clause <sup>176</sup>

CHECK Clause <sup>177</sup>

<sup>174</sup> Constraint Definition <sup>175</sup>

The NULL constraint specifies that the column can store NULL values. It is not valid for columns of serial or complex data types. The CREATE TABLE statement fails with an error if you specify both NOT NULL and NULL constraints on the same column.

The following example creates a standard table with two constraints: **num**, a primary-key constraint on the **acc\_num** column; and **code**, a unique constraint on the **acc\_code** column:

```
CREATE TABLE accounts (
  acc_num INTEGER PRIMARY KEY CONSTRAINT num,
```

174. Informix® extension

175. See [Constraint Definition on page 361](#)

176. See [REFERENCES Clause on page 356](#)

177. See [CHECK Clause on page 360](#)

```
acc_code INTEGER UNIQUE CONSTRAINT code,
acc_descr CHAR(30));
```

The types of constraints used in this example are defined in sections that follow.

## Restrictions on Using the Single-Column Constraint Format

The single-column constraint format cannot specify a constraint that involves more than one column. Thus, you cannot use the single-column constraint format to define a composite key. For information on multiple-column constraints, see [Multiple-Column Constraint Format on page 364](#).

You cannot define a referential constraint or a unique constraint on any column of a RAW table. Only NOT NULL or NULL constraints are supported on RAW tables.

You cannot place unique, primary-key, or referential constraints on BLOB, BYTE, CLOB, or TEXT columns. You can, however, check for NULL or non-NULL values on BYTE or TEXT columns with a check constraint.

If the constraint is on a column that stores encrypted data, Informix® cannot enforce the constraint.

## Using the NOT NULL Constraint

Use the NOT NULL keywords to require that a column receive a value during insert or update operations. If you place a NOT NULL constraint on a column (and no default value is specified), you *must* enter a value into this column when you insert a row or update that column in a row. If you do not enter a value, the database server returns an error, because no default value exists.

The following example creates the **newitems** table. In **newitems**, the column **manucode** does not have a default value nor does it allow NULL values.

```
CREATE TABLE newitems (
  newitem_num INTEGER,
  manucode CHAR(3) NOT NULL,
  promotype INTEGER,
  descrip CHAR(20));
```

When you define a PRIMARY KEY constraint, the database server also silently creates a NOT NULL constraint on the same column, or on the same set of columns that make up the primary key.

You cannot specify NULL as the explicit default value for a column if you also specify the NOT NULL constraint.

The CREATE TABLE statement fails with an error if you specify both a NOT NULL constraint and a NULL constraint on the same column.

The NOT NULL constraint is required for columns of the collection data types LIST, MULTISSET, and SET. No other column constraints are allowed on a collection data type.

## Using the NULL Constraint

Use the `NULL` keyword to specify that a column can store the `NULL` value for its data type. This implies that the column need not receive any value during insert or update operations. The `NULL` constraint is logically equivalent to omitting the `NOT NULL` constraint from the column definition.

The following example creates the `newitems` table. In `newitems`, the column `descrip` does not have a default value, but it allows `NULL` values.

```
CREATE TABLE newitems (
  newitem_num INTEGER,
  manucode CHAR(3) NOT NULL,
  promotype INTEGER,
  descrip CHAR(20) NULL);
```

In the example above, the columns `newitem_num` and `promotype` also allow `NULL` values implicitly, because no `NOT NULL` constraint is defined on them.

The `CREATE TABLE` statement fails with an error if you specify both a `NOT NULL` constraint and a `NULL` constraint on the same column.

You cannot specify both a `NULL` constraint and a `PRIMARY KEY` constraint on the same column, because when the `CREATE TABLE` statement defines a `PRIMARY KEY` constraint, the database server also silently creates a `NOT NULL` constraint on the same column, or on the same set of columns that make up the primary key.

The `NULL` constraint is not valid for columns of the collection data types `LIST`, `MULTISET`, and `SET`, nor for `IDSSECURITYLABEL` columns.

## Using UNIQUE or DISTINCT Constraints

Use the `UNIQUE` or `DISTINCT` keyword to require that a column or set of columns accepts only unique data values. You cannot insert values that duplicate the values of some other row into a column that has a unique constraint. When you create a `UNIQUE` or `DISTINCT` constraint, the database server automatically creates an internal index on the constrained column or columns. (In this context, the keyword `DISTINCT` is a synonym for `UNIQUE`.)

You cannot place a unique constraint on a column that already has a primary-key constraint. You cannot place a unique constraint on a `BYTE` or `TEXT` column.

As previously noted, you cannot place a unique or primary-key constraint on a `BLOB` or `CLOB` column of Informix®.

Opaque data types support a unique constraint only where a secondary-access method supports uniqueness for that type. The default secondary-access method is a generic B-tree, which supports the `equal()` operator function. Therefore, if the definition of the opaque type includes the `equal()` function, a column of that opaque type can have a unique constraint.

The following example creates a simple table that has a unique constraint on one of its columns:

```
CREATE TABLE accounts
  (acc_name CHAR(12),
   acc_num SERIAL UNIQUE CONSTRAINT acc_num);
```

For an explanation of the constraint name, refer to [Declaring a Constraint Name on page 362](#).

## Differences Between a Unique Constraint and a Unique Index

Although a unique index and a unique constraint are functionally similar, besides various differences in the syntax by which you declare, alter, or destroy them, there are additional differences between these two types of database objects:

- In DDL statements, they are registered or dropped in different tables of the system catalog
- In DML statements, enabled unique constraints on a logged table are checked at the end of a statement, but unique indexes are checked on a row-by-row basis, thereby preventing any insert or update of a row that might potentially violate the uniqueness of the specified column (or for a multiple-column column constraint or index, the column list).

For example, if you stored the values 1, 2, and 3 in rows of a logged table that has an INT column, an UPDATE operation on that table that specifies `SET c = c + 1` would fail with an error if there were a unique index on the column `c`, but the statement would succeed if the column had a unique constraint.

---

### Related reference

[Index-type options on page 256](#)

## Using the PRIMARY KEY Constraint

A *primary key* is a column (or a set of columns, if you use the multiple-column constraint format) that contains a non-NULL, unique value for each row in a table. When you define a PRIMARY KEY constraint, the database server automatically creates an internal index on the column or columns that make up the primary key, and silently creates a NOT NULL constraint on the same column or columns.

You can designate only one primary key for a table. If you define a single column as the primary key, then it is unique by definition. You cannot explicitly give the same column a unique constraint.

You cannot place a unique or primary-key constraint on a BLOB or CLOB column.

Opaque types of Informix® support a primary key constraint only where a secondary-access method supports the uniqueness for that type. The default secondary-access method is a generic B-tree, which supports the `equal()` function. Therefore, if the definition of the opaque type includes the `equal()` function, a column of that opaque type can have a primary-key constraint.

You cannot place a primary-key constraint on a BYTE or TEXT column.

In the previous two examples, a unique constraint was placed on the column `acc_num`. The following example creates this column as the primary key for the `accounts` table:

```
CREATE TABLE accounts
  (acc_name CHAR(12),
   acc_num SERIAL PRIMARY KEY CONSTRAINT acc_num);
```

## REFERENCES Clause

Use the REFERENCES clause to establish a referential relationship:

- Within a table (that is, between two columns of the same table)
- Between two tables (in other words, create a foreign key)

This syntax fragment is part of the [Single-Column Constraint Format on page 353](#) and the [Multiple-Column Constraint Format on page 364](#).

REFERENCES Clause

**REFERENCES** *table*

```
(
, column
)
```

<sup>178</sup> **ON DELETE CASCADE**

| Element       | Description          | Restrictions  | Syntax                                  |
|---------------|----------------------|---|---|
| <i>column</i> | A referenced column  | See <a href="#">Restrictions on Referential Constraints on page 357</a> . | <a href="#">Identifier on page 1456</a> |
| <i>table</i>  | The referenced table | Must reside in the same database as the referencing table                 | <a href="#">Identifier on page 1456</a> |

The *referencing* column (the column being defined) is the column or set of columns that refers to the referenced column or set of columns. The referencing column can contain NULL and duplicate values, but values in the referenced column (or set of columns) must be unique.

The relationship between referenced and referencing columns is called a *parent-child* relationship, where the parent is the referenced column (primary key) and the child is the referencing column (foreign key). The referential constraint establishes this parent-child relationship.

When you create a referential constraint, the database server automatically creates an internal index on the constrained column or columns.

## Restrictions on Referential Constraints

You must have the References privilege to create a referential constraint.

When you use the REFERENCES clause, you must observe the following restrictions:

- The referenced and referencing tables must be in the same database.
- The referenced column (or set of columns when you use the multiple-column constraint format) must have a unique or primary-key constraint.
- The data types of the referencing and referenced columns must be identical.

The only exceptions are that a referencing column must be an integer data type if the referenced column is a serial data type:

178. Informix® extension

- For BIGSERIAL referenced columns, use BIGINT referencing columns.
- For SERIAL referenced columns, use INT referencing columns.
- For SERIAL8 referenced columns, use INT8 referencing columns.
- You cannot place a constraint on any column of a RAW table.
- You cannot place a referential constraint on a BYTE, TEXT, BLOB, or CLOB column.
- When you use the single-column constraint format, you can reference only one column.
- When you use the multiple-column constraint format, the maximum number of columns in the REFERENCES clause is 16, and the total length of the columns cannot exceed 390 bytes if the page size is 2 kilobytes. (The maximum length increases with the page size.)

## Default Values for the Referenced Column

If the referenced table is different from the referencing table, you do not need to specify the referenced column; the default column is the primary-key column (or columns) of the referenced table. If the referenced table is the same as the referencing table, you must specify the referenced column.

## Referential Relationships Within a Table

You can establish a referential relationship between two columns of the same table. In the following example, the **emp\_num** column in the **employee** table uniquely identifies every employee through an employee number. The **mgr\_num** column in that table contains the employee number of the manager who manages that employee. In this case, **mgr\_num** references **emp\_num**. Duplicate values appear in the **mgr\_num** column because managers manage more than one employee.

```
CREATE TABLE employee
(
  emp_num INTEGER PRIMARY KEY,
  mgr_num INTEGER REFERENCES employee (emp_num)
);
```

A table in which referential relationships exist among its rows can have a PRIMARY KEY constraint with no explicit foreign key. For the syntax to recursively query a table in which multiple levels of a logical hierarchy exist among the rows, see [Hierarchical Clause on page 819](#).

## Locking Implications of Creating a Referential Constraint

When you create a referential constraint, an exclusive lock is placed on the referenced table. The lock is released when the CREATE TABLE statement is finished. If you are creating a table in a database that supports transaction logging, and you are using transactions, the lock is released at the end of the transaction.

## Examples of the Single-Column Constraint format

These examples illustrate single-column constraint format options to define a foreign-key constraint that is enabled by default, and to declare the name of a disabled referential constraint.

## A referential constraint enabled by default

The following example uses the single-column constraint format to define a referential relationship between the `sub_accounts` and `accounts` tables. (The terms *foreign-key constraint* and *referential constraint* are synonyms.) The `ref_num` column (the foreign key) in the `sub_accounts` table references the `acc_num` column (the primary key) in the `accounts` table.

```
CREATE TABLE accounts (
  acc_num INTEGER PRIMARY KEY,
  acc_type INTEGER,
  acc_descr CHAR(20));
CREATE TABLE sub_accounts (
  sub_acc INTEGER PRIMARY KEY,
  ref_num INTEGER REFERENCES accounts (acc_num),
  sub_descr CHAR(20));
```

The single-column constraint format syntax of the `CREATE TABLE` statement above that defines the `sub_accounts` table does not explicitly specify that the `ref_num` column is a foreign key, but the `REFERENCES` keyword specifies that `ref_num` must have the same value as the `acc_num` column in some row of the `accounts` table. This implies that the `ref_num` column is the foreign key in a referential relationship in which `sub_accounts` is the referencing table, and `accounts` is the referenced table.

In single-column constraint format, you do not explicitly specify that the `ref_num` column is a foreign key. To include the `FOREIGN KEY` keywords when you place a referential constraint on a single column (or on a list of columns that reference the same primary key) of the referencing table, you must instead use the multiple-column constraint format syntax to define the referential constraint.

By default, this constraint on the `sub_accounts` table is enabled without filtering, because no explicit constraint mode is specified. You can use the neither the `DISABLED` or `FILTERING` keyword is specified in the example. The `SET CONSTRAINTS` option to the `SET Database Object Mode` statement can reset the object mode of existing constraints.

Because the `sub_accounts` example above declares no name for the referential constraint, the database server generates an implicit identifier when it registers this constraint in the `sysconstraints` system catalog table, and registers its mode (`E`) in the `sysobjstate` system catalog table.

## A disabled referential constraint

The next `CREATE TABLE` statement creates a `xeno_counts` table, and defines a referential constraint between its `xeno_num` column and the `acc_num` column in the `accounts` table from the first example. This single-column constraint format syntax also includes a constraint definition, specifying `DISABLED` as its constraint mode, and declaring `xeno_constr` as the name of this foreign-key constraint. Here `xeno_accounts` is the referencing table, and `accounts` is the referenced table.

```
CREATE TABLE xeno_counts (
  xeno_acc INTEGER PRIMARY KEY,
  xeno_num INTEGER REFERENCES accounts (acc_num)
  CONSTRAINT xeno_constr DISABLED,
  xeno_descr CHAR(20));
```

In `DISABLED` mode, the `xeno_constr` constraint is not enforced when DML operations produce violating rows in the `xeno_counts` table. To enforce referential integrity, however, you can use the `SET CONSTRAINTS` option to the `SET Database Object Mode` statement to change the constraint mode to `ENABLED`. Alternatively, `SET CONSTRAINTS` can reset the `xeno_constr` constraint to a `FILTERING` mode, after the `START VIOLATIONS` statement associates a violations table with the `xeno_counts` table.

---

**Related reference**[SET CONSTRAINTS statement on page 869](#)[Choosing a Constraint-Mode Option on page 363](#)

## Using the ON DELETE CASCADE Option

Use the ON DELETE CASCADE option to specify whether you want rows deleted in a child table when corresponding rows are deleted in the parent table. If you do not specify cascading deletes, the default behavior of the database server prevents you from deleting data in a table if other tables reference it.

If you specify this option, later when you delete a row in the parent table, the database server also deletes any rows associated with that row (foreign keys) in a child table. The principal advantage to the cascading-deletes feature is that it allows you to reduce the quantity of SQL statements you need to perform delete actions.

For example, the **all\_candy** table contains the **candy\_num** column as a primary key. The **hard\_candy** table refers to the **candy\_num** column as a foreign key. The following CREATE TABLE statement creates the **hard\_candy** table with the cascading-delete option on the foreign key:

```
CREATE TABLE all_candy
(candy_num SERIAL PRIMARY KEY,
 candy_maker CHAR(25));

CREATE TABLE hard_candy
(candy_num INT,
 candy_flavor CHAR(20),
 FOREIGN KEY (candy_num) REFERENCES all_candy
 ON DELETE CASCADE);
```

Because ON DELETE CASCADE is specified for the dependent table, when a row of the **all\_candy** table is deleted, the corresponding rows of the **hard\_candy** table are also deleted. For information about syntax restrictions and locking implications when you delete rows from tables that have cascading deletes, see [Considerations When Tables Have Cascading Deletes on page 490](#).

## CHECK Clause

Use the CHECK clause to designate conditions that must be met *before* data can be assigned to a column during an INSERT or UPDATE statement.

This syntax fragment is part of the [Single-Column Constraint Format on page 353](#) and the [Multiple-Column Constraint Format on page 364](#).

CHECK Clause

**CHECK**

( Condition <sup>179</sup> )

179. See [Condition on page 1144](#)

The *condition* cannot include a user-defined routine.

During an insert or update, if the check constraint of a row evaluates to *false*, the database server returns an error. The database server does not return an error if a row evaluates to NULL for a check constraint. In some cases, you might want to use both a check constraint and a NOT NULL constraint.

## Using a Search Condition

The *search condition* that defines a check constraint cannot contain the following elements: user-defined routines, subqueries, aggregates, host variables, or rowids. In addition, the search condition cannot contain the following built-in variant functions: CURRENT, SYSDATE, USER, CURRENT\_USER, SITENAME, DBSERVERNAME, or TODAY.

When you specify a date value in a search condition, make sure you specify four digits for the year, so that the **DBCENTURY** environment variable has no effect on the condition. When you specify a two-digit year, the **DBCENTURY** environment variable can produce unpredictable results if the condition depends on an abbreviated year value. For more information about **DBCENTURY**, see the *Informix® Guide to SQL: Reference*.

More generally, the database server saves the settings of environment variables from the time of creation of check constraints. If any of these settings are subsequently changed in a way that can affect the evaluation of a condition in a check constraint, the new settings are disregarded, and the original environment variable settings are used when the condition is evaluated.

With a BYTE or TEXT column, you can check for NULL or not-NULL values. This constraint is the only constraint allowed on a BYTE or TEXT column.

## Restrictions When Using the Single-Column Constraint Format

When you use the single-column constraint format to define a check constraint, the check constraint cannot depend on values in other columns of the table. The following example creates the **my\_accounts** table that has two columns with check constraints, each in the single-column constraint format:

```
CREATE TABLE my_accounts (
  chk_id SERIAL PRIMARY KEY,
  acct1 MONEY CHECK (acct1 BETWEEN 0 AND 99999),
  acct2 MONEY CHECK (acct2 BETWEEN 0 AND 99999));
```

Both **acct1** and **acct2** are columns of MONEY data type whose values must be between 0 and 99999. If, however, you want to test that **acct1** has a larger balance than **acct2**, you cannot use the single-column constraint format. To create a constraint that checks values in more than one column, you must use the [Multiple-Column Constraint Format on page 364](#).

## Constraint Definition

Use the constraint definition portion of CREATE TABLE for these purposes:

- To declare a name for the constraint
- To set a constraint to disabled, enabled, or filtering mode.

This syntax fragment is part of the [Single-Column Constraint Format on page 353](#) and the [Multiple-Column Constraint Format on page 364](#).

Constraint Definition

**CONSTRAINT***constraint*

**ENABLED DISABLED**

**FILTERING**

**WITHOUT ERROR WITH ERROR**

| Element           | Description        | Restrictions  | Syntax                                  |
|-------------------|--------------------|---|---|
| <i>constraint</i> | Name of constraint | Must be unique for the table among index and constraint names | <a href="#">Identifier on page 1456</a> |

## Declaring a Constraint Name

The database server implements the constraint as an index. Whenever you use the single- or multiple-column constraint format to place a data restriction on a column, but without declaring a *constraint* name, the database server creates a constraint and adds a row for that constraint in the **sysconstraints** system catalog table.

The database server also generates an identifier and adds a row to the **sysindices** system catalog table for each new primary-key, unique, or referential constraint that does not share an index with an existing constraint. Even if you declare a name for a constraint, the database server generates the name that appears in the **sysindices** table. (The system catalog also includes a view on the **sysindices** table, called **sysindexes**, which also lists each component of a composite index.)

If you want, you can specify a meaningful name for the constraint. The name must be unique among the names of constraints and indexes in the database.

Constraint names appear in error messages having to do with constraint violations. You can use this name when you use the DROP CONSTRAINT clause of the ALTER TABLE statement.

You also specify a constraint name when you change the mode of constraint with the SET Database Object Mode statement or the SET Transaction Mode statement, and in the DROP INDEX statement for constraints that are implemented as indexes with user-defined names.

In an ANSI-compliant database, when you declare the name of a constraint of any type, the combination of the *owner* name and *constraint* name must be unique within the database.

## Constraint Names That the Database Server Generates

If you do not specify a constraint name, the database server generates a constraint name using the following template:

```
constraint_typetabid_constraintid
```

In this template, *constraint\_type* is the letter **u** for unique or primary-key constraints, **r** for referential constraints, **c** for check constraints, and **n** for NOT NULL constraints. In the template, *tabid* and *constraintid* are values from the **tabid** and **constrid** columns of the **sysables** and **sysconstraints** system catalog tables, respectively. For example, the constraint name for a unique constraint might look like "u111\_14" (with a leading blank space).

If the generated name conflicts with an existing identifier, the database server returns an error, and you must then supply an explicit constraint name.

The generated index name in **sysindexes** (or **sysindices**) has this format:

```
[blankspace]tabid__constraintid
```

For example, the index name might be something like " **111\_14** " (quotation marks used here to show the blank space).

## Choosing a Constraint-Mode Option

Use the constraint-mode options (ENABLED, DISABLED, and FILTERING) to control the behavior of constraints in INSERT, DELETE, MERGE, and UPDATE operations.

For constraints that the CREATE TABLE statement defines, these are the options.

### DISABLED

Does not enforce the constraint during INSERT, DELETE, and UPDATE operations

### ENABLED

Enforces the constraint during INSERT, DELETE, and UPDATE operations. If a target row causes a violation of the constraint, the statement fails. This mode is the default.

### FILTERING

Enforces the constraint during INSERT, DELETE, and UPDATE operations, if the START VIOLATIONS statement has created a violations table and a diagnostics table. If a target row causes a violation of the constraint, the statement continues processing. The database server writes the row in question to the violations table associated with the target table, and writes diagnostic information to the associated diagnostics table.

If you choose filtering mode, you can specify the WITHOUT ERROR or WITH ERROR options. The following list explains these ERROR options.

### WITH ERROR

Returns an integrity-violation error when a filtering-mode constraint is violated during an INSERT, DELETE, or UPDATE operation.

### WITHOUT ERROR

Does not return an integrity-violation error when a filtering-mode constraint is violated during an INSERT, DELETE, or UPDATE operation. This is the default ERROR option.

#### Note:

For the FILTERING WITHOUT ERROR mode to have these effects, you must also use the START VIOLATIONS TABLE statement to start the violations and diagnostics tables for the target table on which the constraints are defined. You can issue that statement

- either before you set any constraints on the table to a filtering mode,
- or after you set constraints to a filtering mode, but before any users perform INSERT, DELETE, or UPDATE operations on rows in the table.

Constraint modes are registered in the sysobjstate system catalog table.

### **NOVALIDATE modes for foreign-key or check constraints**

The modes listed above are only a subset of the constraint modes that the SET CONSTRAINTS option to the SET Database Object Mode statement can specify while it is resetting the mode of an existing foreign-key or check constraint. They are also a subset of the constraint modes that the ALTER TABLE ADD CONSTRAINT statement can specify while creating a new foreign-key or check constraint on an existing table.

The ALTER TABLE ADD CONSTRAINT and SET CONSTRAINTS statements can specify one of these additional constraint modes by including the `NOVALIDATE` keyword in the constraint definition. The effect is that the database server skips the checking of existing rows for violations when the constraint is being created or enabled, thereby reducing the time and resources required for processing the DDL statement. When that statement completes execution, however, each `NOVALIDATE` mode automatically reverts to an `ENABLED` or `FILTERING` mode. Thus, the `NOVALIDATE` keyword does not prevent enforcement of referential integrity or check conditions during subsequent DML operations on the table, because the `NOVALIDATE` modes do not persist beyond the DDL statement that defined them.

Because most tables are empty when they are created, referential-integrity checking of existing rows typically does not occur during table creation, and the CREATE TABLE statement does not support `NOVALIDATE` constraint modes. Those modes can be efficient, however, in contexts where non-empty tables with foreign-key or check constraints need to be moved to another database or to a data warehouse.

### **Multiple-Column Constraint Format**

Use the multiple-column constraint format to associate one or more columns with a constraint. This alternative to the single-column constraint format allows you to associate multiple columns with a constraint.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#) and the [OF TYPE Clause on page 369](#).

Constraint Definition <sup>183</sup>

| Element       | Description                          | Restrictions               | Syntax                                  |
|---------------|--------------------------------------|----------------------------|---|
| <i>column</i> | Columns on which to place constraint | Not BYTE, TEXT, BLOB, CLOB | <a href="#">Identifier on page 1456</a> |

A multiple-column constraint has these cardinality and size restrictions:

- It can specify no more than 16 column names.
- In Informix®, the maximum total length of the list of columns depends on the page size, according to this formula:

$$\text{MAXLength} = (((\text{PageSize} - 93) / 5) - 1)$$

- For a page size of 2K, the total length cannot exceed 390 bytes.
- For a page size of 16K, the total length cannot exceed 3257 bytes.

Here the slash ( / ) symbol represents integer division.

When you define a unique constraint (by using the UNIQUE or DISTINCT keyword), a column cannot appear in the constraint list more than once.

Using the multiple-column constraint format, you can perform these tasks:

180. Informix® extension

181. See [REFERENCES Clause on page 356](#)

182. See [CHECK Clause on page 360](#)

183. See [Constraint Definition on page 361](#)

- Create data-integrity constraints for a set of one or more columns
- Declare a mnemonic name for a constraint
- Specify the constraint-mode option that controls the behavior of a constraint during insert, delete, and update operations.

When you use this format, you can create composite primary and foreign keys, or define check constraints that compare data in different columns.

See also the section [Differences Between a Unique Constraint and a Unique Index on page 356](#).

## Restrictions with the Multiple-Column Constraint Format

When you use the multiple-column constraint format, you cannot define any default values for columns. In addition, you cannot establish a referential relationship between two columns of the same table.

To define a default value for a column, or to establish a referential relationship between two columns of the same table, refer to [Single-Column Constraint Format on page 353](#) or to [Referential Relationships Within a Table on page 358](#) respectively.

## Using Large-Object Types in Constraints

You cannot place unique, primary-key, or referential (FOREIGN KEY) constraints on BYTE or TEXT columns. You can, however, check for NULL or non-NULL values with a check constraint.

You cannot place unique or primary-key constraints on BLOB or CLOB columns. If the constraint is on a set of columns that includes a column that stores encrypted data, Informix® cannot enforce the constraint.

You can find detailed discussions of specific constraints in the following sections:

| <b>Constraint</b> | <b>For more information, see</b>                                 | <b>For an example, see</b>  |
|-------------------|--|---|

| DISTINCT          | <a href="#">Using UNIQUE or DISTINCT Constraints on page 355</a> | <a href="#">Examples of the Multiple-Column Constraint Format on page 367</a> |
| FOREIGN KEY       | <a href="#">Using the FOREIGN KEY Constraint on page 366</a>     | <a href="#">Defining Composite Primary and Foreign Keys on page 367</a>       |
| PRIMARY KEY       | <a href="#">Using the PRIMARY KEY Constraint on page 356</a>     | <a href="#">Defining Composite Primary and Foreign Keys on page 367</a>       |
| UNIQUE            | <a href="#">Using UNIQUE or DISTINCT Constraints on page 355</a> | <a href="#">Examples of the Multiple-Column Constraint Format on page 367</a> |

## Using the FOREIGN KEY Constraint

A foreign key *joins* and establishes dependencies between tables. That is, it creates a referential constraint. (For more information on referential constraints, see the [REFERENCES Clause on page 356](#).)

A foreign key references a unique or primary key in a table. For every entry in the foreign-key columns, a matching entry must exist in the unique or primary-key columns if all foreign-key columns contain non-NULL values.

You cannot specify BYTE or TEXT columns as foreign keys.

You cannot specify BLOB or CLOB columns as foreign keys.

## Examples of the Multiple-Column Constraint Format

The following example creates a standard table, called **order\_items**, with a unique constraint, called **items\_constr**, using the multiple-column constraint format:

```
CREATE TABLE order_items
(
  order_id SERIAL,
  line_item_id INT not null,
  unit_price DECIMAL(6,2),
  quantity INT,
  UNIQUE (order_id,line_item_id) CONSTRAINT items_constr
);
```

For constraint names, see [Declaring a Constraint Name on page 362](#).

## Defining Check Constraints Across Columns

When you use the multiple-column constraint format to define check constraints, a check constraint can apply to more than one column in the same table. (You cannot, however, create a check constraint whose *condition* uses a value from a column in another table.)

This example compares two columns, **acct1** and **acct2**, in the new table:

```
CREATE TABLE my_accounts
(
  chk_id SERIAL PRIMARY KEY,
  acct1 MONEY,
  acct2 MONEY,
  CHECK (0 < acct1 AND acct1 < 99999),
  CHECK (0 < acct2 AND acct2 < 99999),
  CHECK (acct1 > acct2)
);
```

In this example, the **acct1** column must be greater than the **acct2** column, or the insert or update fails.

## Defining Composite Primary and Foreign Keys

When you use the multiple-column constraint format, you can create a composite key. A *composite key* specifies multiple columns for a primary-key or foreign-key constraint.

The next example creates two tables. The first table has a composite key that acts as a primary key, and the second table has a composite key that acts as a foreign key.

```
CREATE TABLE accounts (
  acc_num INTEGER,
  acc_type INTEGER,
  acc_descr CHAR(20),
  PRIMARY KEY (acc_num, acc_type));

CREATE TABLE sub_accounts (
  sub_acc INTEGER PRIMARY KEY,
  ref_num INTEGER NOT NULL,
  ref_type INTEGER NOT NULL,
  sub_descr CHAR(20),
  FOREIGN KEY (ref_num, ref_type) REFERENCES accounts
    (acc_num, acc_type));
```

In this example, the foreign key of the **sub\_accounts** table, **ref\_num** and **ref\_type**, references the composite key, **acc\_num** and **acc\_type**, in the **accounts** table. If, during an insert or update, you tried to insert a row into the **sub\_accounts** table whose value for **ref\_num** and **ref\_type** did not exactly correspond to the values for **acc\_num** and **acc\_type** in an existing row in the **accounts** table, the database server would return an error.

A referential constraint must have a one-to-one relationship between referencing and referenced columns. In other words, if the primary key is a set of columns (a composite key), then the foreign key also must be a set of columns that corresponds to the composite key.

Because of the default behavior of the database server, when you create the foreign-key reference, you do not need to reference the composite-key columns (**acc\_num** and **acc\_type**) explicitly. You can rewrite the references section of the previous example as follows:

```
FOREIGN KEY (ref_num, ref_type) REFERENCES accounts
```

## Default Index Creation Strategy for Constraints

When you create a table with unique or primary-key constraints, the database server creates a system-generated, internal index that is unique and ascending for each constraint.

When you drop a primary-key or foreign-key constraint, the corresponding system-generated index is also dropped. However, you can preserve the index by renaming it with the `RENAME INDEX` statement.

When you create a table with a referential constraint, the database server creates an internal index that is ascending and that allows duplicate values for each column that you specify in the referential constraint.

An internal index occupies the same storage location as its table. For fragmented tables, the fragments of an internal index occupy the same dbspace partitions that you specify for the table fragments (or in some cases, the database dbspace).

If you require an index fragmentation strategy that is independent of the underlying table fragmentation, do not define the constraint when you create the table. Instead, use the CREATE INDEX statement to create a unique index with the desired fragmentation strategy. Then use the ALTER TABLE statement to add the constraint. The new constraint uses the previously defined index.

**Important:** In a database without logging, *detached checking* is the only kind of constraint checking available. Detached checking means that constraint checking is performed on a row-by-row basis.

## OF TYPE Clause

Use the OF TYPE clause to create a *typed table* for an object-relational database. A typed table is a table in which every row is an object of the named ROW data type that you specify in this clause.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

OF TYPE Clause

**OF TYPE** *row\_type*

(  
 , Multiple-Column Constraint Format <sup>184</sup>  
 )

**UNDER** *supertable*

| Element           | Description   | Restrictions   | Syntax                                  |
|-------------------|---|--|---|
| <i>row_type</i>   | Name of the ROW type on which this table is based               | Must be a named ROW data type registered in the local database | <a href="#">Identifier on page 1456</a> |
| <i>supertable</i> | Name of the table from which this table inherits its properties | Must already exist as a typed table                            | <a href="#">Identifier on page 1456</a> |

If you use the UNDER clause, the *row\_type* must be derived from the ROW type of the *supertable*. A type hierarchy must already exist in which the named ROW type of the new table is a subtype of the named ROW type of the *supertable*.

*Jagged rows* are any set rows from a table hierarchy in which the number of columns is not fixed among the typed tables within the hierarchy. Some APIs, such as Informix® ESQL/C and Informix® JDBC Driver, do not support queries that return jagged rows.

When you create a typed table, CREATE TABLE cannot specify names for its columns, because the column names were declared when you created the ROW type. Columns of a typed table correspond to the fields of the named ROW type. The ALTER TABLE statement cannot add additional columns to a typed table.

For example, suppose you create a named ROW type, **student\_t**, as follows:

184. See [Multiple-Column Constraint Format on page 364](#)

185. See [Specialized columns on page 372](#)

```
CREATE ROW TYPE student_t
(name          VARCHAR(30),
 average      REAL,
 birthdate    DATETIME YEAR TO DAY);
```

If a table is assigned the type **student\_t** in the OF TYPE clause, the table is a typed table whose columns are of the same name and data type, and in the same order, as the fields of the named ROW type **student\_t**. For example, the following CREATE TABLE statement creates a typed table named **students** whose type is **student\_t**:

```
CREATE TABLE students OF TYPE student_t;
```

The **students** table has the following columns:

```
name          VARCHAR(30)
average      REAL
birthdate    DATETIME YEAR TO DAY
```

For more information about named ROW types, refer to the [CREATE ROW TYPE statement on page 307](#).

## Using Large-Object Data in Typed Tables

Use the BLOB or CLOB instead of BYTE or TEXT data types when you create a typed table that contains columns for large objects. For backward compatibility, you can create a named-ROW type that contains BYTE or TEXT fields and use that ROW type to re-create an existing (untyped) table as a typed table. Although you can use a ROW type that contains BYTE or TEXT fields to create a typed table, such a ROW type is not valid as a column. You can, however, use a ROW type that contains BLOB or CLOB fields both in typed tables and in columns.

## Using the UNDER Clause

Use the UNDER clause to specify inheritance (that is, define the new table as a subtable). The subtable inherits properties from the specified supertable. In addition, you can define new properties specific to the subtable.

Continuing the example shown in [OF TYPE Clause on page 369](#), the following statements create a typed table, **grad\_students**, that inherits all of the columns of the **students** table but also has columns for **adviser** and **field\_of\_study** that correspond to fields in the **grad\_student\_t** ROW type:

```
CREATE ROW TYPE grad_student_t
(adviser      CHAR(25),
 field_of_study CHAR(40)) UNDER student_t;

CREATE TABLE grad_students OF TYPE grad_student_t UNDER students;
```

When you use the UNDER clause, the subtable inherits these properties:

- All columns in the supertable
- All constraints defined on the supertable
- All indexes defined on the supertable
- All triggers defined on the supertable.

- All referential integrity constraints
- The access method
- The storage option specification (including fragmentation strategy)

If a subtable defines no fragments, but if its supertable has fragments defined, then the subtable inherits the fragments of the supertable.

**Tip:** Any heritable attributes that are added to a supertable after subtables have been created are automatically inherited by existing subtables. You do not need to add all heritable attributes to a supertable before you create its subtables.

## Restrictions on Table Hierarchies

Inheritance occurs in one direction only, namely from supertable to subtable. Properties of subtables are *not* inherited by supertables. The section [System Catalog Information on page 371](#) lists the inherited database objects for which the system catalog maintains no information regarding subtables.

No two tables in a table hierarchy can have the same data type. For example, the final line of the next code example is invalid, because the tables **tab2** and **tab3** cannot have the same row type (**rowtype2**):

```
create row type rowtype1 (...);
create row type rowtype2 (...) under rowtype1;
create table tab1 of type rowtype1;
create table tab2 of type rowtype2 under tab1;
create table tab3 of type rowtype2 under tab1; -- This is not valid.
```

## Access Privileges on Tables

The discretionary access privileges on a table describe both who can access the information in the table and who can create new tables.

For more information about discretionary access privileges, see the description of the [GRANT statement on page 592](#) statement.

In an ANSI-compliant database, no default table-level privileges exist. You must grant these privileges explicitly.

Setting the environment variable **NODEFDAC** to `yes` prevents default privileges from being granted to PUBLIC on new tables in a database that is not ANSI compliant, as described in the *Informix® Guide to SQL: Reference*.

**Important:** Enabling **NODEFDAC** withholds default table access or routine access privileges from PUBLIC when the object is registered in the system catalog, but the **NODEFDAC** setting cannot prevent the PUBLIC group from being granted the same privileges by a user who holds the necessary access privileges on the new table or on the new UDR.

For more information about discretionary access privileges, see the *Informix® Guide to SQL: Tutorial*.

## System Catalog Information

When you create a table, the database server adds information about the table to the **systables** system catalog table, and column information to **syscolumns** system catalog table. The **sysfragments** system catalog table contains information about fragmentation strategies and the storage location of fragments. The **sysblobs** system catalog table contains information about the location of dbspaces and of simple large objects. (The **syschunks** table in the **sysmaster** database contains information about the location of smart large objects.)

The **sysstabauth**, **syscolauth**, **sysfragauth**, **sysprocauth**, **sysusers**, and **sysxtdtypeauth** tables contain information about the discretionary access privileges that various CREATE TABLE options require.

The **sysextcols**, **sysextdfiles**, and **sysexternal** tables contain additional information about objects that the CREATE EXTERNAL TABLE statement registers in the database.

The **systables**, **sysxtdtypes**, and **sysinherits** system catalog tables provide information about typed tables. For typed-table hierarchies, constraints, indexes, and triggers are recorded in the system catalog for the supertable, but not for subtables that inherit them. Fragmentation information, however, is recorded for both supertables and subtables. For more information about inheritance, refer to the *Informix® Guide to SQL: Tutorial*.

## Specialized columns

You can create specialized columns to support Enterprise Replication, high availability, or row-level auditing.

### Specialized columns

```
.WITH--+-AUDIT-----+-----><
      '-CRCOLS----'
      '-ERKEY-----'
      '-REPLCHECK--'
      '-VERCOLS----
```

There is no required order among multiple WITH options in the same CREATE TABLE statement.

## Using the WITH AUDIT Clause

Use the WITH AUDIT keywords to create a table that will be included in the set of tables that are audited at the row level if selective row-level is enabled.

When you create a table with the WITH AUDIT clause, row-level audit events in that table are recorded when selective row-level auditing is turned on. Applying the WITH AUDIT attribute to a table by itself does not enable selective row-level auditing. This type of auditing is enabled when the ADTROWS parameter of the `adtcfg` file is set to 1 or 2 by using the `onaudit -R` command.

## Using the WITH CRCOLS Option

Use the WITH CRCOLS keywords to create two shadow columns that Enterprise Replication uses for conflict resolution. The first column, **cdrserver**, contains the identity of the database server where the last modification occurred. The second column, **cdrtime**, contains the time stamp of the last modification. You must add these columns before you can use time stamps for UDR conflict resolution. These two columns are hidden shadow columns, because they cannot be indexed and cannot be viewed in system catalog tables.

For most database operations, the **cdrserver** and **cdrtime** columns are hidden. For example, if you include the WITH CRCOLS keywords when you create a table, the **cdrserver** and **cdrtime** columns have the following behavior:

- They are not returned by queries that specify an asterisk ( \* ) as the projection list, as in the statement:

```
SELECT * FROM tablename;
```

- They do not appear in DB-Access when you ask for information about the columns of the table.
- They are not included in the number of columns (**ncols**) in the **systables** system catalog table entry for *tablename*.

To view the contents of **cdrserver** and **cdrtime**, you must explicitly specify the columns in the projection list of a SELECT statement, as the following example shows:

```
SELECT cdrserver, cdrtime FROM tablename;
```

For more information about how to use this option, refer to the .

---

## Using the WITH ERKEY Keywords

Use the WITH ERKEY keywords to create the ERKEY shadow columns that Enterprise Replication uses for a replication key.

The ERKEY shadow columns (**ifx\_erkey\_1**, **ifx\_erkey\_2**, and **ifx\_erkey\_3**) are visible shadow columns because they are indexed and can be viewed in system catalog tables. After you create the ERKEY shadow columns, a new unique index and a unique constraint are created on the table using these columns. Enterprise Replication uses that index as the replication key.

For most database operations, the ERKEY columns are hidden. For example, if you include the WITH ERKEY keywords when you create a table, the ERKEY columns have the following behavior:

- They are not returned by queries that specify an asterisk ( \* ) as the projection list, as in the statement:

```
SELECT * FROM tablename;
```

- They do appear in DB-Access when you ask for information about the columns of the table.
- They are included in the number of columns (**ncols**) in the **systables** system catalog table entry for *tablename*.

To view the contents of the ERKEY columns, you must explicitly specify the columns in the projection list of a SELECT statement, as the following example shows:

```
SELECT ifx_erkey_1, ifx_erkey_2, ifx_erkey_3 FROM customer;
```

### Example

## Example

In the following example, the ERKEY shadow columns are added to the **customer** table:

```
CREATE TABLE customer (id INT) WITH ERKEY;
```

## Using the WITH REPLCHECK Keywords

Use the WITH REPLCHECK keywords to create the **ifx\_replcheck** shadow column that Enterprise Replication uses for consistency checking.

The **ifx\_replcheck** column is a visible shadow column because it can be indexed and can be viewed in system catalog tables. After you create the **ifx\_replcheck** shadow column, you must create a new unique index on the primary key and the **ifx\_replcheck** column. The **ifx\_replcheck** shadow column must be the last column in the index. Enterprise Replication uses that index to speed consistency checking.

For most database operations, the **ifx\_replcheck** column is hidden. For example, if you include the WITH REPLCHECK keywords when you create a table, the **ifx\_replcheck** column has the following behavior:

- It is not returned by queries that specify an asterisk ( \* ) as the projection list, as in the statement:

```
SELECT * FROM tablename;
```

- It does appear in DB-Access when you ask for information about the columns of the table.
- It is included in the number of columns (**ncols**) in the **systables** system catalog table entry for *tablename*.

To view the contents of the **ifx\_replcheck** column, you must explicitly specify the columns in the projection list of a SELECT statement, as the following example shows:

```
SELECT ifx_replcheck FROM customer;
```

## Example

### Example

In the following example, the **ifx\_replcheck** shadow column is added to the **customer** table:

```
CREATE TABLE customer (id int) WITH REPLCHECK;
```

## Using the WITH VERCOLS Option

Use the WITH VERCOLS keywords to create two shadow columns that Informix® uses to support update operations on secondary servers.

The first column, **ifx\_insert\_checksum**, contains a checksum of the row when it was first created. The second column, **ifx\_row\_version**, contains a version number of the row. When a row is first inserted, **ifx\_insert\_checksum** is generated, and **ifx\_row\_version** will be set to one. Each time the row is updated, **ifx\_row\_version** is incremented by one, but

**ifx\_insert\_checksum** does not change. These two columns are visible shadow columns because they can be indexed and can be viewed in system catalog tables.

For most database operations, the **ifx\_insert\_checksum** and **ifx\_row\_version** columns are hidden. For example, if you include the WITH VERCOLS keywords when you create a table, the **ifx\_insert\_checksum** and **ifx\_row\_version** columns have the following behavior:

- They are not returned by queries that specify an asterisk ( \* ) as the projection list, as in the statement:

```
SELECT * FROM tablename;
```

- They appear in DB-Access when you ask for information about the columns of the table.
- They are included in the number of columns (**ncols**) in the **systables** system catalog table entry for *tablename*.

To view the contents of **ifx\_insert\_checksum** and **ifx\_row\_version**, you must explicitly specify the column names in the projection list of a SELECT statement, as the following example shows:

```
SELECT ifx_insert_checksum, ifx_row_version FROM tablename;
```

When row versioning is enabled, **ifx\_row\_version** is incremented by one each time the row is updated; however, row updates made by Enterprise Replication do not increment the row version. To update the row version on a server using Enterprise Replication, you must include the **ifx\_row\_version** column in the replicate participant definition.

For more information about how to use this option, refer to the *Informix® Administrator's Guide*.

## SECURITY POLICY Clause

The optional Security Policy clause can use the following syntax to specify the name of an existing security policy that is thereby associated with the table.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

SECURITY POLICY Clause

**SECURITY POLICY***policy*

| Element       | Description               | Restrictions               | Syntax                                  |
|---------------|---------------------------|----------------------------|---|
| <i>policy</i> | Name of a security policy | Must exist in the database | <a href="#">Identifier on page 1456</a> |

### Usage

Only DBSECADM can create a table that includes the Security Policy clause to specify a security policy for the table.

### Restrictions on adding a security policy

The following guidelines apply to tables that can be protected by including a valid SECURITY POLICY clause in the CREATE TABLE statement, and that also include a column of data type IDSSECURITYLABEL that stores an LBAC label component of the same security policy.

- A table is not protected unless it has a security policy associated with it and has either rows secured, or has at least one column secured.
  - Having rows secured indicates that the table is a *protected table* with *row-level* granularity.
  - Having at least one column secured indicates that the table is a *protected table* with *column-level* granularity.
- Securing rows with the `IDSSECURITYLABEL` column clause fails if the table does not have a security policy associated with it.
- Securing a column with the `COLUMN SECURED WITH` clause fails if the table does not have a security policy associated with it.
- A table can have at most one security policy.
- A table can have any number of protected columns. Each protected column can have a different security label, or several protected columns can share the same security label, but all labels must have the same security policy.
- A security policy cannot be associated with a temporary table, nor with a typed table in a table hierarchy.

## Storage options

Use the `FRAGMENT BY` clause, `PUT` clause, `EXTENT` size options, and `COMPRESSED` option of the `CREATE TABLE` statement to specify the storage location, the distribution scheme, the extent size for the table, and whether the table is enabled for the automatic compression of large amounts of new row data.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

### Storage Options

#### IN

*dbspace*

*extspace*

`FRAGMENT BY` clause <sup>186</sup>

`PUT` clause <sup>187</sup>

187. See [PUT Clause on page 378](#)

188. See [EXTENT SIZE Options on page 390](#)

189. See [COMPRESSED option for tables on page 391](#)

| Element         | Description  | Restrictions | Syntax                                    |
|-----------------|--|--------------|---|
| <i>extspace</i> | Name declared in the <code>onspaces</code> command to a storage area outside the database server | Must exist   | See documentation for your access method. |

## Usage

The storage options that specify the location, distribution scheme, and extent size for the table are an extension to the ANSI/ISO standard for SQL syntax.

If you use the `USING` access-method clause to specify an access method, that method must support the storage space.

You can specify a `dbspace` for the table that is different from the storage location for the database, or fragment the table among `dbspaces`, or among named fragments in one or more `dbspaces`.

If you specify no `IN` clause nor fragmentation scheme, the new table is stored in the same `dbspace` where the current database is stored. However, if you enabled automatic location and fragmentation, tables are created and fragmented in `dbspaces` that are chosen by the server. To enable the automatic location and fragmentation of tables, set the `AUTOLOCATE` configuration parameter or session environment variable to a positive integer. The value of the integer represents the number of fragments to initially allocate to the table. Additional fragments are added as the table grows.

## Sbspaces for smart large objects

You can use the `PUT` clause to specify `sbspace` storage locations and storage characteristics for smart large objects, such as `BLOB` or `CLOB` column values.

**Note:** If your table contains simple large objects (`TEXT` or `BYTE`), you can specify a separate `blobspace` for each object.

## Dbspaces in tenant databases

If the table is in a tenant database, the `dbspace` must be a dedicated `dbspace` in the tenant database properties list. If the table is not in a tenant database, the `dbspace` cannot be the name of a `dbspace` that is dedicated to a tenant database.

---

### Related reference

[Large-Object Data Types on page 1180](#)

[USING Access-Method Clause on page 394](#)

## Using the IN Clause

Use the `IN` clause of the `CREATE TABLE` statement to specify a storage space for the table. The storage space that you specify must already exist.

You can use the `IN` clause to isolate a table. For example, if the **history** database is in the **db1** `dbspace`, but you want the **family** data placed in a separate `dbspace` called **famdata**, use the following statements:

```
CREATE DATABASE history IN dbs1;

CREATE TABLE family
(
  id_num      SERIAL(101) UNIQUE,
  name        CHAR(40),
  nickname    CHAR(20),
  mother      CHAR(40),
  father      CHAR(40)
)
IN famdata;
```

For more information about how to store and manage your tables in separate dbspaces, see your *Informix® Administrator's Guide*.

In general, use the `extspace` storage option in conjunction with the [USING Access-Method Clause on page 394](#). For more information, refer to the documentation of your access method.

If `IN dbspace` is the only storage specification for the new table, then by default 16 kilobytes of storage (or enough storage for four pages, if 4 pages require more than 16 kilobytes) are allocated for the first extent size at the time of table creation.

No storage is allocated for the first extent, however, if the `CREATE TABLE` statement includes none of the following storage specifications:

- `EXTENT SIZE`
- `NEXT SIZE`
- `IN dbspace`.

In this case, storage allocation for the first extent is deferred until the first row is stored in the table.

The same storage allocation deferral applies to tables defined by the `CREATE TEMP TABLE` statement that do not include any of the storage specifications listed above.

When rows are first inserted into a table for which extent allocation has been deferred, the default size for the first extent is 16 kilobytes. If 16 kilobytes are insufficient for 4 pages, the first extent size will be 4 pages.

When reverting a Version 11.70 or later database server to an earlier release that does not support deferred extent allocation for empty tables, you must either drop or else insert a row into any empty database table that you wish to revert. Empty external tables that do not support `INSERT` operations must be dropped.

---

## PUT Clause

Use the `PUT` clause to specify the storage spaces and their characteristics for each column that will contain smart large objects.

This syntax fragment is part of the [Storage options on page 376](#).

PUT Clause

**PUT**

```
,
column IN (
, sbspace
)
(
,
EXTENT SIZE kilobytes
NO LOG LOG
HIGH INTEG MODERATE INTEG
NO KEEP ACCESS TIME KEEP ACCESS TIME
)
```

| Element          | Description   | Restrictions  | Syntax                                      |
|------------------|---|---|---|
| <i>column</i>    | Column to store in <i>sbspace</i>                   | Must contain a BLOB, CLOB, user-defined, or complex data type   | <a href="#">Identifier on page 1456</a>     |
| <i>kilobytes</i> | Number of kilobytes to allocate for the extent size | Must be an integer value  | <a href="#">Literal Number on page 1419</a> |
| <i>sbspace</i>   | Name of a storage area for smart large objects      | Must exist<br><br>If the table is in a tenant database, the <i>sbspace</i> must be a dedicated <i>sbspace</i> in the tenant database properties list.<br><br>If the table is not in a tenant database, the <i>sbspace</i> cannot be the name of an <i>sbspace</i> that is dedicated to a tenant database. | <a href="#">Identifier on page 1456</a>     |

The specified column cannot be in the form *column.field*. That is, the smart large object that you are storing cannot be one field of a ROW type.

### Specifying the storage location

Each smart large object is stored in a single *sbspace*. The SBSPACENAME configuration parameter specifies the system default *sbspace* in which smart large objects are created, unless the PUT clause specifies another *sbspace*.

For example, the following statement defines **tabwblob** as a table whose only column is of data type BLOB. The column name is declared as **image01**, and the PUT clause specifies the storage location for all of its BLOB objects as **sbspace01**:

```
CREATE TABLE tabwblob
(
  image01 BLOB
) PUT image01 IN (sbspace01);
```

For the example above to be valid, the **sbspace01** must already exist. Because the no other options to the PUT clause are specified, **sbspace01** has default values for its extent size and for the other storage characteristics that the PUT clause can define, including `NO LOG`, `HIGH INTEG`, and `NO KEEP ACCESS TIME`, as defined below.

The PUT clause can specify storage locations for a list of BLOB and CLOB columns. The following example defines **tabw2blobs** as a table with two columns, where column **image02** is of type BLOB, and column **commentary03** is of type CLOB. In the next example, the PUT clause specifies that all the smart large objects in both columns are stored in the same **sbspace01** smart large object space:

```
CREATE TABLE tabw2blobs
(
  image02 BLOB,
  commentary03 CLOB
) PUT image02 IN (sbspace01),
  commentary03 IN (sbspace01);
```

You can specify that more than one sbspace stores the same BLOB or CLOB column. This distributes the smart large objects in a round-robin distribution scheme, so that the number of smart large objects in each sbspace is approximately equal. The comma-separated list of sbspaces for a single column must be delimited by parentheses.

The next example defines **tabw2sblobs** as a table with two columns, where column **image04** is of type BLOB, and column **commentary05** is of type CLOB. The PUT clause specifies that the BLOB objects in column **image04** are stored in two sbspaces, **sbspace01** and **sbspace02**, and all the CLOB objects in column **image05** are stored in sbspace **sbspace03**:

```
CREATE TABLE tabw2sblobs
(
  image04 BLOB,
  commentary05 CLOB
) PUT image04 IN (sbspace01,sbspace02),
  commentary05 IN (sbspace03);
```

If an INSERT or MERGE operation adds six new rows to the table in this example,

- three of the **image04** BLOB objects of will be stored in **sbspace01**,
- the other three **image04** BLOB objects will be stored in **sbspace02**,
- and all six **commentary05** CLOB objects will be stored in **sbspace03**.

When you distribute smart large objects across different sbspaces, you can work with smaller sbspaces. If you limit the size of an sbspace, backup and archive operations can perform more quickly.

## Specifying sbspace characteristics

The following storage options are available to store BLOB and CLOB data:

### Option

#### Effect

### EXTENT SIZE

Specifies a lower limit on how many kilobytes can be stored in a smart-large-object extent. The database server might round the specified *kilobytes* value up, so that the extent size is an integer multiple of the sbspace page size.

**HIGH INTEG**

This high data-integrity option produces user-data pages that contain a page header and a page trailer to detect incomplete writes and data corruption. This option is the default data-integrity behavior.

**MODERATE INTEG**

This data-integrity option produces user-data pages that contain a page header but no page trailer. This option cannot compare the page header with the page trailer to detect incomplete writes and data corruption.

**KEEP ACCESS TIME**

This maintains a record in the smart-large-object metadata of the system time when the smart large object was last read or written.

**NO KEEP ACCESS TIME**

Does not record the system time when the smart large object was last read or written. This provides better performance than the KEEP ACCESS TIME option, and is the default tracking behavior.

**LOG**

Follows the logging procedure used with the current database log for the corresponding smart large object. This option can generate large amounts of log traffic and increase the risk of filling the logical log.

**NO LOG**

Turns off logging. This option is the default behavior.

The comma-separated list of keyword options that define sbspace characteristics must be enclosed in parentheses, and immediately follows the sbspace (or the list of sbspaces) that stores the BLOB or CLOB column. In the following example, the PUT clause specifies that the unlogged **sbspace01** and **sbspace02** sbspaces that store the BLOB objects of column **image04** have characteristics different from **sbspace03**, a logged sbspace that stores CLOB objects of column **commentary05**:

```
CREATE TABLE tabw2sblobs
(
  image04 BLOB,
  commentary05 CLOB
) PUT image04 IN (sbspace01,sbspace02) (KEEP ACCESS TIME, MODERATE INTEG),
  commentary05 IN (sbspace03) (EXTENT SIZE 30, LOG);
```

When you turn logging on for a smart large object, you must immediately perform a level-0 backup to be able to recover and restore the smart large object.

The **syscolattns** system catalog table contains one row for each *sbspace* and *column* combination in the PUT clause:

- The **syscolattns.extentsize** column stores the extent size, based on the *kilobytes* value.
- The **syscolattns.flags** column stores a bitmap corresponding to the logging and access time status, and data integrity setting.

If a user-defined or complex data type contains more than one large object, the specified large-object storage options apply to all large objects in the type, unless the storage options are overridden when the large object is created.

**Important:** The PUT clause does not affect the storage of simple-large-object data types (BYTE and TEXT). For information on how to store BYTE and TEXT data, see [Large-Object Data Types on page 1180](#).

## Alternative to full logging

Instead of full logging, you can turn off logging when you load the smart large object initially and then turn logging back on once the object is loaded.

Use the NO LOG option to turn off logging. If you use NO LOG, you can restore the smart-large-object metadata later to a state in which no structural inconsistencies exist. In most cases, no transaction inconsistencies will exist either, but that result is not guaranteed.

The following statement creates the **greek** table. Data values for the table are fragmented into the **db1** and **db2** dbspaces. The PUT clause assigns the smart-large-object data in the **gamma** and **delta** columns to the **sb1** and **sb2** sbspaces, respectively. The TEXT data values in the **eps** column are assigned to the **blb1** blobspace.

```
CREATE TABLE greek
(alpha INTEGER,
 beta VARCHAR(150),
 gamma CLOB,
 delta BLOB,
 eps TEXT IN blb1)
FRAGMENT BY EXPRESSION
alpha <= 5 IN db1, alpha > 5 IN db2
PUT gamma IN (sb1), delta IN (sb2);
```

## FRAGMENT BY clause

Use the FRAGMENT BY clause to create a fragmented table and to specify its storage distribution scheme. The keywords PARTITION BY are a synonym for FRAGMENT BY.

This syntax fragment is part of the [Storage options on page 376](#).

FRAGMENT BY clause for tables

**WITH ROWIDS**

**FRAGMENT**

**PARTITION**

**BY**

**ROUND ROBIN**

**IN**

, *dbspace*

,

**PARTITION** *partition*

**IN** *dbspace*

**EXPRESSION** Expression Fragment Clause <sup>192</sup>

**RANGE** ( *fragment\_key* )

Interval Fragment Clause <sup>190</sup>

**LIST** ( *fragment\_key* ) List Fragment Clause <sup>191</sup>

| Element             | Description  | Restrictions  | Syntax                                  |
|---------------------|--|---|---|
| <i>column</i>       | Column to which to apply the fragmentation strategy  | Must be a column within the table   | <a href="#">Identifier on page 1456</a> |
| <i>dbspace</i>      | Dbospace to store the table fragment   | You can specify no more than 2,048 <i>dbspaces</i> . All <i>dbspaces</i> that store the fragments must have the same page size. | <a href="#">Identifier on page 1456</a> |
| <i>fragment_key</i> | Cast, column, or function expression on a table column. This is the expression on which the table is fragmented. | Columns must be from the current table only   | <a href="#">Expression on page 1193</a> |
| <i>partition</i>    | Name declared here for a fragment  | Must be unique among the names of fragments of the table  | <a href="#">Identifier on page 1456</a> |

When you fragment a table, the IN keyword is followed by the name of the storage space where a table fragment is to be stored.

## Using the WITH ROWIDS Option

Nonfragmented tables contain a hidden column called **rowid**, but by default, fragmented tables have no **rowid** column. You can use the WITH ROWIDS keywords to add the **rowid** column to a fragmented table. Each row is automatically assigned

190. See

191. See [List fragment clause on page 388](#)

192. See [Expression Fragment Clause on page 385](#)

a unique **rowid** value that remains stable for the life of the row and that the database server can use to find the physical location of the row. Each row requires an additional four bytes to store the **rowid**.

**Important:**

This is a deprecated feature. The query optimizer might not use an index scan when explicit **rowid** shadow columns are defined on fragmented tables. When creating new applications, use primary keys as a method of row identification instead of using **rowid** values.

You cannot use the WITH ROWIDS clause with typed tables.

## Fragmenting by ROUND ROBIN

In a round-robin distribution scheme, specify at least two dbspaces where you want the fragments to be placed, or specify at least two fragment names in one or more dbspaces. As records are inserted into the table, they are placed in the first available fragment. The database server balances the load among the specified fragments as you insert records and distributes the rows in such a way that the fragments always maintain approximately the same number of rows ( $\pm 100$ ). A newly-added round-robin fragment will be favored exclusively by inserts and loads until it no longer has the fewest rows among the table's fragments.

In this distribution scheme, the database server must scan all fragments when it searches for a row.

**Important:**

The FRAGMENT BY ROUND ROBIN clause overrides the automatic location and fragmentation of tables, which is enabled when the AUTOLOCATE configuration parameter or the AUTOLOCATE session environment option is set to a positive integer.

When automatic location and fragmentation is enabled, the database server automatically determines

- the table extent sizes,
- the dbspaces where the fragments are stored,
- and a ROUND ROBIN distributed-storage strategy for the new table.

### Round-robin fragmentation with large object data types

For simple large objects in tables that contain BYTE or TEXT columns and that are fragmented by round-robin, you can reserve space for inserting BYTE and TEXT data by setting the PN\_STAGELOB\_THRESHOLD configuration parameter. For information about how the database server stages simple large objects in round-robin fragments, see the description of PN\_STAGELOB\_THRESHOLD in your .

For smart large objects in tables that contain BLOB or CLOB columns, you can use the PUT clause to specify round-robin fragmentation in a list of sbspaces. When you include the PUT clause in the CREATE TABLE statement (or in the CREATE TEMP TABLE statement or in the ALTER TABLE statement), you have the options to include or not include a FRAGMENT

An arbitrary rule specifies fragment expressions based on a predefined SQL expression that typically uses OR clauses to group data, as the following example shows:

```
FRAGMENT BY EXPRESSION
  zip_num = 95228 OR zip_num = 95443 IN dbsp2,
  zip_num = 91120 OR zip_num = 92310 IN dbsp4,
  REMAINDER IN dbsp5;
```

**Warning:** See the note about the **DBCENTURY** environment variable and date values in fragment expressions in the section [Logging Options on page 346](#).

## REMAINDER keyword

Use the REMAINDER keyword to specify the storage space in which to store valid values that fall outside the specified expression or expressions. If you do not specify a remainder, and a row is inserted or updated with values that do not correspond to any fragment definition, the database server returns an error.

The following example uses an arbitrary rule to define five fragments for specific values of the **c1** column, and a sixth fragment for all other values:

```
CREATE TABLE T1 (c1 INT) FRAGMENT BY EXPRESSION
  PARTITION PART_1 (c1 = 10) IN dbsp1,
  PARTITION PART_2 (c1 = 20) IN dbsp1,
  PARTITION PART_3 (c1 = 30) IN dbsp1,
  PARTITION PART_4 (c1 = 40) IN dbsp2,
  PARTITION PART_5 (c1 = 50) IN dbsp2,
  PARTITION PART_6 REMAINDER IN dbsp2;
```

Here the first three fragments are stored in partitions of the **dbsp1** dbspace, and the other fragments, including the remainder, are stored in named fragments of the **dbsp2** dbspace. Explicit fragment names are required in this example, because each dbspace has multiple partitions.

## Fragmentation in NLCASE INSENSITIVE databases

In databases with the NLSCASE INSENSITIVE property, operations on NCHAR and NVARCHAR data ignore lettercase, so that the database server treats case variants among strings composed of same sequence letters as duplicates. If the fragment keys for a table that is fragmented by expression are NCHAR or NVARCHAR columns, then each fragment defined by a character expression stores all lettercase variants that match the expression that defines the fragment. For example, for the expression `lname = 'Garcia'` where **lname** is a column of type NCHAR or NVARCHAR, rows with the following values in that column would all be stored in the same fragment, because the case-insensitive expression evaluates to TRUE for these (and similar) string values:

```
'Garcia' 'garcia' 'GARCIA' 'GarCia' 'gARCia'
```

For more information about NLSCASE INSENSITIVE databases, see [CREATE DATABASE statement on page 201](#), [Duplicate rows in NLSCASE INSENSITIVE databases on page 779](#), and [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

## User-Defined Functions in Fragment Expressions

For rows that include user-defined data types, you can use comparison conditions or user-defined functions to define the range rules. In the following example, comparison conditions define the range rules for the **long1** column, which contains an opaque data type:

```
FRAGMENT BY EXPRESSION
  long1 < '3001' IN dbsp1,
  long1 BETWEEN '3001' AND '6000' IN dbsp2,
  long1 > '6000' IN dbsp3;
```

An implicit, user-defined cast converts `3001` and `6000` to the opaque type.

Alternatively, you can use user-defined functions to define the range rules for the opaque data type of the **long1** column:

```
FRAGMENT BY EXPRESSION
  (lessthan(long1,'3001')) IN dbsp1,
  (greaterthanorequal(long1,'3001') AND
  lessthanorequal(long1,'6000')) IN dbsp2,
  (greaterthan(long1,'6000')) IN dbsp3;
```

Explicit user-defined functions require parentheses around the entire fragment expression before the IN clause, as the previous example shows.

User-defined functions in a fragment expression can be written in SPL or in the C or Java™ language. These functions must satisfy four requirements:

- They must evaluate to a Boolean value.
- They must be nonvariant.
- They must reside within the same database as the table.
- They must not generate OUT nor INOUT parameters.

For information on how to create UDRs for fragment expressions, refer to *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Partial Index in Fragment Expressions

Starting 14.10xC2 onwards, Informix supports FRAGMENT BY EXPRESSION partial index.

A *partial index* is an index built over a subset of a table. The subset is defined by a conditional expression (called the *predicate* of the partial index). The index contains entries for only those table rows that satisfy the predicate.

Partial indexes avoid indexing common values. As the query searching for a common value will not use the index, there is no point in keeping those rows in the index. This reduces the size of the index, which will speed up queries that do use the index. It will also speed up many table update operations because the index does not need to be updated in all cases.

### Example 1: Setting up a Partial Index to Exclude Common Values

```
create table tab1 (n int, n2 int, n4 int, cc char(16));
-- insert 10,000 rows
with cte(n) as (
  select 1 as n
  union all
  select n+1 from cte where n < 10000
```

```

)
insert into tab1
select n,
       case when mod(n,10) == 0 then n else null end,
       mod(n,4),
       n from cte;

```

To create a partial index that suits the above example for non-null values, create index as:

```

create index idx1 on tab1(n) fragment by expression
      (n2 is null) in dbs1 INDEX OFF,
      remainder in dbs2;

```

“oncheck -pk | grep ‘^Key’ | wc -l” shows only 1000 rows are indexed.

The query that can use this index would be:

```

select count(*) from tab1 where n < 1000 and n2 is not null;

```

The query that cannot use this index would be:

```

select count(*) from tab1 where n < 1000;

```

## Example 2: Setting up a Partial Index to Exclude Un-wanted Values

If you have a table that contains customers from different states, where one specific state records take up a small fraction of the total table and yet those are the most-accessed rows, you can improve performance by creating an index on just that specific state rows. The command to create the index:

```

create index zip_ix on customer(zipcode)
      fragment by expression
      (state = 'CA') in dbs1,
      remainder in INDEX OFF;

```

The query that can use this index would be:

```

select fname, lname from customer
      where zipcode >= '94117'
      and state='CA';

```

**Note:** A partial index can be used in a query only if the system can recognize that the WHERE condition of the query mathematically implies the predicate of the index..

## List fragment clause

Use the List Fragment clause to specify a list of fragment key values to store in the same fragment. The rows assigned to each fragment must match the fragment key value (or one of a comma-separated list of fragment key values) that defines the fragment.

This syntax fragment is part of the [FRAGMENT BY clause on page 382](#).

List Fragment Clause

```
,
PARTITIONpartitionList Expression ClauseINdbspace
193PARTITIONpartition REMAINDERINdbspace
```

List Expression Clause

**VALUES**

```
(
, const_expr
)
193IS NULL
```

| Element           | Description  | Restrictions  | Syntax  |
|-------------------|--|---|---|
| <i>const_expr</i> | Constant expression that defines the list of fragment key values for the fragment to store | Must be a quoted string or a literal value. Each value in the list must be unique among the lists for fragments of the same object.   | <a href="#">Constant Expressions on page 1235</a> |
| <i>dbspace</i>    | <i>dbspace</i> to store the fragment   | You can specify no more than 2,048 <i>dbspaces</i> . All of these <i>dbspaces</i> must have the same page size.   | <a href="#">Identifier on page 1456</a>           |
| <i>partition</i>  | Name that you declare here for a fragment  | Must be unique among the names of fragments of the same object. If a table and its index use the same list fragmentation strategy, each index fragment must have the same name as the corresponding table fragment. | <a href="#">Identifier on page 1456</a>           |

Fragmenting by list defines fragments that are each based upon a list of discrete values of the fragment key.

You can use this fragmentation strategy when the values of the fragment key are categories on a nominal scale that has no quantified order within the set of categories. Fragmenting by list is useful when a table contains a finite set of values for the fragment key and queries on the table have an equality predicate on the fragment key. For example, you can fragment data geographically, based on a list of the states or provinces within a country. The rows that are stored in each fragment can be restricted to a single fragment key value, or to a list of values representing some logical subset of fragment key values, provided that no fragment key value is shared by two or more fragments.

Fragmenting by list also helps to logically segregate data.

Fragmenting by list supports these features:

- Both a table and its indexes can be fragmented by list.
- The fragment key can be a column expression based on a single column or on multiple columns.
- The list can optionally include a remainder fragment.
- The list can optionally include a NULL fragment that stores only NULL values.

193. Use this path no more than once

Fragmenting a table by list (or fragmenting an index, in the CREATE INDEX statement) must satisfy these requirements:

- The list that includes NULL (or IS NULL) cannot include any other value.
- The fragment key must be based on a single row.
- The fragment key must be a column expression. This *constant expression* can be based on a single column or on multiple columns.
- Lists cannot include duplicate *constant expression* values. Each value must be unique within the FRAGMENT BY LIST clause.

Load, INSERT, MERGE, or UPDATE operations on tables fragmented BY LIST can fail at runtime under these circumstances:

- The fragment key for a row evaluates to NULL, but the FRAGMENT BY LIST clause defined no NULL fragment.
- The fragment key for a row matches no *constant expression* value for any fragment, but no remainder fragment is defined.

### REMAINDER and NULL fragments in list-based storage distribution

You can optionally define a REMAINDER fragment to store rows that do not match the list of fragment key values for any fragment.

You can optionally define a NULL fragment to store rows with missing fragment key values by specifying only `IS NULL` or `NULL` after the VALUES keyword in the List Expression clause for the fragment. You cannot include `NULL` or `IS NULL` in an expression list that also includes any other expression. (In this context, `NULL` and `IS NULL` are keyword synonyms.)

If no NULL fragment is defined, and an operation attempts to insert a row that is missing data for the fragment key, the result depends on whether a REMAINDER fragment exists:

- If a REMAINDER fragment is defined, the row is stored in the REMAINDER fragment.
- If no REMAINDER fragment is defined, the database server issues an exception.

If no REMAINDER fragment is defined, and an INSERT, UPDATE, MERGE, or other DML operation attempts to store a row whose fragment key does not match a list value for any fragment, the database server issues an exception.

When you define a list-based partitioning scheme for a table or index, the fragment list can include no more than one NULL fragment, and no more than one REMAINDER fragment.

If a table that is partitioned BY LIST has no NULL or REMAINDER fragment, but you subsequently determine that either or both of these fragments are needed, you can add a NULL fragment or a REMAINDER fragment, or both, to the fragment list by using the ADD option to the ALTER FRAGMENT statement. For more information, see [ADD Clause on page 47](#).

## EXTENT SIZE Options

The EXTENT SIZE options can define the size of storage extents allocated to the table.

This syntax fragment is part of the [Storage options on page 376](#).

## EXTENT SIZE Options

**EXTENT SIZE** *first\_kilobytes***NEXT SIZE** *next\_kilobytes*

| Element                | Description   | Restrictions   | Syntax                                  |
|------------------------|---|--|---|
| <i>first_kilobytes</i> | Length in kilobytes of the first extent for the table; default is 16 kilobytes. | Must return a positive number; maximum is the chunk size | <a href="#">Expression on page 1193</a> |
| <i>next_kilobytes</i>  | Length in kilobytes of each subsequent extent; default is 16 kilobytes.         | Must return a positive number; maximum is the chunk size | <a href="#">Expression on page 1193</a> |

**Usage**

The minimum length of *first\_kilobytes* (and of *next\_kilobytes*) is four times the disk-page size on your system. For example, if you have a 2-kilobyte page system, the minimum length is 8 kilobytes.

If the CREATE TABLE (or the CREATE TEMP TABLE) statement includes no IN dbspace clause, no EXTENT SIZE specification, and no NEXT SIZE specification, no storage is allocated for the table until at least one data row is inserted into it. The default size of the first extent is either 16 kilobytes or 4 pages.

The next example specifies a first extent of 20 kilobytes and allows the rest of the extents to use the default size:

```
CREATE TABLE emp_info
(
  f_name      CHAR(20),
  l_name      CHAR(20),
  position    CHAR(20),
  start_date  DATETIME YEAR TO DAY,
  comments    VARCHAR(255)
)
EXTENT SIZE 20;
```

If a table contains no data, you can use the ALTER TABLE MODIFY EXTENT SIZE or ALTER TABLE MODIFY NEXT SIZE statements of SQL to change the size of the first extent and of the next extent of the empty table. These operations are not supported, however, for tables that contain one or more rows. For more information about these options to the ALTER TABLE statement, see [MODIFY EXTENT SIZE on page 154](#) and [MODIFY NEXT SIZE clause on page 155](#).

If you need to revise the extent sizes of a table, you can modify the first extent and next-extent sizes in the generated schema files of an unloaded table. For example, to make a database more efficient, you might unload a table, modify the extent sizes in the schema files, and then create and load a new table. For information about how to optimize extents, see your *Informix® Administrator's Guide*.

**Related reference**

[MODIFY NEXT SIZE clause on page 155](#)

## COMPRESSED option for tables

Use the COMPRESSED option of the CREATE TABLE statement to enable the automatic compression of large amounts of row data when the data is loaded into the table or table fragment.

After you create a table with the COMPRESSED option, the database server automatically creates a compression dictionary and compresses the in-row data after 2000 or more rows of data are loaded into a table or fragment. If the data is loaded by a light append, the first 2000 rows and all subsequent rows are compressed. If the data is loaded by another method, all subsequent rows after the first 2000 rows are compressed. To compress the original 2000 rows, run the SQL administration API task() or admin() function with the table compress or fragment compress argument.

The COMPRESSED option enables only the compression of in-row data. The COMPRESSED option does not enable the automatic compression of simple large objects in dbspaces or indexes. (You can use the COMPRESSED keyword of the CREATE INDEX statement to create a compressed B-tree index.)

The following example creates a table that is set up for the automatic compression:

```
CREATE TABLE cust5 ( ...) COMPRESSED;
```

The following example also creates a table named **t**, which defines first and next extent sizes and is set up for the automatic compression:

```
CREATE TABLE t(c int, d int) EXTENT SIZE 32 NEXT SIZE 32 COMPRESSED;
```

To disable the automatic compression of data in new rows, run an SQL administration API task() or admin() function with the table uncompress argument. To re-enable automatic compression, run the SQL administration API task() or admin() function with the table compress argument on the table. You can control compression for a table fragment with the fragment uncompress and fragment compress arguments.

## LOCK MODE Options

Use the LOCK MODE options to specify the locking granularity of the new table.

The following table describes the locking-granularity options.

| Granularity | Effect   |
|-------------|--|
| PAGE        | <p>Obtains and releases one lock on a whole page of rows</p> <p>If neither the <b>IFX_DEF_TABLE_LOCKMODE</b> environment variable nor the <b>DEF_TABLE_LOCKMODE</b> configuration parameter has set a default locking granularity, this is the system default.</p> <p>Page-level locking is especially useful when you know that the rows are grouped into pages in the same order that you are using to process all the rows. For example, if you are processing the contents of a table in the same order as its cluster index, page locking is appropriate.</p> |
| ROW         | <p>Obtains and releases one lock per row</p> <p>Row-level locking provides the highest level of concurrency. If you are using many rows at one time, however, the lock-management overhead can become significant. You might also exceed</p>   |

| Granularity | Effect  |
|-------------|---|
|             | the maximum number of locks available, depending on the configuration of your database server, but Informix® can support up to 18 million locks on 32-bit platforms, or 600 million locks on 64-bit platforms. Only tables with row-level locking can support the LAST COMMITTED isolation level feature. |

### Examples of setting the locking granularity

The following CREATE TABLE statement defines a new table **tsTab\_j** with column **id** of type INT and column **ts** of the **TIMESERIES(ts\_data\_j)** extended data type, with ROW as the locking granularity:

```
CREATE TABLE IF NOT EXISTS tsTab_j(
  id INT NOT NULL PRIMARY KEY,
  ts TIMESERIES(ts_data_j)
) LOCK MODE ROW;
```

In the next example, a user who holds the DBSECADAM role creates a **Tab5** table with both row-level and column-level granularity of LBAC protection, and with PAGE as the locking granularity. is

```
CREATE TABLE Tab5 (C1 IDSSECURITYLABEL,
  C2 int,
  C3 char (10) COLUMN SECURED WITH label6)
SECURITY POLICY company
LOCK MODE PAGE;
```

This ALTER TABLE . . . LOCK MODE statement can change the locking granularity, as in this example for the **Tab5** table:

```
ALTER TABLE Tab5 LOCK MODE(ROW);
```

#### Important:

The SET LOCK MODE statement of SQL has no effect on the locking granularity of tables. For the syntax and semantics, see [SET LOCK MODE statement on page 982](#).

## Precedence and Default Behavior

In Informix®, you do not need to specify the lock mode each time you create a new table. You can globally set the locking granularity of all new tables in the following environments:

- Database session of an individual user

You can set the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable to specify the lock mode of new tables during your current session.

- Database server (all sessions on the database server)

If you are a DBA, you can set the `DEF_TABLE_LOCKMODE` configuration parameter in the `ONCONFIG` file to determine the lock mode of all new tables in the database server.

If you are not a DBA, you can set the `IFX_DEF_TABLE_LOCKMODE` environment variable for the database server, before you run **oninit**, to specify the lock mode of all new tables of the database server.

The `LOCK MODE` setting in a `CREATE TABLE` statement takes precedence over the settings of the `IFX_DEF_TABLE_LOCKMODE` environment variable and the `DEF_TABLE_LOCKMODE` configuration parameter.

If `CREATE TABLE` specifies no lock mode setting, the default mode depends on the setting of the `IFX_DEF_TABLE_LOCKMODE` environment variable or the `DEF_TABLE_LOCKMODE` configuration parameter. For information about `IFX_DEF_TABLE_LOCKMODE`, refer to the *Informix® Guide to SQL: Reference*. For information about the `DEF_TABLE_LOCKMODE` configuration parameter, refer to the .

## USING Access-Method Clause

The `USING` Access Method clause can specify an access method.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

`USING` Access-Method Clause

### USING

```
Specific Name 194
,
(
, config_keyword
= 'config_value'
)
```

| Element               | Description   | Restrictions  | Syntax                                     |
|-----------------------|---|---|--|
| <i>config_keyword</i> | Configuration keyword associated with the specified access method | No more than 18 bytes. The access method must exist.          | Literal keyword                            |
| <i>config_value</i>   | Value of the specified configuration keyword                      | No more than 236 bytes. Must be defined by the access method. | <a href="#">Quoted String on page 1424</a> |

A *primary-access method* is a set of routines to perform DDL and DML operations, such as create, drop, insert, delete, update, and scan, to make a table available to the database server. Informix® provides a built-in primary-access method.

You store and manage a virtual table either outside of the database server in an extspace or inside the database server in an sbospace. (See [Storage options on page 376](#).) You can access a virtual table with SQL statements. Access to a virtual table requires a user-defined primary-access method.

194. See [Specific Name on page 1521](#)

DataBlade® modules can provide other primary-access methods to access virtual tables. When you access a virtual table, the database server calls the routines associated with that access method rather than the built-in table routines. For more information on these other primary-access methods, refer to your access-method documentation.

You can retrieve a list of configuration values for an access method from a table descriptor (**mi\_am\_table\_desc**) using the MI\_TAB\_AMPARAM macro. Not all keywords require configuration values.

The access method must already exist. For example, if an access method called **textfile** exists, you can specify it with the following syntax:

```
CREATE TABLE mybook
  (... )
  IN myextspace
  USING textfile (DELIMITER='');
```

## Statistics options of the CREATE TABLE statement

Use the Statistics Options clause of the CREATE TABLE statement to set the values of the STATCHANGE property of a fragmented or nonfragmented table, and the STATLEVEL property of a fragmented table.

This syntax fragment is part of the [CREATE TABLE statement on page 335](#).

Statistics Options

**STATCHANGE AUTO**

**STATCHANGE**

**AUTO** *change\_threshold*

**STATLEVEL AUTO**

**STATLEVEL**

**FRAGMENT TABLE AUTO**

| Element                 | Description  | Restrictions                            | Syntax                                      |
|-------------------------|--|---|---|
| <i>change_threshold</i> | Percentage of changed data rows that defines stale distribution statistics | Must be an integer in the range 0 - 100 | <a href="#">Literal Number on page 1419</a> |

### Usage

These table attributes control the threshold for automatic recalculation (STATCHANGE) and the granularity (STATLEVEL) of data distribution statistics.

The Statistics Options clause of the CREATE TABLE statement can define table statistics properties that allow the user to control the actions of

- UPDATE STATISTICS, when that SQL statement is run without the `FOR` keyword,
- and of UPDATE STATISTICS FOR TABLE, when that statement runs in LOW, MEDIUM, or HIGH mode.

The two table properties that the Statistics Options clause can set are STATCHANGE and STATLEVEL.

### The STATCHANGE property

The STATCHANGE table attribute specifies the minimum percentage of changes (from UPDATE, DELETE, MERGE, and INSERT operations on the rows in the table or fragment since the previous calculation of distribution statistics) to consider the statistics stale. You can specify an integer value in the range 0 - 100, or you can use the AUTO keyword to apply the current STATCHANGE configuration parameter setting in the ONCONFIG file or in the session environment variable as the default change threshold value.

The automatic mode for selectively updating table and fragment statistics can be enabled in any of the following ways:

- The AUTO\_STAT\_MODE configuration parameter is set to 1 (or is not set). Enables automatic mode as the system default.
- The AUTO\_STAT\_MODE session environment variable is set to `ON`. Enables automatic mode during the current session.
- The UPDATE STATISTICS statement includes the `AUTO` keyword. Enables automatic mode while that UPDATE STATISTICS statement is running.

#### Important:

Enabling automatic mode has no effect, however, on any of these UPDATE STATISTICS statements:

- UPDATE STATISTICS statements that end with the `FORCE` keyword.
- UPDATE STATISTICS statements that include the `FOR FUNCTION`, `FOR PROCEDURE`, `FOR ROUTINE`, or `FOR SPECIFIC` keywords.

While automatic mode is enabled, UPDATE STATISTICS statements use the explicit or default STATCHANGE value to identify table, index, or fragment distributions statistics in the system catalog that are missing or stale, and selectively updates only the missing or stale statistics. For more information about the automatic mode for UPDATE STATISTICS operations, see the description of the AUTO\_STAT\_MODE configuration parameter in the *Informix® Administrator's Reference*. See also [AUTO\\_STAT\\_MODE session environment option on page 912](#) and [Using the FORCE and AUTO keywords on page 1060](#).

### The STATLEVEL property

The STATLEVEL property of a fragmented table can determine the level of granularity of its data distributions and index statistics. It can take one of the following three values, with `AUTO` being the default, if no value is specified at creation time:

- `TABLE` specifies that all distributions for the table be created at the table level.
- `FRAGMENT` specifies that distributions be created and maintained for each fragment.
- `AUTO` specifies that the database server apply criteria at run time to determine whether fragment-level distributions are necessary. These criteria require that all of the following conditions are true:

- The SYSSBSPACENAME configuration parameter setting specifies an existing sbspace.
- The table is fragmented by an EXPRESSION, INTERVAL, or LIST strategy.
- The table has more than a million rows.

If any of these criteria are not satisfied, the database server creates table-level distributions, rather than fragment-level.

These properties are always applied. If the STATLEVEL setting is AUTO, this setting overrides the default values.

**Note:** The SYSSBSPACENAME configuration parameter, which must be set when the database server instance is initialized, specifies the sbspace in which the database server stores fragment-level data distribution statistics. These statistics are stored as BLOB objects in the **enddist** column of the **syfragsdist** system catalog table. For the database server to support fragment level statistics, the SYSSBSPACENAME configuration parameter setting specifies an existing sbspace.

If you use the Statistics Options clause to set the STATLEVEL property to FRAGMENT, the database server returns an error if either of the following is true:

- The SYSSBSPACENAME configuration parameter is not set.
- The sbspace that SYSSBSPACENAME specifies was not properly allocated by the onspaces -c -S command.

## CREATE TEMP TABLE statement

Use the CREATE TEMP TABLE statement to create a temporary table in the current database.

### Syntax

```
CREATE TEMP TABLE IF NOT EXISTS table(
, Column Definition195
,
, Multiple-Column Constraint Format197 Column Definition195
)
WITH NO LOG
196 Storage Options198
LOCK MODE Options199
USING Access-Method Clause200
```

195. See [Column definition on page 399](#)

196. Informix® extension

197. See [Multiple-Column Constraint Format on page 400](#)

198. See [Storage options for temporary tables on page 402](#)

199. See [LOCK MODE Options on page 392](#)

200. See [USING Access-Method Clause on page 394](#)

| Element      | Description                    | Restrictions   | Syntax                                  |
|--------------|--------------------------------|--|---|
| <i>table</i> | Name declared here for a table | Must be unique in session.<br>See <a href="#">Declaring a name for a temporary table on page 398</a> | <a href="#">Identifier on page 1456</a> |

## Usage

You must have the Connect privilege on the database to create a temporary table. The temporary table is visible only to the user who created it.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a temporary table of the specified name already exists in the current session.

You can also define indexes and constraints on temporary tables that you define with the CREATE TEMP TABLE statement.

In DB-Access, using the CREATE TEMP TABLE statement outside the CREATE SCHEMA statement generates warnings if you set **DBANSIWARN**.

In ESQL/C, the CREATE TEMP TABLE statement generates warnings if you use the **-ansi** flag or set the **DBANSIWARN** environment variable.

---

## Declaring a name for a temporary table

A temporary table is associated with a session, not with a database. When you create a temporary table, you cannot create another temporary table with the same name (even for another database) until you drop the first temporary table or end the session.

The name of a temporary table must follow the naming requirements for SQL identifiers, but it cannot be a component of a qualified database-object name. When you create a temporary table with the CREATE TEMP TABLE statement, you cannot specify any authorization identifier as its *owner*. Unlike a permanent table, a temporary table cannot be referenced in an SQL statement by qualifying its identifier with an *owner* name, or a *database* name, or a *database server* name.

The name of a temporary table must be different from the name of any other table, view, sequence object, or synonym in the current database server. Otherwise, the temporary table takes precedence in your session over any permanent table of

the same name. The name that you declare for the temporary table, however, need not be different from the temporary table names that are declared in other sessions of the same database server.

If you issue a cross-database DML statement that references a remote permanent table while your local database contains a temporary table with the same name, the DML statement accesses that local temporary table, rather than the remote permanent table.

## Column definition

Use the Column Definition segment of the CREATE TEMP TABLE statement to declare the name and the data type (and optionally a default value and constraints) of a single column of the temporary table.

Column Definition

*column*

Data Type<sup>201</sup>

<sup>204</sup> DEFAULT Clause<sup>202</sup>

<sup>204</sup>Single-Column Constraint Format<sup>203</sup>

| Element       | Description                                  | Restrictions                | Syntax                                  |
|---------------|--|-----------------------------|---|
| <i>column</i> | Name declared here for a column in the table | Must be unique in its table | <a href="#">Identifier on page 1456</a> |

This portion of the CREATE TEMP TABLE statement resembles the corresponding syntax segment in the CREATE TABLE statement. The differences include these:

- You cannot define a referential constraint on the column.
- The data type cannot be IDSSECURITYLABEL.
- The SECURED WITH *label* option is not supported for temporary tables.

Just as when you create permanent tables, any explicit or default storage size specification for a column of a built-in character type, such as CHAR, VARCHAR, NCHAR, NVARCHAR, or VARCHAR, is interpreted in units of bytes, unless the SQL\_LOGICAL\_CHAR configuration parameter is set to enable logical character semantics for datatype declarations. See the for more information about the effect of the SQL\_LOGICAL\_CHAR setting in locales that support multibyte code sets, such as **UTF-8**, where a single logical character can require more than one byte of storage.

201. See [Data Type on page 1163](#)

202. See [DEFAULT clause of CREATE TABLE on page 350](#)

203. See [Single-Column Constraint Format on page 399](#)

204. Use this path no more than once

## Single-Column Constraint Format

Use the single-column constraint format to create one or more data-integrity constraints for a single column in a temporary table.

Single-Column Constraint Format

**NULL NOT NULL**

**UNIQUE**

<sup>205</sup>**DISTINCT**

**PRIMARY KEY**

CHECK Clause<sup>206</sup>

This is a subset of the syntax of [Single-Column Constraint Format on page 353](#) that the CREATE TABLE statement supports.

You can find detailed discussions of specific constraints in these sections.

### **Constraint**

**For more information, see**

### **CHECK**

[CHECK Clause on page 360](#)

### **DISTINCT**

[Using UNIQUE or DISTINCT Constraints on page 355](#)

### **NOT NULL**

[Using the NOT NULL Constraint on page 354](#)

### **NULL**

[Using the NULL Constraint on page 354](#)

### **PRIMARY KEY**

[Using the PRIMARY KEY Constraint on page 356](#)

### **UNIQUE**

[Using UNIQUE or DISTINCT Constraints on page 355](#)

Constraints that you define on temporary tables are always enabled.

## Multiple-Column Constraint Format

Use the multiple-column constraint format to associate one or more columns with a constraint. This alternative to the single-column constraint format allows you to associate multiple columns with a constraint.

205. Informix® extension

206. See [CHECK Clause on page 360](#)

Multiple-Column Constraint Format

**NOT NULL NULL**

**UNIQUE**

<sup>207</sup>**DISTINCT**

**PRIMARY KEY**

(

, *column*

)

CHECK Clause<sup>208</sup>

| Element       | Description   | Restrictions   | Syntax                                  |
|---------------|---|--|---|
| <i>column</i> | Name of column or columns on which the constraint is placed | Must be unique in a table, but the same name can be in different tables of the same database | <a href="#">Identifier on page 1456</a> |

This is a subset of the syntax of [Multiple-Column Constraint Format on page 364](#) that the CREATE TABLE statement supports.

This alternative to the single-column constraint segment of CREATE TEMP TABLE can associate multiple columns with a constraint. Constraints that you define on temporary tables are always enabled.

The following table indicates where you can find detailed discussions of specific constraints.

| Constraint  | For more information, see  | For an example, see   |
|-------------|--|---|
| CHECK       | <a href="#">CHECK Clause on page 360</a>                         | <a href="#">Defining Check Constraints Across Columns on page 367</a>         |
| DISTINCT    | <a href="#">Using UNIQUE or DISTINCT Constraints on page 355</a> | <a href="#">Examples of the Multiple-Column Constraint Format on page 367</a> |
| PRIMARY KEY | <a href="#">Using the PRIMARY KEY Constraint on page 356</a>     | <a href="#">Defining Composite Primary and Foreign Keys on page 367</a>       |
| UNIQUE      | <a href="#">Using UNIQUE or DISTINCT Constraints on page 355</a> | <a href="#">Examples of the Multiple-Column Constraint Format on page 367</a> |

See also the section [Differences Between a Unique Constraint and a Unique Index on page 356](#).

## Using the WITH NO LOG option

Use the WITH NO LOG option to reduce the overhead of transaction logging for the temporary table. If you specify WITH NO LOG, data manipulation language (DML) operations on the temporary table are not included in the transaction log records.

207. Informix® extension

208. See [CHECK Clause on page 360](#)

The WITH NO LOG keywords are required on all temporary tables that you create in temporary dbspaces. Within a cluster environment, the WITH NO LOG keywords are required when you create a temporary table on a secondary server.

If the ONCONFIG parameter TEMPTAB\_NOLOG is set to 1, logging of temporary tables is disabled and all temporary tables are non-logging by default. This setting can improve the performance of operations that use temporary tables, such as HDR operations. The WITH NO LOG option is not needed when the TEMPTAB\_NOLOG setting has disabled logging of temporary tables. For information about how to set the TEMPTAB\_NOLOG parameter, see your .

If you use the WITH NO LOG option in a database that does not use logging, the WITH NO LOG keywords of the CREATE TEMP TABLE statement have no effect. If your database does not support transaction logging, every table behaves as if the WITH NO LOG option were specified.

The ALTER TABLE statement cannot change the logging status of a temporary table. Once you turn off logging on a temporary table, you cannot turn it back on; a temporary table, therefore, is either always logged or else never logged.

The following temporary table is not logged in a database that uses transaction logging:

```
CREATE TEMP TABLE tab2 (fname CHAR(15), lname CHAR(15))
WITH NO LOG;
```

Like all data definition language (DDL) statements of SQL, the CREATE TEMP TABLE statement above that creates tab2 is logged. The WITH NO LOG keywords, however, prevent transaction logging of any DELETE, INSERT, LOAD, MERGE, SELECT, UNLOAD, or UPDATE operations on tab2.

## Storage options for temporary tables

Use the Storage Options segment of the CREATE TEMP TABLE statement to specify the storage location and distribution scheme for the table. This is an extension to the ANSI/ISO standard for SQL syntax.

Storage Options

**IN**

*dbspace*

*extspace*

FRAGMENT BY Clause<sup>209</sup>

PUT Clause<sup>210</sup>

EXTENT SIZE Options<sup>211</sup>

| Element         | Description  | Restrictions       | Syntax                                  |
|-----------------|--|--------------------|---|
| <i>dbspace</i>  | Dbpace or temporary dbspace in which to store the temporary table.               | Must already exist | <a href="#">Identifier on page 1456</a> |
| <i>extspace</i> | Name that <b>onspaces</b> assigned to a storage area outside the database server | Must already exist | See documentation for access method.    |

209. See [FRAGMENT BY clause on page 382](#)

210. See [PUT Clause on page 378](#)

211. See [EXTENT SIZE Options on page 390](#)

Only temporary tables that include BLOB or CLOB columns can include the PUT clause as a storage option.

If you specify a temporary dbspace after the IN keyword, the database server does not perform any logical logging nor physical logging of the temporary table. You cannot mirror a temporary dbspace.

If you specify no extent size option, the default extent size is 8 pages.

To create a fragmented, unique index on a temporary table, you must specify an explicit expression-based distribution scheme for a temporary table in the CREATE TEMP TABLE statement. (Fragmentation of the index by ROUND ROBIN is not supported, and fragmentation by LIST or by INTERVAL is automatic, for a unique index on a table that uses a list or interval storage partitioning strategy.)

## Where temporary tables are stored

The distribution scheme that you specify with the CREATE TEMP TABLE statement (either with the IN clause or the FRAGMENT BY clause) takes precedence over the information that the **DBSPACETEMP** environment variable or the DBSPACETEMP configuration parameter specifies.

If you do not specify an explicit distribution scheme for a temporary table, its storage location depends on the **DBSPACETEMP** environment variable (or DBSPACETEMP configuration parameter) setting.

- If **DBSPACETEMP** and DBSPACETEMP are not set, all temporary tables are created without fragmentation in the same dbspace where the database was created (or in **rootdbs**, if the database was not created in another dbspace).
- If only one dbspace for temporary tables is specified by **DBSPACETEMP** (or by DBSPACETEMP, if **DBSPACETEMP** is not set), all temporary tables are created without fragmentation in the specified dbspace.
- If **DBSPACETEMP** (or DBSPACETEMP, if **DBSPACETEMP** is not set) specifies two or more dbspaces for temporary tables, then each temporary table is created in one of the specified dbspaces.

In a non-logging database, each temporary table is created in a temporary dbspace; in databases that support transaction logging, the temporary table is created in a standard dbspace. The database server tracks which of these dbspaces was most recently used, and when it receives the next request to allocate temporary storage, the database server uses the next available dbspace (in a round-robin pattern) to allocate I/O operations evenly among the dbspaces.

For example, if you create three temporary tables in a database with logging where **DBSPACETEMP** specifies **tempspc1**, **tempspc2**, and **tempspc3** as the default dbspaces for temporary tables, then the first table is created in the dbspace called **tempspc1**, the second table is created in **tempspc2**, and the third one is created in **tempspc3**, if these are the only requests for temporary storage.

Temporary tables created with SELECT INTO TEMP and WITH NO LOG are spread across the dbspaces listed in the DBSPACETEMP configuration parameter or **DBSPACETEMP** environment variable. Thus, the **DBSPACETEMP** (or DBSPACETEMP) settings that specify multiple dbspaces can result in round-robin fragmentation across all dbspaces in the temporary dbspace.

If you create a temporary table and specify WITH NO LOG, operations on the temporary table are not included in the transaction log records. If there is a logged space in the DBSPACETEMP list, the temporary table created with the SELECT ..

INTO TEMP WITH NO LOG option is fragmented by a round-robin distribution scheme in the non-logged temporary dbspaces. For example, if from a list of 10 dbspaces, only one dbspace is logged, the table is fragmented by a round-robin distribution scheme in the 9 non-logged temporary dbspaces.

The following example shows how to insert data into a temporary table called **result\_tmp** to output to a file the results of a user-defined function (**f\_one**) that returns multiple rows:

```
CREATE TEMP TABLE result_tmp( ... );
INSERT INTO result_tmp EXECUTE FUNCTION f_one();
UNLOAD TO 'file' SELECT * FROM result_tmp;
```

## Differences between temporary and permanent tables

Compared to permanent tables, temporary tables differ in these ways:

- They have fewer types of constraints available.
- They have fewer options that you can specify.
- They are not visible to other users or sessions.
- They do not appear in the system catalog tables.
- They are not preserved, as described in the section [Duration of temporary tables on page 404](#).

The INFO statement and the **Info Menu** option of DB-Access cannot reference temporary tables.

## Duration of temporary tables

The duration of a temporary table depends on whether or not it is logged.

A logged temporary table exists until one of the following events occurs:

- The application disconnects.
- The DROP TABLE statement is issued on the temporary table.
- The database is closed.

When any of these events occurs, the temporary table is deleted.

Nonlogging temporary tables include tables that were created using the WITH NO LOG option of CREATE TEMP TABLE.

A nonlogging temporary table exists until one of the following situations occurs:

- The application disconnects.
- The DROP TABLE statement is issued on the temporary table.
- The database is closed, and the nonlogging temporary table includes at least one column of a user-defined type, or of a built-in opaque data type. (The Informix® built-in opaque data types include BLOB, BOOLEAN, BSON, CLOB, JSON, LVARCHAR, and IDSSECURITYLABEL.)

If the nonlogging temporary table does not include any columns of UDTs or of built-in opaque data types, you can use that table to transfer data from one database to another while the application remains connected, because the table is not destroyed when the database is closed. You must use a permanent table (or some other strategy) if the data to be transferred includes UDTs or built-in opaque data types.

## CREATE TRIGGER statement

Use the CREATE TRIGGER statement to define a trigger on a table. You can also use CREATE TRIGGER to define an INSTEAD OF trigger on a view.

This is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### CREATE TRIGGER IF NOT EXISTS

Owner Name<sup>212</sup>

*trigger*

Trigger on a Table<sup>213</sup>

INSTEAD OF Trigger on a View<sup>214</sup>

**ENABLED DISABLED**

| Element        | Description                                  | Restrictions   | Syntax                                  |
|----------------|--|--|---|
| <i>trigger</i> | Name that you declare here for a new trigger | Must be unique among the names of triggers in the current database | <a href="#">Identifier on page 1456</a> |

### Usage

A *trigger* is a database object that, unless disabled, automatically executes a specified set of SQL statements, called the *trigger action*, when a specified *trigger event* occurs.

The trigger event that initiates the trigger action can be an INSERT, DELETE, UPDATE, or a SELECT statement. The MERGE statement can also be the triggering event for an UPDATE, DELETE, or INSERT trigger. The event definition must specify the table or view on which the trigger is defined. (SELECT or UPDATE events for triggers on tables can also specify one or more columns.)

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a trigger of the specified name is already defined on a table or view in the current database.

You can use the CREATE TRIGGER statement in two distinct ways:

- You can define a trigger on a table in the current database.
- You can also define an INSTEAD OF trigger on a view in the current database.

212. See [Owner name on page 1488](#)

213. See [Defining a Trigger Event and Action on page 407](#)

214. See [INSTEAD OF Triggers on Views on page 439](#)

Any SQL statement that is an instance of the trigger event is called a *triggering statement*. When the event occurs, triggers defined on tables and triggers defined on views differ in whether the triggering statement is executed:

- For tables, the trigger event and the trigger action both execute.
- For views, only the trigger action executes, instead of the event.

That is, if you define an INSTEAD OF trigger on an updatable view, the database server does not perform the DML operation that corresponds to the *trigger event*, but instead performs the specified *trigger action* on the view or on its base table.

**Important:** In some cases, however, after the CREATE TRIGGER statement defines queries on a table or on a column as triggering events for enabled Select triggers, the database server does not execute the trigger action when the query executes. For a list of contexts where this is the expected behavior, see [Circumstances When a Select Trigger Is Not Activated on page 419](#). For a similar list of contexts where the trigger actions of enabled Insert, Delete, or Update triggers on views are not executed, see [Restrictions on INSTEAD OF Triggers on Views on page 443](#).

The CREATE TRIGGER statement can support the integrity of data in the database by defining rules by which specified DML operations (the triggering events) cause the database server to take specified actions. The following sections describe the syntax elements.

| Clause                               | Page   | Effect                                     |

| Element            | Description  | Restrictions                       | Syntax                                  |
|--------------------|--|------------------------------------|---|
| column             | The name of a column in the triggering <i>table</i>  | Must exist                         | <a href="#">Identifier on page 1456</a> |
| correlation        | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a triggered action   | Must be unique in this trigger     | <a href="#">Identifier on page 1456</a> |
| <i>table, view</i> | Name or synonym of the triggering table or view. The <i>table</i> or <i>view</i> can include an <i>owner.</i> qualifier. | Must exist in the current database | <a href="#">Identifier on page 1456</a> |

The left-hand portion of the main diagram (including the *table* or *view*) defines the *trigger event* (sometimes called the *triggering event*). The rest of the diagram declares correlation names and defines the *trigger action* (sometimes called the *triggered action*).

For the syntax to specify the triggered action of triggers on tables, see [Action Clause on page 419](#) and [Correlated Table Action on page 425](#).

For the syntax to specify the triggered action of INSTEAD OF triggers on views, see [The Action Clause of INSTEAD OF Triggers on page 442](#).

## Restrictions on Triggers

To create a trigger on a table (or an INSTEAD OF trigger on a view), you must own the table or view, or have DBA privilege. For the relationship between the privileges of the trigger owner and those of other users, see [Privileges to Execute Trigger Actions on page 435](#).

The table on which you create a trigger must exist in the current database. You cannot create a trigger on any of the following types of tables:

- A diagnostics table, a violations table, or a table in another database
- A temporary table or a system catalog table
- A table object that the CREATE EXTERNAL TABLE or CREATE SEQUENCE statement created.

In DB-Access, if you want to define a trigger as part of a schema, place the CREATE TRIGGER statement inside a CREATE SCHEMA statement.

If you are embedding the CREATE TRIGGER statement in Informix® ESQL/C programs, you cannot use a host variable in the trigger definition.

You can use the DROP TRIGGER statement to remove an existing trigger. If you use the DROP TABLE or DROP VIEW statement to remove triggering tables or views from the database, all triggers on those tables or views are also dropped.

The ON EXCEPTION statement of SPL has no effect when it is issued from a trigger routine, nor from the Action clause or the Correlated Action clause of a trigger.

218. See [REFERENCING Clause for Insert triggers on page 423](#)

219. See [INSTEAD OF Triggers on Views on page 439](#)

The triggered action of an Insert trigger that increments a BIGSERIAL, SERIAL, or SERIAL8 column does not update the **sqlca.sqlerrd[1]** field of the SQL Communication Area structure. The triggered INSERT operation can successfully increment the serial counter for the column, but the value of the **sqlca.sqlerrd[1]** field remains zero, rather than being reset to the new serial value.

You cannot define a DELETE trigger on a table that has a referential constraint that specifies ON DELETE CASCADE.

UNION subqueries cannot be triggering events. If a valid UNION subquery specifies a column on which a Select trigger has been defined, the query succeeds, but the trigger (or the INSTEAD OF trigger on a view) is ignored.

The database server cannot use parallel processing for some triggered actions. PDQ is automatically disabled in the FOR EACH ROW section for any DML statement that corresponds to the type of triggering event:

- SELECT statements in the Action clause of a Select trigger
- DELETE or MERGE statements in the Action clause of a Delete trigger
- INSERT or MERGE statements in the Action clause of an Insert trigger
- UPDATE or MERGE statements in the Action clause of an Update trigger.

The scope of this restriction on PDQ is the FOR EACH ROW section. It has no effect on DML statements in the BEFORE or AFTER sections of the Action clause.

For additional restrictions on INSTEAD OF triggers on views, see [Restrictions on INSTEAD OF Triggers on Views on page 443](#).

## Trigger Modes

You can set a trigger mode to enable or disable a trigger when you create it.

Figure 4. Trigger Modes

### **DISABLED ENABLED**

You can create triggers on tables or on views in ENABLED or DISABLED mode.

- When a trigger is created in ENABLED mode, the database server executes the trigger action when the trigger event is encountered. (If you specify no mode when you create a trigger, ENABLED is the default mode.)
- When a trigger is created in DISABLED mode, the trigger event does not cause execution of the trigger action. In effect, the database server ignores the trigger and its action, even though the **systriggers** system catalog table maintains information about the disabled trigger.

You can also use the SET TRIGGERS option of the Database Object Mode statement to set an existing trigger to the ENABLED or DISABLED mode.

After a DISABLED trigger is enabled by the SET TRIGGERS statement, the database server can execute the trigger action when the trigger event is encountered, but the trigger does not perform retroactively. The database server does not attempt to execute the trigger for rows that were selected, inserted, deleted, or updated while the trigger was disabled and before it was enabled.

**Warning:** Because the behavior of a trigger varies according to its ENABLED or DISABLED mode, be cautious about disabling a trigger. If disabling a trigger will eventually destroy the semantic integrity of the database, do not disable the trigger.

## Trigger Inheritance in a Table Hierarchy

By default, any trigger that you define on a typed table of Informix® is inherited by all its subtables.

In versions of Informix® earlier than version 11.10, however, if you define a trigger on a subtable of a typed table, that trigger overrides any trigger for the same type of triggering event (Select, Delete, Insert, or Update) that the subtable inherits from its supertable. In this version of Informix®, however, a table can inherit more than one trigger that the same triggering event activates, so both triggers are defined for the same type of event on the subtable.

In all versions of Informix®, a trigger that you set on a subtable is inherited by all its dependent tables, but has no effect on its supertable.

This behavior is important when you require a trigger to be enabled in a supertable, but to be disabled in its subtable.

In Informix® 10.00 and in earlier versions, you cannot use the SET TRIGGERS option of the SET Database Object Mode statement to disable an inherited trigger selectively within a hierarchy. In this release, however, disabling a trigger on a table within a table hierarchy has no effect on inherited triggers. For example, the following statement has no effect on triggers on table objects that are above or below *subtable* within a table hierarchy:

```
SET TRIGGERS FOR subtable DISABLED
```

Similarly, the DROP TRIGGER statement cannot destroy an inherited trigger without also destroying the trigger on the supertable. In this situation, you must instead define a trigger with no Action clause on the subtable. Because triggers are not additive, this empty trigger overrides the inherited trigger and executes for the subtable and for any subtables under the subtable, which are not subject to further overrides.

## Triggers and SPL Routines

You cannot define a trigger in an SPL routine that is called inside a DML (data manipulation language) statement, as listed in [Data Manipulation Language Statements on page 9](#). Thus, the following statement returns an error if the **sp\_items** procedure includes the CREATE TRIGGER statement:

```
INSERT INTO items EXECUTE PROCEDURE sp_items;
```

You can use the CREATE FUNCTION or CREATE PROCEDURE statement of SQL with the REFERENCING clause to define *trigger routines* that include the FOR *table* or FOR *view* specification. These UDRs must include the REFERENCING clause that declares *correlation* names for OLD or NEW column values in the specified *table* or *view*. Triggers on the *table* or *view* can invoke the trigger routine from the FOR EACH ROW section of the Triggered Action list. Triggers can also invoke non-trigger routines from the BEFORE and AFTER sections of the Triggered Action list, but these UDRs cannot use *correlation* names to reference the NEW or OLD column values. The REFERENCING clause in a trigger routine supports the same syntax as in the CREATE TRIGGER statement, as described in the section [REFERENCING Clauses on page 422](#).

Multiple triggers that the same triggering event executes can invoke more than one trigger routine, and these trigger routines can access the same NEW or OLD column values by using SPL variables that have the same names or different names. When a single triggering event executes multiple triggers, the order of execution is not guaranteed, but all of the BEFORE triggered actions execute before any of the FOR EACH ROW triggered actions, and all of the AFTER triggered actions execute after all of the FOR EACH ROW triggered actions.

For UDRs that are not trigger routines, SPL variables are not valid in CREATE TRIGGER statements. An SPL routine cannot perform INSERT, DELETE, or UPDATE operations on any table or view that is not local to the current database. See also [Rules for SPL Routines on page 434](#) for additional restrictions on SPL routines that are invoked in triggered actions.

## Trigger Events

The *trigger event* specifies what DML statements can initiate the trigger. The event can be an INSERT, DELETE, or UPDATE operation on the *table* or *view*, or a SELECT operation that queries the *table*. Each CREATE TRIGGER statement must specify exactly one trigger event. Any SQL statement that is an instance of the trigger event is called a *triggering statement*.

For each *table*, you can define triggers that are activated by INSERT, DELETE, UPDATE, or SELECT statements. For each *view*, you can define INSTEAD OF triggers that are activated by INSERT, DELETE, or UPDATE statements. Multiple triggers on the same table or view can be activated by different types of trigger events or by the same type of trigger event.

You cannot specify a DELETE event if the triggering table has a referential constraint that specifies ON DELETE CASCADE.

You are responsible for guaranteeing that the triggering statement returns the same result with and without the trigger action on a table. See also the sections [Action Clause on page 419](#) and [Triggered Action on a Table on page 425](#).

A triggering statement from an external database server can activate the trigger.

As the following example shows, an Insert trigger on **newtab**, managed by **dbserver1**, is activated by an INSERT statement from **dbserver2**. The trigger executes as if the INSERT originated on **dbserver1**.

```
-- Trigger on stores_demo@dbserver1:newtab
CREATE TRIGGER ins_tr INSERT ON newtab
  REFERENCING new AS post_ins
  FOR EACH ROW(EXECUTE PROCEDURE nt_pct (post_ins.mc));
-- Triggering statement from dbserver2
INSERT INTO stores_demo@dbserver1:newtab
  SELECT item_num, order_num, quantity, stock_num, manu_code,
  total_price FROM items;
```

Informix® also supports INSTEAD OF triggers on views, which are initiated when a triggering DML operation references the specified view. The INSTEAD OF trigger replaces the trigger event with the specified trigger action on a view, rather than execute the triggering INSERT, DELETE, or UPDATE operation. A *view* can have any number of INSTEAD OF trigger defined for each type of INSERT, DELETE, or UPDATE triggering event.

## Trigger Events with Cursors

For triggers on tables, if the triggering statement uses a cursor, each part of the trigger action (including BEFORE, FOR EACH ROW, and AFTER, if these are specified for the trigger) is activated for each row that the cursor processes.

This behavior differs from what occurs when a triggering statement does not use a cursor and updates multiple rows. In this case, any BEFORE and AFTER triggered actions execute only once, but the FOR EACH ROW action list is executed for each row processed by the triggering statement. For additional information about trigger actions, see [Action Clause on page 419](#)

## Privileges on the Trigger Event

You must have appropriate Insert, Delete, Update, or Select privilege on the triggering table or view to execute a triggering INSERT, DELETE, UPDATE, or SELECT statement as the trigger event. The triggering statement might still fail, however, if you do not also have the privileges necessary to execute one of the SQL statements in the trigger action. When the trigger actions are executed, the database server checks your privileges for each SQL statement in the trigger definition, as if the statement were being executed independently of the trigger. For information on the privileges needed to execute the trigger actions, see [Privileges to Execute Trigger Actions on page 435](#).

## Performance Impact of Triggers

The INSERT, DELETE, UPDATE, and SELECT statements that initiate triggers might appear to execute slowly because they execute additional SQL statements, and the user might not know that other actions are occurring.

The execution time for a trigger event depends on the complexity of the trigger action and whether it initiates other triggers. The time increases as the number of cascading triggers increases. For more information on triggers that initiate other triggers, see [Cascading Triggers on page 436](#).

## INSERT Events and DELETE Events

INSERT and DELETE events on tables are defined by those keywords and by the ON *table* clause, using the following syntax.

INSERT or DELETE Event on a Table

### INSERT DELETE

**ON***table*

| Element      | Description                  | Restrictions               | Syntax                                  |
|--------------|------------------------------|----------------------------|---|
| <i>table</i> | Name of the triggering table | Must exist in the database | <a href="#">Identifier on page 1456</a> |

An Insert trigger is activated when an INSERT statement includes the specified *table* (or a synonym for *table*) in its INTO clause. Similarly, a Delete trigger is activated when a DELETE statement includes the specified *table* (or a synonym for *table*) in its FROM clause.

The MERGE statement can also activate an Insert trigger, if the specified *table* of the Insert trigger is the target table of a MERGE statement that includes the Insert clause. Similarly, the MERGE statement can also activate a Delete trigger, if the specified *table* of the Delete trigger is the target table of a MERGE statement that includes the Delete clause.

The TRUNCATE TABLE statement does not activate Delete triggers when it removes all the rows from a table. If an enabled Delete trigger is defined for a table on which you do not hold the Alter privilege, the database server returns an error if you attempt to truncate that table, even though the TRUNCATE statement cannot be the triggering event for a Delete trigger. (For more information about the discretionary access privileges that truncate operations require, see the [TRUNCATE statement on page 1025](#).)

For triggers on views, the INSTEAD OF keywords must immediately precede the INSERT, DELETE, or UPDATE keyword that specifies the type of trigger event, and the name or synonym of a *view* (rather than of a table) must follow the ON keyword. The section [INSTEAD OF Triggers on Views on page 439](#) describes the syntax for defining INSTEAD OF trigger events.

Any number of Insert triggers, and any number of Delete triggers, can be defined on the same table.

If you define a trigger on a subtable within a table hierarchy, and the subtable supports cascading deletes, then a DELETE operation on the supertable activates the Delete triggers on the subtable.

See also the section [Re-Entrancy of Triggers on page 431](#) for information about dependencies and restrictions on the actions of Insert triggers and Delete triggers.

## UPDATE Event

UPDATE events (and SELECT events) can include an optional *column* list.

UPDATE Event

**UPDATE**

**OF**

, *column*

**ON***table*

| Element       | Description                       | Restrictions                       | Syntax                                  |
|---------------|-----------------------------------|------------------------------------|---|
| <i>column</i> | Column that activates the trigger | Must exist in the triggering table | <a href="#">Identifier on page 1456</a> |
| <i>table</i>  | Name of the triggering table      | Must exist in the database         | <a href="#">Identifier on page 1456</a> |

The *column* list is optional. If you omit the OF *column* list, updating any column of *table* activates the trigger.

The OF *column* clause is not valid for an INSTEAD OF trigger on a view.

An UPDATE on the triggering table can activate the trigger in two cases:

- The UPDATE statement references any column in the *column* list.
- The UPDATE event definition has no OF *column* list specification.

Whether it updates one column or more than one column from the *column* list, a triggering UPDATE statement activates each Update trigger only once.

The MERGE statement can also activate an Update trigger, if the specified *table* of a trigger with no *columns* list is the target table of the MERGE statement, or if the Update clause of the MERGE statement references a column in the *column* list of the Update trigger.

## Defining Multiple Update Triggers

Multiple Update triggers on a table can include the same or different columns. In the following example, **trig3** on the **items** table includes in its column list **stock\_num**, which is a triggering column in **trig1**.

```
CREATE TRIGGER trig1 UPDATE OF item_num, stock_num ON items
  REFERENCING OLD AS pre NEW AS post
  FOR EACH ROW(EXECUTE PROCEDURE proc1());
CREATE TRIGGER trig2 UPDATE OF manu_code ON items
  BEFORE(EXECUTE PROCEDURE proc2());
CREATE TRIGGER trig3 UPDATE OF order_num, stock_num ON items
  BEFORE(EXECUTE PROCEDURE proc3());
```

When an UPDATE statement updates multiple columns that have different triggers, the firing order is based on the lowest-numbered column that is defined in the triggers that actually fired, regardless of whether that lowest-numbered column was actually the triggering column when the trigger fired. If several Update triggers are set on the same column or on the same set of columns, however, the order of trigger execution is not guaranteed.

The following example shows that table **taba** has four columns (**a**, **b**, **c**, **d**):

```
CREATE TABLE taba (a int, b int, c int, d int);
```

Define **trig1** as an update on columns **a** and **c**, and define **trig2** as an update on columns **b** and **d**, as the following example shows:

```
CREATE TRIGGER trig1 UPDATE OF a, c ON taba
  AFTER (UPDATE tabb SET y = y + 1);

CREATE TRIGGER trig2 UPDATE OF b, d ON taba
  AFTER (UPDATE tabb SET z = z + 1);
```

The following example shows a triggering statement for the Update trigger:

```
UPDATE taba SET (b, c) = (b + 1, c + 1);
```

Then **trig1** for columns **a** and **c** executes first, and **trig2** for columns **b** and **d** executes next. In this case, the smallest column number in the two triggers is column 1 (**a**), and the next is column 2 (**b**).

## SELECT Event

DELETE and INSERT events are defined by those keywords (and the ON *table* clause), but SELECT and UPDATE events also support an optional *column* list.

SELECT Event

**SELECT**

**OF**

, *column*

**ON**

'*owner*'.

*table*

| Element       | Description                       | Restrictions                              | Syntax                                  |
|---------------|-----------------------------------|---|---|
| <i>column</i> | Column that activates the trigger | Must exist in the triggering <i>table</i> | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>  | Owner of <i>table</i>             | Must own <i>table</i>                     | <a href="#">Owner name on page 1488</a> |
| <i>table</i>  | Name of the triggering table      | Must exist in the database                | <a href="#">Identifier on page 1456</a> |

If you define more than one Select trigger on the same table, the *column* list is optional, and the *column* lists for each trigger can be unique or can duplicate that of another Select trigger.

A SELECT on the triggering table can activate the trigger in two cases:

- The SELECT statement references any column in the *column* list.
- The SELECT event definition has no OF *column* list specification.

(Sections that follow, however, describe additional circumstances that can affect whether or not a SELECT statement activates a Select trigger.)

Whether it specifies one column or more than one column from the *column* list, a triggering SELECT statement activates the Select trigger only once.

The action of a Select trigger cannot include an UPDATE, INSERT, or DELETE on the triggering table. The action of a Select trigger can include UPDATE, INSERT, and DELETE actions on tables other than the triggering table. The following example defines a Select trigger on one column of a table:

```
CREATE TRIGGER mytrig
  SELECT OF cola ON mytab REFERENCING OLD AS pre
  FOR EACH ROW (INSERT INTO newtab VALUES('for each action'));
```

You cannot specify a SELECT event for an INSTEAD OF trigger on a view.

## Circumstances When a Select Trigger Is Activated

A query on the triggering table activates a Select trigger in these cases:

- The SELECT statement is a stand-alone SELECT statement.
- The SELECT statement occurs within a UDR called in a select list.
- The SELECT statement is a subquery in the Projection list.
- The SELECT statement is a subquery in the FROM clause.
- The SELECT statement occurs within a UDR called by EXECUTE PROCEDURE or EXECUTE FUNCTION.
- The SELECT statement selects data from a supertable in a table hierarchy. In this case the SELECT statement activates Select triggers for the supertable and all the subtables in the hierarchy.

For information on SELECT statements that do not activate a Select trigger, see [Circumstances When a Select Trigger Is Not Activated on page 419](#).

## Stand-alone SELECT Statements

A Select trigger is activated if the triggering column appears in the select list of the Projection clause of a stand-alone SELECT statement.

For example, if a Select trigger is defined to execute whenever column **col1** of table **tab1** is selected, then both of the following stand-alone SELECT statements activate the Select trigger:

```
SELECT * FROM tab1;
SELECT col1 FROM tab1;
```

## SELECT Statements Within UDRs in the Select List

A Select trigger is activated by a UDR if the UDR contains a SELECT statement within its statement block, and the UDR also appears in the Projection clause of a SELECT statement.

For example, assume that an enabled Select trigger is defined on the table **tab1**, and that a UDR named **my\_rtn** contains this SELECT statement in its statement block:

```
SELECT col1 FROM tab1;
```

Now suppose that the following SELECT statement invokes the **my\_rtn** UDR in its projection list:

```
SELECT my_rtn() FROM tab2;
```

This SELECT statement activates the Select trigger defined on column **col1** of table **tab1** when the **my\_rtn** UDR is executed.

## UDRs that EXECUTE PROCEDURE or EXECUTE FUNCTION call

A Select trigger is activated by a UDR if the UDR contains a SELECT statement within its statement block that queries the table, and the UDR is called by an EXECUTE PROCEDURE or the EXECUTE FUNCTION statement.

For example, assume that an enabled Select trigger is defined on the table **tab1**, and that the user-defined routine named **my\_rtn** contains the following SELECT statement in its statement block:

```
SELECT col1 FROM tab1;
```

Now suppose that the following statement invokes the **my\_rtn** routine:

```
EXECUTE PROCEDURE my_rtn();
```

This statement activates the Select trigger defined on column **col1** of table **tab1** when the SELECT statement within the statement block is executed.

## Subqueries in the Select List

A Select trigger can be activated by a subquery that appears in the select list of the Projection clause of a SELECT statement.

For example, if an enabled Select trigger is defined on **col1** of **tab1**, the subquery in the following SELECT statement activates that trigger:

```
SELECT (SELECT col1 FROM tab1 WHERE col1=1), colx, coly FROM tabz;
```

## Subqueries in the FROM Clause of SELECT

Table expressions in the FROM clause of a SELECT statement can be the triggering event on a table that is referenced by an uncorrelated subquery. In the following example, the subquery that specifies a table expression is the triggering event for any enabled Select triggers that are defined on **col1** of **tab1**:

```
SELECT vcol FROM (SELECT FIRST 5 col1 FROM tab1 ORDER BY col1 ) vtab(vcol);
```

## Subqueries in the WHERE Clause of DELETE or UPDATE

Subqueries that are specified using the Condition with Subquery syntax in the WHERE clause of the DELETE statement or the UPDATE statement cannot be the triggering event for a Select trigger.

In the following example, the subquery is not the triggering event for any enabled Select triggers that are defined on **col2** of **tab1**:

```
DELETE tab1 WHERE EXISTS
  (SELECT col2 FROM tab1 WHERE col2 > 1024);
```

The DELETE operation in same example, however, activates any enabled Delete triggers that are defined on tab1. No enabled Select trigger on tab1 can be activated by a subquery within a DELETE statement that modifies a table referenced in the FROM clause of the subquery.

Similarly, the subquery in the WHERE clause of the following UPDATE statement is not the triggering event for any enabled Select triggers that are defined on **col3** of **tab1**:

```
UPDATE tab1 SET col3 = col3 + 10
  WHERE col3 > ANY
    (SELECT col3 from tab1 WHERE col3 > 1);
```

The same example activates any enabled Update trigger that is defined on col3 of tab1, but no Select trigger can be updated by the subquery. For additional restrictions on Select triggers, see [Circumstances When a Select Trigger Is Not Activated on page 419](#).

## Select Triggers in Table Hierarchies

A subtable in the Informix® database inherits the Select triggers that are defined on its supertable. When you select from a supertable, the SELECT statement activates the Select triggers on the supertable and the inherited Select triggers on the subtables in the table hierarchy.

For example, assume that table **tab1** is the supertable and table **tab2** is the subtable in a table hierarchy. If the Select trigger **trig1** is defined on table **tab1**, a SELECT statement on table **tab1** activates the Select trigger **trig1** for the rows in table **tab1** and the inherited Select trigger **trig1** for the rows in table **tab2**.

If you add a Select trigger to a subtable, this Select trigger does not override the Select trigger that the subtable inherits from its supertable, but increases the number of Select triggers on the subtable. For example, if the Select trigger **trig1** is defined on column **col1** in supertable **tab1**, the subtable **tab2** inherits this trigger. If you define a Select trigger named **trig2** on column **col1** in subtable **tab2**, and a SELECT statement selects from **col1** in supertable **tab1**, this SELECT statement activates trigger **trig1** for the rows in table **tab1** and both triggers **trig1** and **trig2** for the rows in table **tab2**.

## Circumstances When a Select Trigger Is Not Activated

A SELECT statement on the triggering table does not activate a Select trigger in certain circumstances:

- If a subquery or UDR that contains the triggering SELECT statement appears in any clause of a SELECT statement other than the Projection clause or the FROM clause, the Select trigger is not activated.

For example, if the subquery or UDR appears in the WHERE clause or HAVING clause of a SELECT statement, the SELECT statement within the subquery or UDR does not activate the Select trigger.

- If the trigger action of a Select trigger calls a UDR that includes a triggering SELECT statement, the Select trigger on the SELECT in the UDR is not activated. Cascading Select triggers are not supported.
- If a SELECT statement contains a built-in aggregate or user-defined aggregate in its Projection clause, the Select trigger is not activated. For example, the following SELECT statement does not activate a Select trigger defined on **col1** of **tab1**:

```
SELECT MIN(col1) FROM tab1;
```

- A SELECT statement that includes a set operator (including INTERSECT, MINUS, EXCEPT, UNION, or UNION ALL) does not activate a Select trigger.
- The SELECT clause of INSERT does not activate a Select trigger.
- A subquery in the WHERE clause of the DELETE or UPDATE statement cannot activate a Select trigger on the same table that the DELETE or UPDATE statement is modifying.
- If the Projection clause of a SELECT includes the DISTINCT or UNIQUE keywords, the SELECT statement does not activate a Select trigger.
- Select triggers are not supported on scroll cursors.
- If a SELECT statement refers to a remote triggering table, the Select trigger is not activated on the remote database server.
- Columns in the ORDER BY list of a query activate no Select triggers (nor any other triggers) unless they are also listed in the Projection clause.

An exception to the last restriction is that a Select trigger can be activated by a column in the ORDER BY list of a subquery in the FROM clause, whether or not the same column also appears in the Projection clause. In the following example, a table expression that includes **col1** in the ORDER BY clause (but not in the select list of the Projection clause) is the triggering event for any enabled Select triggers that are defined on **col1** of **tab1**:

```
SELECT vcol FROM (SELECT col2 FROM tab1 ORDER BY col1 ) vtab(vcol);
```

## Action Clause

The Action clause defines the SQL statements that are executed when the trigger is activated. For a trigger on a table, there can be up to three sections in the Action clause: BEFORE, AFTER and FOR EACH ROW.

- The BEFORE actions are executed once for each triggering event, before the database server performs the triggering DML operation.
- The AFTER actions are also executed once for each triggering DML event, after the operation on the table is complete, in the context of the triggering statement.
- The FOR EACH ROW actions are executed for each row that is inserted, updated, deleted or selected in the DML operation, after the DML operation is executed on each row, but before the database server writes the values into the log and into the table.

If the same table has multiple triggers that are activated by the same triggering event, the order of trigger execution is not guaranteed, but all of the BEFORE triggered actions execute before any of the FOR EACH ROW triggered actions, and all of the AFTER triggered actions execute after all of the FOR EACH ROW triggered actions.

When you define an INSTEAD OF trigger on a view, the BEFORE and AFTER keywords are not supported, but the FOR EACH ROW section of the Action clause is valid. See the section [INSTEAD OF Triggers on Views on page 439](#) for the syntax of specifying triggered actions on a view.

The Action clause has the following syntax.

Action Clause

**BEFORE**

Triggered Action<sup>220</sup>

**FOR EACH ROW**

Triggered Action<sup>220</sup>

**AFTER**

Triggered Action<sup>220</sup>

For the trigger to have any effect on the table, you must define at least one triggered action, using the keywords BEFORE, FOR EACH ROW, or AFTER to indicate when the action occurs relative to execution of the triggering event.

You can specify actions for any or all of these three options on a single trigger, but any BEFORE action list must be specified first, and any AFTER action list must be specified last. For more information on the Action clause when a REFERENCING clause is also specified, see [Correlated Table Action on page 425](#).

## BEFORE Actions

The list of BEFORE trigger actions execute once before the triggering statement executes. Even if the triggering statement does not process any rows, the database server executes the BEFORE trigger actions.

## FOR EACH ROW Actions

After a row of the triggering table is processed, the database server executes all of the statements of the FOR EACH ROW trigger action list; this cycle is repeated for every row that the triggering statement processes. (But if the triggering statement does not insert, delete, update, or select any rows, the database server does not execute the FOR EACH ROW trigger actions.)

The FOR EACH ROW action list of a Select trigger is executed once for each instance of a row. For example, the same row can appear more than once in the result of a query joining two tables. For more information on FOR EACH ROW actions that reference specific values in rows that the triggering statement processes, see [REFERENCING Clauses on page 422](#).

220. See [Triggered Action on a Table on page 425](#)

As noted in the section [Restrictions on Triggers on page 409](#), parallel data processing is disabled in FOR EACH ROW trigger actions for DML statements that correspond to the type of trigger event. For example, the database server does not apply PDQ to UPDATE statements in the FOR EACH ROW section of the Action clause of an Update trigger, nor to DELETE statements in the FOR EACH ROW section of the Action clause of a Delete trigger. This restriction on PDQ processing does not apply to DML statements in the BEFORE or AFTER sections of the Action clause.

## AFTER Actions

The specified set of AFTER trigger actions executes once after the action of the triggering statement is complete. If the triggering statement does not process any rows, the AFTER trigger actions still execute.

## Actions of Multiple Triggers

When an UPDATE or MERGE statement activates multiple triggers, the trigger actions merge. Assume that **taba** has columns **a**, **b**, **c**, and **d**, as this example shows:

```
CREATE TABLE taba (a INT, b INT, c INT, d INT);
```

Next, assume that you define **trig1** on columns **a** and **c**, and **trig2** on columns **b** and **d**. If both triggers specify BEFORE, FOR EACH ROW, and AFTER actions, then the trigger actions are executed in the following order:

1. BEFORE action list for trigger (**a**, **c**)
2. BEFORE action list for trigger (**b**, **d**)
3. FOR EACH ROW action list for trigger (**a**, **c**)
4. FOR EACH ROW action list for trigger (**b**, **d**)
5. AFTER action list for trigger (**a**, **c**)
6. AFTER action list for trigger (**b**, **d**)

The database server treats all the triggers that are activated by the same triggering statement as a single trigger, and the trigger action is the merged-action list. All the rules that govern a trigger action apply to the merged list as one list, and no distinction is made between the two original triggers.

## Guaranteeing Row-Order Independence

In a FOR EACH ROW triggered-action list, the result might depend on the order of the rows being processed. You can ensure that the result is independent of row order by following these suggestions:

- Avoid selecting the triggering table in the FOR EACH ROW section.
  - If the triggering statement affects multiple rows in the triggering table, the result of the SELECT statement in the FOR EACH ROW section varies as each row is processed. This condition also applies to any cascading triggers. See [Cascading Triggers on page 436](#).
- In the FOR EACH ROW section, avoid updating a table with values derived from the current row of the triggering table.

If the trigger actions modify any row in the table more than once, the final result for that row depends on the order in which rows from the triggering table are processed.

- Avoid modifying a table in the FOR EACH ROW section that is selected by another statement in the same FOR EACH ROW trigger action, including any cascading trigger actions.

If FOR EACH ROW actions modify a table, the changes might not be complete when a subsequent action of the trigger refers to the table. In this case, the result might differ, depending on the order in which rows are processed.

The database server does not enforce rules to prevent these situations because doing so would restrict the set of tables from which a trigger action can select. Furthermore, the result of most trigger actions is independent of row order. Consequently, you are responsible for ensuring that the results of the trigger actions are independent of row order.

## REFERENCING Clauses

The REFERENCING clause for any event declares a *correlation* name (or for Update triggers, two *correlation* names) that can be used to qualify column values in the triggering table. These names enable FOR EACH ROW actions to reference new or old column values in the result of trigger events.

They also enable FOR EACH ROW actions to reference old column values that existed in the triggering table prior to modification by trigger events.

Correlation names are not valid if the triggered action includes both the INSERT statement and the BEFORE WHEN or AFTER WHEN keywords. This restriction does not affect triggered actions that specify the FOR EACH ROW keywords without the BEFORE or AFTER keywords, or that include no INSERT statement.

The REFERENCING clause syntax that is described here for the CREATE TRIGGER statement is also valid in CREATE FUNCTION and CREATE PROCEDURE statements that define a trigger routine, provided that the CREATE FUNCTION or CREATE PROCEDURE statement also includes the FOR *table\_object* clause to specify the table or view whose FOR EACH ROW actions can invoke the trigger routine.

## REFERENCING Clause for Delete

The REFERENCING clause for a Delete trigger can declare a correlation name for the deleted value in a column.

REFERENCING Clause for Delete

### REFERENCINGOLD

#### AS

*correlation*

| Element            | Description   | Restrictions  | Syntax                                  |
|--------------------|---|---|---|
| <i>correlation</i> | Name that you declare here to qualify an old column value (as <i>correlation.column</i> ) in a triggered action | Must be unique within this CREATE TRIGGER statement | <a href="#">Identifier on page 1456</a> |

The *correlation* is a qualifier for the column value in the triggering table before the triggering statement executed. The *correlation* is in scope in the FOR EACH ROW trigger action list. See [Correlated Table Action on page 425](#).

To use a correlation name in a trigger action to refer to an old column value, prefix the column name with the correlation name and a period ( . ) symbol. For example, if the NEW *correlation* name is **post**, refer to the new value for the column **fname** as **post.fname**.

If the trigger event is a DELETE statement, using the new correlation name as a qualifier causes an error, because the column has no value after the row is deleted. For the rules that govern the use of correlation names, see [Using Correlation Names in Triggered Actions on page 429](#).

You can use the REFERENCING clause for Delete only if you define a FOR EACH ROW trigger action.

## REFERENCING Clause for Insert triggers

The REFERENCING clause for an Insert trigger can declare a correlation name for the inserted value in a column.

REFERENCING Clause for Insert triggers

### REFERENCINGNEW

#### AS

*correlation*

| Element            | Description  | Restrictions  | Syntax                                  |
|--------------------|--|---|---|
| <i>correlation</i> | Name that you declare here to qualify a new column value (as <i>correlation.column</i> ) in a triggered action | Must be unique within this CREATE TRIGGER statement | <a href="#">Identifier on page 1456</a> |

The *correlation* is a name for the new column value after the triggering statement has executed. Its scope of reference is only the FOR EACH ROW trigger action list; see [Correlated Table Action on page 425](#). To use the correlation name, precede the column name with the *correlation* name, followed by a period ( . ) symbol. Thus, if the NEW *correlation* name is **post**, refer to the new value for the column **fname** as **post.fname**.

If the trigger event is an INSERT statement, using the old *correlation* name as a qualifier causes an error, because no value exists before the row is inserted. For the rules that govern how to use correlation names, see [Using Correlation Names in Triggered Actions on page 429](#). You can use the INSERT REFERENCING clause only if you define a FOR EACH ROW trigger action.

The following example illustrates use of the INSERT REFERENCING clause. This example inserts a row into **backup\_table1** for every row that is inserted into **table1**. The values that are inserted into **col1** and **col2** of **backup\_table1** are an exact copy of the values that were just inserted into **table1**.

```
CREATE TABLE table1 (col1 INT, col2 INT);
CREATE TABLE backup_table1 (col1 INT, col2 INT);
CREATE TRIGGER before_trig
  INSERT ON table1 REFERENCING NEW AS new
  FOR EACH ROW
  (
    INSERT INTO backup_table1 (col1, col2)
```

```
VALUES (new.col1, new.col2)
);
```

As the preceding example shows, the REFERENCING clause for INSERT triggers allows you to refer to data values produced by the trigger action.

## REFERENCING Clause for Update

The REFERENCING clause for an Update trigger can declare correlation names for the original value and for the updated value in a column.

REFERENCING Clause for Update

### REFERENCING

<sup>221</sup> **OLD**

<sup>221</sup> **NEW**

### AS

*correlation*

| Element            | Description  | Restrictions  | Syntax                                  |
|--------------------|--|---|---|
| <i>correlation</i> | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a triggered action | Must be unique within this CREATE TRIGGER statement | <a href="#">Identifier on page 1456</a> |

The OLD *correlation* is the name of the value of the column in the triggering table before execution of the triggering statement; the NEW *correlation* identifies the corresponding value after the triggering statement executes.

The scope of reference of the *correlation* names that you declare here is only within the FOR EACH ROW trigger action list. See [Correlated Table Action on page 425](#).

To refer to an old or new column value, prefix the column name with the *correlation* name and a period ( . ) symbol. For example, if the new *correlation* name is **post**, you can refer to the new value in column **fname** as **post.fname**.

If the trigger event is an UPDATE statement, you can define both old and new *correlation* names to refer to column values before and after the triggering UPDATE statement. For rules that govern the use of *correlation* names, see [Using Correlation Names in Triggered Actions on page 429](#).

You can use the UPDATE REFERENCING clause only if you define a FOR EACH ROW trigger action.

## REFERENCING Clause for Select

The REFERENCING clause for a Select trigger can declare a correlation name for the value in a column.

221. Use path no more than once

REFERENCING Clause for Select

## REFERENCING

### OLD

### AS

*correlation*

| Element            | Description  | Restrictions  | Syntax                                  |
|--------------------|--|---|---|
| <i>correlation</i> | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a triggered action | Must be unique within this CREATE TRIGGER statement | <a href="#">Identifier on page 1456</a> |

This has the same syntax as the [REFERENCING Clause for Delete on page 422](#). The scope of reference of the *correlation* name that you declare here is only within the FOR EACH ROW trigger action list. See [Correlated Table Action on page 425](#).

You use the *correlation* name to refer to an old column value by preceding the column name with the *correlation* name and a period ( . ) symbol. For example, if the old *correlation* name is **pre**, you can refer to the old value for the column **fname** as **pre.fname**.

If the trigger event is a SELECT statement, using the new *correlation* name as a qualifier causes an error because the column does not have a new value after the column is selected. For the rules that govern the use of correlation names, see [Using Correlation Names in Triggered Actions on page 429](#).

You can use the SELECT REFERENCING clause only if you define a FOR EACH ROW trigger action.

## Correlated Table Action

Use the Correlated Trigger Action clause to define the SQL statements that are executed as the trigger action when a triggering event activates a trigger on a table.

Correlated Table Action

**BEFORE**Triggered-Action<sup>222</sup>

**FOR EACH ROW**Triggered-Action<sup>222</sup>

**AFTER**Triggered-Action<sup>222</sup>

If the CREATE TRIGGER statement contains an INSERT REFERENCING clause, a DELETE REFERENCING clause, an UPDATE REFERENCING clause, or a SELECT REFERENCING clause, you must include a FOR EACH ROW triggered-action list in the Action clause. You can also include BEFORE and AFTER triggered-action lists, but they are optional.

For information on the BEFORE, FOR EACH ROW, and AFTER triggered-action lists, see [Action Clause on page 419](#)

## Triggered Action on a Table

The Triggered Action specifies a list of SQL statements to execute when a trigger is activated. The BEFORE, FOR EACH ROW, and AFTER sections of the Action Clause can each specify different list of triggered actions for the same trigger.

222. See [Triggered Action on a Table on page 425](#)

Triggered Action

```
,
WHEN(
Condition223
)
(
,
INSERT Statement224
DELETE Statement225
UPDATE Statement226
EXECUTE PROCEDURE Statement227
EXECUTE FUNCTION Statement228
)
```

For a trigger on a table, the trigger action consists of an optional WHEN condition and the action statements. You can specify a triggered-action list for each WHEN clause, or you can specify a single list (of one or more trigger actions) if you include no WHEN clause.

Database objects that are referenced explicitly in the trigger action or in the definition of the trigger event, such as tables, columns, and UDRs, must exist when the CREATE TRIGGER statement defines the new trigger.

The following Update trigger includes no WHEN clause, but invokes the SPL routine **upd\_items\_p1()** as its triggered action whenever the **quantity** column of the **items** table is updated:

```
CREATE TRIGGER up_itemqty
UPDATE OF quantity ON items
BEFORE(EXECUTE PROCEDURE upd_items_p1);
```

If no **upd\_items\_p1()** routine is registered in the database when this CREATE TRIGGER statement is issued, the database server issues an error, and no **up\_itemqty** trigger is created.

**Attention:** When you specify a date expression in the WHEN condition or in an action statement, make sure to specify four digits instead of two digits for the year. For more about abbreviated years, see the description of **DBCENTURY** in the *Informix® Guide to SQL: Reference*, which also describes how the behavior of some database objects can be affected by environment variable settings. Like fragmentation expressions, check constraints, and UDRs, triggers are stored in the system catalog with the creation-time settings of environment variables that can affect the evaluation of expressions like the WHEN condition. The database server ignores any subsequent changes to those settings when evaluating expressions in those database objects.

---

223. See [Condition](#) on page 1144

224. See [INSERT statement](#) on page 638

225. See [DELETE statement](#) on page 486

226. See [UPDATE statement](#) on page 1037

227. See [EXECUTE PROCEDURE statement](#) on page 557

228. See [EXECUTE FUNCTION statement](#) on page 549

## WHEN Condition

The WHEN condition makes the triggered action dependent on the outcome of a test. When you include a WHEN condition in a triggered action, the statements in the triggered action list execute only if the condition evaluates to `true`. If the WHEN condition evaluates to `false` or `unknown`, then the statements in the triggered action list are not executed.

If the triggered action is in a FOR EACH ROW section, its condition is evaluated for each row. For example, the triggered action in the following trigger executes only if the condition in the WHEN clause is true:

```
CREATE TRIGGER up_price
  UPDATE OF unit_price ON stock
  REFERENCING OLD AS pre NEW AS post
  FOR EACH ROW WHEN(post.unit_price > pre.unit_price * 2)
  (INSERT INTO warn_tab VALUES(pre.stock_num, pre.order_num,
    pre.unit_price, post.unit_price, CURRENT));
```

An SPL routine that executes inside the WHEN condition carries the same restrictions as a UDR that is called in a data manipulation statement. That is, the SPL routine cannot contain certain SQL statements. For information on which statements are restricted, see [Restrictions on SPL Routines in Data-Manipulation Statements on page 1525](#).

## Action Statements

The triggered-action statements can be INSERT, DELETE, UPDATE, EXECUTE FUNCTION, or EXECUTE PROCEDURE statements. If the action list contains multiple statements, and the WHEN condition is satisfied (or is absent), then these statements execute in the order in which they appear in the list.

## UDRs as Triggered Actions

Calls to user-defined functions and procedures, including trigger routines, can be triggered actions. The triggered action list of the FOR EACH ROW clause can include calls to UDRs that call `mi_trigger*( )` functions. Triggered actions are the only context in which a trigger routine of Informix® can be invoked. For restrictions on the calling context and the syntax of trigger routines, see [The REFERENCING and FOR Clauses on page 245](#).

You can use the EXECUTE FUNCTION statement to call any user-defined function or trigger function. Use the EXECUTE PROCEDURE statement to call any user-defined procedure or trigger procedure.

In contexts where Boolean expressions are valid, the Boolean operators SELECTING, INSERTING, DELETING, and UPDATING are valid in trigger routines and in other UDRs that are invoked in triggered action statements. These operators return TRUE ('t') if the triggering event matches the DML operation that matches the name of the operator; otherwise they return FALSE ('f'). A single trigger routine can be designed to perform different triggered actions for different types of triggering events, using these Boolean operators to execute program blocks that are appropriate to the type of trigger.

For restrictions on using SPL routines as triggered actions, see [Rules for SPL Routines on page 434](#) and [Triggers and SPL Routines on page 411](#).

## Achieving a Consistent Result

To guarantee that the triggering statement returns the same result with and without the triggered actions, make sure that the triggered actions in the BEFORE and FOR EACH ROW sections do not modify any table referenced in the following clauses:

- WHERE clause
- SET clause in the UPDATE statement
- SELECT clause
- EXECUTE PROCEDURE clause or EXECUTE FUNCTION clause in a multiple-row INSERT statement.

## Declaring keywords of SQL as correlation names

If you use the INSERT, DELETE, UPDATE, or EXECUTE keywords as a *correlation* identifier in any of the following clauses inside a triggered action list, you must qualify them by the *owner* name, the *table* name, or both:

- FROM clause of a SELECT statement
- INTO clause of the EXECUTE PROCEDURE or EXECUTE FUNCTION statement
- GROUP BY clause
- SET clause of the UPDATE statement.

The database server issues a syntax error if these keywords are *not* qualified when you include these clauses inside a triggered action.

If you use the keyword as a column name, it must be qualified by the table name; for example, **table.update**. If both the table name and the column name are keywords, they must be qualified by the owner name (for example, **owner.insert.update**). If the owner name, table name, and column name are all keywords, the owner name must be in quotation marks; for example, **'delete'.insert.update**. (These are general rules regarding reserved words as identifiers, rather than special cases for triggers. Your code will be easier to read and to maintain if you avoid using the keywords of SQL as identifiers.)

The only exception is when these keywords are the first table or column name in the list, and you do not need to qualify them. For example, **delete** in the following statement does not need to be qualified because it is the first column listed in the INTO clause:

```
CREATE TRIGGER t1 UPDATE OF b ON tab1
FOR EACH ROW (EXECUTE PROCEDURE p2() INTO delete, d);
```

The following statements show examples in which you must qualify the column name or the table name:

- FROM clause of a SELECT statement

```
CREATE TRIGGER t1 INSERT ON tab1
BEFORE (INSERT INTO tab2 SELECT * FROM tab3, 'owner1'.update);
```

- INTO clause of an EXECUTE PROCEDURE statement

```
CREATE TRIGGER t3 UPDATE OF b ON tab1
FOR EACH ROW (EXECUTE PROCEDURE p2() INTO
d, tab1.delete);
```

An INSTEAD OF trigger on a view cannot include the EXECUTE PROCEDURE INTO statement among its triggered actions.

- GROUP BY clause of a SELECT statement

```
CREATE TRIGGER t4 DELETE ON tab1
  BEFORE (INSERT INTO tab3 SELECT deptno, SUM(exp)
  FROM budget GROUP BY deptno, budget.update);
```

- SET clause of an UPDATE statement

```
CREATE TRIGGER t2 UPDATE OF a ON tab1
  BEFORE (UPDATE tab2 SET a = 10, tab2.insert = 5);
```

## Using Correlation Names in Triggered Actions

These rules apply when you use correlation names in triggered actions:

- You can use the correlation names as qualifiers for the old and new column values in SQL statements of the FOR EACH ROW triggered-action list and in the WHEN condition.
- The WHEN conditions and FOR EACH ROW clauses of multiple triggers on the same table can use different correlated variables in the REFERENCING clauses of triggers and of trigger routines to reference values in the same column.
- The old and new correlation names refer to all rows affected by the triggering statement.
- You cannot use the correlation name to qualify a column name in the GROUP BY, the SET, or the COUNT DISTINCT clause.
- The scope of reference of the correlation names is the entire trigger definition. This scope is statically determined, meaning that it is limited to the trigger definition; it does not encompass cascading triggers or columns that are qualified by a table name in a UDR that is a triggered action, except for trigger routines that are invoked in the FOR EACH ROW clause.

For additional information on using correlation names in trigger routines, see [Rules for SPL Routines on page 434](#).

## When to Use Correlation Names

In SQL statements of the FOR EACH ROW list, you must qualify all references to columns in the triggering table with either the old or new correlation name, unless the statement is valid independent of the triggered action.

In other words, if a column name inside a FOR EACH ROW triggered action list is not qualified by a correlation name, even if it is qualified by the triggering table name, it is interpreted as if the statement were independent of the triggered action. No special effort is made to search the definition of the triggering table for the non-qualified column name.

For example, assume that the following DELETE statement is a triggered action inside the FOR EACH ROW section of a trigger:

```
DELETE FROM tab1 WHERE col_c = col_c2;
```

For the statement to be valid, both **col\_c** and **col\_c2** must be columns from **tab1**. If **col\_c2** is intended to be a correlation reference to a column in the triggering table, it must be qualified by either the old or the new correlation name. If **col\_c2** is not a column in **tab1** and is not qualified by either the old or new correlation name, you get an error.

In a statement that is valid independent of the triggered action, a column name with no *correlation* qualifier refers to the current value in the database.

In the triggered action for trigger **t1** in the next example, **mgr** in the WHERE clause of the correlated subquery is an unqualified column in the triggering table. In this case, **mgr** refers to the current column value in **empsal** because the INSERT statement is valid independent of the triggered action.

```
CREATE DATABASE db1;
CREATE TABLE empsal (empno INT, salary INT, mgr INT);
CREATE TABLE mgr (eno INT, bonus INT);
CREATE TABLE biggap (empno INT, salary INT, mgr INT);

CREATE TRIGGER t1 UPDATE OF salary ON empsal
AFTER (INSERT INTO biggap SELECT * FROM empsal WHERE salary <
      (SELECT bonus FROM mgr WHERE eno = mgr));
```

In a triggered action, an unqualified column name from the triggering table refers to the current column value, but only when the triggered statement is valid independent of the triggered action.

## Qualified Versus Unqualified Value

The following table summarizes what value is retrieved when the **column** name is qualified by the *old* or by the *new* correlation name after various trigger events.

| Trigger Event               | <i>old.column</i> | <i>new.column</i>  |
|-----------------------------|-------------------|--------------------|
| INSERT                      | No value (error)  | Inserted value     |
| UPDATE (column updated)     | Original value    | Current® value (U) |
| UPDATE (column not updated) | Original value    | Original value (N) |
| DELETE                      | Original value    | No value (error)   |
| SELECT                      | Original value    | No value (error)   |

When a correlation name has no value, an error is issued only when an SQL or SPL statement referencing the undefined correlation is executed, rather than when the correlation name is declared. Refer to the following key when you read the previous table.

### Term

#### Meaning

#### Original value

Value before the triggering event

**Current® value**

Value after the triggering event

**(N)**

Cannot be changed by triggered action

**(U)**

Can be updated by triggered actions; updated value might be different from the original value because of preceding triggered actions.

Outside a FOR EACH ROW triggered-action list, you cannot qualify a column from the triggering table with either the old correlation name or the new correlation name; it always refers to the current value in the database.

Statements in the trigger action list use whatever collating order was in effect when the trigger was created, even if a different collation is in effect when the trigger action is executed. See [SET COLLATION statement on page 862](#) for details of how to specify a collating order different from what **DB\_LOCALE** specifies.

## Re-Entrancy of Triggers

In some cases a trigger can be re-entrant. In these cases the triggered action can reference the triggering table. In other words, both the trigger event and the triggered action can operate on the same table. The following list summarizes the situations in which triggers can be re-entrant and the situations in which triggers cannot be re-entrant:

- The trigger action of an Update trigger cannot be an INSERT or DELETE of the table that the trigger event updated.
- Similarly, the trigger action of an Update trigger cannot be an UPDATE of a column that the trigger event updated. (But the trigger action of an Update trigger can update a column that was not updated by the trigger event.)

For example, assume that the following UPDATE statement, which updates columns **a** and **b** of **tab1**, is the triggering statement:

```
UPDATE tab1 SET (a, b) = (a + 1, b + 1);
```

Now consider the trigger actions in the following example. The first UPDATE statement is a valid trigger action, but the second one is not, because it updates column **b** again.

```
UPDATE tab1 SET c = c + 1;    -- OK
UPDATE tab1 SET b = b + 1;  -- INVALID
```

- If the trigger has an UPDATE event, the trigger action can be an EXECUTE PROCEDURE or EXECUTE FUNCTION statement with an INTO clause that references a column that was updated by the trigger event or any other column in the triggering table.

When an EXECUTE PROCEDURE or EXECUTE FUNCTION statement is the trigger action, the INTO clause for an UPDATE trigger is valid only in FOR EACH ROW trigger actions, and column names that appear in the INTO clause must be from the triggering table.

The following statement illustrates the appropriate use of the INTO clause:

```
CREATE TRIGGER upd_totpr UPDATE OF quantity ON items
  REFERENCING OLD AS pre_upd NEW AS post_upd
  FOR EACH ROW(EXECUTE PROCEDURE
```

```
calc_totpr(pre_upd.quantity,post_upd.quantity,
pre_upd.total_price) INTO total_price);
```

The column that follows the INTO keyword must be in the triggering table, but need not have been updated by the trigger event.

When the INTO clause appears in the EXECUTE PROCEDURE or EXECUTE FUNCTION statement, the database server updates the specified columns with values returned from the UDR, immediately upon returning from the UDR.

- If the trigger has an INSERT event, the trigger action cannot be an INSERT or DELETE statement that references the triggering table.
- If the trigger has an INSERT event, the trigger action can be an UPDATE statement that references a column in the triggering table, but this column cannot be a column for which a value was supplied by the trigger event.

If the trigger has an INSERT event, and the trigger action updates the triggering table, the columns in both statements must be mutually exclusive. For example, assume that the triggering statement inserts values for columns **cola** and **colb** of table **tab1**:

```
INSERT INTO tab1 (cola, colb) VALUES (1,10);
```

Now consider the following trigger actions. The first UPDATE is valid, but the second one is not, because it updates column **colb** even though the trigger event already supplied a value for column **colb**:

```
UPDATE tab1 SET colc=100; --OK
UPDATE tab1 SET colb=100; --INVALID
```

- If the trigger has an INSERT event, the trigger action can be an EXECUTE PROCEDURE or EXECUTE FUNCTION statement with an INTO clause that references a column that was supplied by the trigger event or a column that was not supplied by the trigger event.

When an EXECUTE PROCEDURE or EXECUTE FUNCTION statement is the trigger action, you can specify the INTO clause for an INSERT trigger only when the trigger action occurs in the FOR EACH ROW list. In this case, the INTO clause can contain only column names from the triggering table.

The following statement illustrates the valid use of the INTO clause:

```
CREATE TRIGGER ins_totpr INSERT ON items
REFERENCING NEW AS new_ins
FOR EACH ROW (EXECUTE PROCEDURE calc_totpr
(0, new_ins.quantity, 0) INTO total_price);
```

The column that follows the INTO keyword can be a column in the triggering table that was supplied by the trigger event, or a column in the triggering table that was not supplied by the trigger event.

When the INTO clause appears in the EXECUTE PROCEDURE or the EXECUTE FUNCTION statement, the database server immediately updates the specified columns with values returned from the UDR.

- If the trigger action is a SELECT statement, the SELECT statement can reference the triggering table. The SELECT statement can be a trigger action in the following instances:
  - The SELECT statement appears in a subquery in the WHEN clause or in a trigger-action statement.
  - The trigger action is a UDR, and the SELECT statement appears inside the UDR.

## Re-Entrancy and Cascading Triggers

The cases when a trigger cannot be re-entrant apply recursively to all cascading triggers, which are considered part of the initial trigger. In particular, this rule means that a cascading trigger cannot update any columns in the triggering table that were updated by the original triggering statement, including any nontriggering columns affected by that statement. For example, assume this UPDATE statement is the triggering statement:

```
UPDATE tab1 SET (a, b) = (a + 1, b + 1);
```

In the cascading triggers of the next example, **trig2** fails at runtime because it references column **b**, which the triggering UPDATE statement updates:

```
CREATE TRIGGER trig1 UPDATE OF a ON tab1-- Valid
  AFTER (UPDATE tab2 SET e = e + 1);

CREATE TRIGGER trig2 UPDATE OF e ON tab2-- Invalid
  AFTER (UPDATE tab1 SET b = b + 1);
```

Now consider the following SQL statements. When the final UPDATE statement is executed, column **a** is updated and the trigger **trig1** is activated.

The trigger action again updates column **a** with an EXECUTE PROCEDURE INTO statement.

```
CREATE TABLE temp1 (a INT, b INT, e INT);
INSERT INTO temp1 VALUES (10, 20, 30);

CREATE PROCEDURE proc(val iINT) RETURNING INT,INT;
  RETURN val+10, val+20;
END PROCEDURE;

CREATE TRIGGER trig1 UPDATE OF a ON temp1
  FOR EACH ROW (EXECUTE PROCEDURE proc(50) INTO a, e);

CREATE TRIGGER trig2 UPDATE OF e ON temp1
  FOR EACH ROW (EXECUTE PROCEDURE proc(100) INTO a, e);

UPDATE temp1 SET (a,b) = (40,50);
```

Several questions arise from this example of cascading triggers. First, should the update of column **a** activate trigger **trig1** again? The answer is no. Because the trigger was activated, it is not activated a second time. If the trigger action is an EXECUTE PROCEDURE INTO or EXECUTE FUNCTION INTO statement, the only triggers that are activated are those that are defined on columns that are mutually exclusive from the columns updated until then (in the cascade of triggers) in that table. Other triggers are ignored.

Another question that arises from the example is whether trigger **trig2** should be activated. The answer is yes. The trigger **trig2** is defined on column **e**. Until now, column **e** in table **temp1** has not been modified. Trigger **trig2** is activated.

A final question that arises from the example is whether triggers **trig1** and **trig2** should be activated after the trigger action in **trig2** is performed. The answer is no. Neither trigger is activated. By this time columns **a** and **e** have been updated once, and triggers **trig1** and **trig2** have been executed once. The database server ignores and does not activate these triggers. For more about cascading triggers, see [Cascading Triggers on page 436](#).

As noted earlier, an INSTEAD OF trigger on a view cannot include the EXECUTE PROCEDURE INTO statement among its trigger actions. In addition, an error results if two views each have INSERT INSTEAD OF triggers with actions defined to perform INSERT operations on the other view.

## Rules for SPL Routines

In addition to the rules listed in [Re-Entrancy of Triggers on page 431](#), the following guidelines apply to an SPL routine that is specified as a trigger action:

- The SPL routine cannot be a cursor function (one that returns more than one row) in a context where only one row is expected.
- You cannot use the old or new correlation name inside the SPL routine unless the CREATE FUNCTION or CREATE PROCEDURE statement includes the REFERENCING clause that defines the UDR as a trigger routine. If you need to use the corresponding values in a routine that is not a trigger routine, you must pass them as parameters. In this case, the routine should be independent of triggers, and the old or new correlation name does not have any meaning outside the trigger.
- A trigger routine must include the REFERENCING clause that can declare a correlation name for OLD or NEW column values that SPL statements in the trigger routine can reference.
- A trigger routine must include the FOR *table\_object* clause that specifies the name of the table or view in the local database whose triggers can invoke this routine. The triggered action cannot call a trigger routine that does not specify the triggering table or view.
- Only trigger routines invoked in the FOR EACH ROW section of the Triggered Action list can operate directly on old or new correlation names that are defined in the REFERENCING clause of the trigger or of the trigger routine.
- Trigger routines can be invoked only in the FOR EACH ROW section of the Triggered Action list in the trigger definition.
- Correlated variables for OLD or NEW values can appear in the IF statement of SPL and in CASE expressions.
- Only correlated variables for NEW values can be on the left-hand side of a LET expression that references correlated variables. In this case, the FOR clause of the SPL routine must specify a table, rather than a view, and the trigger whose action invokes the SPL routine cannot be an INSTEAD OF trigger.
- Both OLD and NEW values can be on the right-hand side of a LET expression.
- Only trigger routines that are invoked in the FOR EACH ROW clause can use the Boolean operators SELECTING, INSERTING, DELETING, and UPDATING. These operators return TRUE ('t') if the triggering event matches the DML operation referenced by the name of the operator, and they return FALSE ('f') otherwise.
- The IF statement of SPL and CASE expressions of SQL can specify these operators as the condition in a trigger routine.
- Trigger routines must be written in the SPL language. They cannot be written in an external language, such as the C or Java™ language, but the trigger routine can include calls to external language routines, such as the **mi\_trigger** application programming interface for trigger introspection.
- Trigger routines cannot reference savepoints. Any changes to the data values or to the schema of the database by a triggered action must be committed or rolled back in their entirety. Informix® does not support the ROLLBACK TO SAVEPOINT statement in a trigger routine for the partial rollback of a triggered action.

For more information about the **mi\_trigger** API, refer to the *Informix® DataBlade® API Programmer's Guide* and to the *Informix® DataBlade® API Function Reference*.

When you use an SPL routine as a trigger action, the database objects that the routine references are not checked until the routine is executed.

See also the SPL restrictions in [Triggers and SPL Routines on page 411](#).

## Privileges to Execute Trigger Actions

If you do not own the trigger, but the access privileges held by the trigger owner include WITH GRANT OPTION, then for each triggered SQL statement you inherit the privileges of the trigger owner (with grant option), in addition to any privileges that have been granted to you individually, or through an active or default role that you hold, or that you hold as a member of the PUBLIC group. If the triggered action calls a UDR, you need Execute privilege on the UDR, or the trigger owner must have Execute privilege with grant option.

**Important:** As a security precaution, discretionary access privileges that the user holds only from a role (but that were not granted to the user individually or as member of the PUBLIC group) cannot provide access to tables outside the current database through a triggered action or through a trigger routine.

As a security precaution, however, discretionary access privileges that the user holds only from a role (but that were not granted to the user individually or as member of the PUBLIC group) cannot provide access to tables outside the current database through a triggered action or through a trigger routine.

While executing the UDR, however, you do not inherit the privileges of the trigger owner; instead, you receive the privileges granted with the UDR, depending on whether the routine is a DBA-privileged or an owner-privileged UDR:

### 1. Privileges for a DBA-privileged UDR

When a UDR is registered with the DBA keyword, and you are granted the Execute privilege on the UDR, the database server automatically grants you temporary DBA privileges that are available only when you are executing the UDR.

### 2. Privileges for an owner-privileged UDR

If the UDR was created without the DBA keyword, but the owner of the UDR was granted the necessary privileges on the underlying database objects with the WITH GRANT OPTION keywords, then you inherit these privileges when you are granted the Execute privilege on the UDR.

For a UDR that is not DBA privileged, all non-qualified database objects that the UDR references are implicitly qualified by the name of the UDR owner.

If the UDR owner has no WITH GRANT OPTION privilege, you have your original privileges on the underlying database objects when the UDR executes. For more information on privileges on SPL routines, refer to the *Informix® Guide to SQL: Tutorial*.

A view that has no INSTEAD OF trigger has only Select (with grant option) privilege. If an INSTEAD OF trigger is created on it, however, then the view has Insert (with grant option) privilege during creation of the trigger. The view owner can now grant

only Select and Insert privileges to others. This is independent of the trigger action. It is not necessary to obtain Execute (with grant option) privilege on the procedure or function. By default, Execute privilege (without grant option) is granted on each UDR in the action list.

You can use roles with triggers. Role-related statements (CREATE ROLE, DROP ROLE, GRANT, REVOKE, and SET ROLE) and SET SESSION AUTHORIZATION statements are valid in a UDR that the triggered action invokes. Privileges that a user acquired by enabling a role or by a SET SESSION AUTHORIZATION statement are not relinquished when a trigger is executed.

On a complex view (one with columns from more than one table), only the owner or DBA can create an INSTEAD OF trigger. The owner receives Select privileges when the trigger is created. Only after obtaining the required Execute privileges can the owner of the view grant privileges to other users. When the trigger on the complex view is dropped, all of these privileges are revoked.

## Creating a Trigger Action That Anyone Can Use

### About this task

For a trigger to be executable by anyone who has the privileges to execute the triggering statement, you can ask the DBA to create a DBA-privileged UDR and grant you the Execute privilege with the WITH GRANT OPTION right.

You then use the DBA-privileged UDR as the trigger action. Anyone can execute the trigger action because the DBA-privileged UDR carries the WITH GRANT OPTION right. When you activate the UDR, the database server applies privilege-checking rules for a DBA.

## Cascading Triggers

The database server allows triggers other than Select triggers to cascade, meaning that the trigger actions of one trigger can activate another trigger. (For further information on the restriction against cascading Select triggers, see [Circumstances When a Select Trigger Is Activated on page 416](#).)

The maximum number of triggers in a cascading series is 61: the initial trigger plus a maximum of 60 cascading triggers. When the number of cascading triggers in a series exceeds the maximum, the database server returns error number -748, with the following message:

```
Exceeded limit on maximum number of cascaded triggers.
```

The next example illustrates a series of cascading triggers that enforce referential integrity on the **manufact**, **stock**, and **items** tables in the **stores\_demo** database. When a manufacturer is deleted from the **manufact** table, the first trigger, **del\_manu**, deletes all the items of that manufacturer from the **stock** table. Each DELETE in the **stock** table activates a second trigger, **del\_items**, that deletes all **items** of that manufacturer from the **items** table. Finally, each DELETE in the **items** table triggers SPL routine **log\_order**, creating a record of any orders in the **orders** table that can no longer be filled.

```
CREATE TRIGGER del_manu
  DELETE ON manufact REFERENCING OLD AS pre_del
  FOR EACH ROW(DELETE FROM stock WHERE manu_code = pre_del.manu_code);
CREATE TRIGGER del_stock
  DELETE ON stock REFERENCING OLD AS pre_del
  FOR EACH ROW(DELETE FROM items WHERE manu_code = pre_del.manu_code);
CREATE TRIGGER del_items
```

```
DELETE ON items REFERENCING OLD AS pre_del
FOR EACH ROW(EXECUTE PROCEDURE log_order(pre_del.order_num));
```

When you are not using logging, referential integrity constraints on both the **manufact** and **stock** tables prohibit the triggers in this example from executing. When you use logging, however, the triggers execute successfully because constraint checking is deferred until all the trigger actions are complete, including the actions of cascading triggers. For more information about how constraints are handled when triggers execute, see [Constraint Checking on page 437](#).

The database server prevents loops of cascading triggers by not allowing you to modify the triggering table in any cascading trigger action, except with an UPDATE statement that does not modify any column that the triggering UPDATE statement updated, or with an INSERT statement. An INSERT trigger can define UPDATE trigger actions on the same table.

## Constraint Checking

When you use logging, the database server defers constraint checking on the triggering statement until after the statements in the triggered-action list execute. This is equivalent to executing a SET CONSTRAINTS ALL DEFERRED statement before executing the triggering statement. After the trigger action is completed, the database server effectively executes a SET CONSTRAINTS *constraint* IMMEDIATE statement to check the constraints that were deferred. This action allows you to write triggers so that the trigger action can resolve any constraint violations that the triggering statement creates. For more information, see [SET Database Object Mode statement on page 871](#).

Consider the following example, in which the table **child** has constraint **r1**, which references the table **parent**. You define trigger **trig1** and activate it with an INSERT statement. In the trigger action, **trig1** checks to see if **parent** has a row with the value of the current **cola** in **child**; if not, it inserts it.

```
CREATE TABLE parent (cola INT PRIMARY KEY);
CREATE TABLE child (cola INT REFERENCES parent CONSTRAINT r1);
CREATE TRIGGER trig1 INSERT ON child
REFERENCING NEW AS new
FOR EACH ROW
WHEN((SELECT COUNT (*) FROM parent
      WHERE cola = new.cola) = 0)
-- parent row does not exist
(ININSERT INTO parent VALUES (new.cola));
```

When you insert a row into a table that is the child table in a referential constraint, the row might not exist in the parent table. The database server does not immediately return this error on a triggering statement. Instead, it allows the trigger action to resolve the constraint violation by inserting the corresponding row into the parent table. As the previous example shows, you can check within the trigger action to see whether the parent row exists, and if so, you can provide logic to bypass the INSERT action.

For a database without logging, the database server does not defer constraint checking on the triggering statement. In this case, the database server immediately returns an error if the triggering statement violates a constraint.

You cannot use the SET Transaction Mode statement in a trigger action. The database server checks this restriction when you activate a trigger, because the statement could occur inside a UDR.

## Preventing Triggers from Overriding Each Other

When you activate multiple triggers with an UPDATE statement, a trigger can possibly override the changes that an earlier trigger made. If you do not want the trigger actions to interact, you can split the UPDATE statement into multiple UPDATE statements, each of which updates an individual column.

As another alternative, you can create a single update trigger for all columns that require a trigger action. Then, inside the trigger action, you can test for the column being updated and apply the actions in the desired order. This approach, however, is different from having the database server apply the actions of individual triggers, and it has the following disadvantages:

- If the triggering UPDATE statement sets a column to the current value, you cannot detect the UPDATE, so the trigger action is skipped. You might wish to execute the trigger action, even though the value of the column has not changed.
- If the trigger has a BEFORE action, it applies to all columns, because you cannot yet detect whether a column has changed.

## Tables in Remote Databases

You cannot create triggers on tables or views that reside outside the current database. You can, however, define a trigger on a local table whose trigger action manipulates a table in another database of the local server instance, or a table in a database of another server instance.

The following example defines an Update trigger on the **newtab** table in the current database of the local Informix® server instance, **dbserver1**, to which the session is connected. Here the trigger action specifies an UPDATE operation on the **items** table of the **stores\_demo** database of the remote **dbserver2** Informix® server instance:

```
CREATE TRIGGER upd_nt UPDATE ON newtab
REFERENCING NEW AS post
FOR EACH ROW(UPDATE stores_demo@dbserver2:items
SET quantity = post.qty WHERE stock_num = post.stock
AND manu_code = post.mc);
```

In summary, triggers registered in the local database can support local, cross-database, and cross-server trigger actions:

- local trigger actions on a table in the local database
- cross-database trigger actions on a table in another database of the local server instance
- cross-server trigger actions on a table in a database of a remote server instance.

The cross-server triggered action of a trigger that is defined in a database of a remote server instance can be the event that activates one or more triggers in the local database, but in this case, triggered actions of the local trigger cannot be cross-server operations. If a SELECT, DELETE, INSERT, MERGE, or UPDATE statement from a remote database server is the event that activates a local trigger whose action specifies a table in a database of a remote server instance, the trigger actions fail.

For example, the following combination of trigger action and triggering statement results in an error when the triggering statement executes:

```
-- Trigger action from dbserver1 to dbserver3:
CREATE TRIGGER upd_nt UPDATE ON newtab
REFERENCING NEW AS post
```

```

FOR EACH ROW(UPDATE stores_demo@dbserver3:items
  SET quantity = post.qty WHERE stock_num = post.stock
  AND manu_code = post.mc);

-- Triggering statement from dbserver2:
UPDATE stores_demo@dbserver1:newtab
  SET qty = qty * 2 WHERE s_num = 5
  AND mc = 'ANZ';

```

The UPDATE statement above returns an error at run time, because a cross-server triggering event cannot trigger another cross-server action.

**Important:** As a security precaution, discretionary access privileges that a user holds only from a role cannot provide access to tables outside the current database through a view or through a trigger. Cross-database trigger actions and cross-server trigger actions require access privileges on the non-local database and table that were granted directly to the user, or granted to the PUBLIC group.

## Logging and Recovery

You can create triggers for databases, with and without logging. If the trigger fails in a database that has transaction logging, the triggering statement and trigger actions are rolled back, as if the actions were an extension of the triggering statement, but the rest of the transaction is not rolled back.

In a database that does not have transaction logging, however, you cannot roll back when the triggering statement fails. In this case, you are responsible for maintaining data integrity in the database. The UPDATE, INSERT, or DELETE action of the triggering statement occurs before the trigger actions in the FOR EACH ROW section. If the trigger action fails for a database without logging, the application must restore the row that was changed by the triggering statement to its previous value.

If a trigger action calls a UDR, but the UDR terminates in an exception-handling section, any actions that modify data inside that section are rolled back with the triggering statement. In the following partial example, when the exception handler traps an error, it inserts a row into the table **logtab**:

```

ON EXCEPTION IN (-201)
  INSERT INTO logtab values (errno, errstr);
  RAISE EXCEPTION -201
END EXCEPTION;

```

When the RAISE EXCEPTION statement returns the error, however, the database server rolls back this INSERT because it is part of the trigger actions. If the UDR is executed outside a trigger action, the INSERT is not rolled back.

The UDR that implements a trigger action cannot contain any BEGIN WORK, COMMIT WORK, or ROLLBACK WORK statements. If the database has transaction logging, you must either begin an explicit transaction before the triggering statement, or the statement itself must be an implicit transaction. In any case, no other transaction-related statement is valid inside the UDR.

You can use triggers to enforce referential actions that the database server does not currently support. In a database without logging, you are responsible for maintaining data integrity when the triggering statement fails.

## INSTEAD OF Triggers on Views

Use INSTEAD OF triggers to define a specified action for the database server to perform when a trigger on a view is activated, rather than execute the triggering INSERT, DELETE, MERGE, or UPDATE statement.

### Syntax

**CREATE TRIGGER***trigger*

**INSTEAD OF**

Trigger on a View

**ENABLED DISABLED**

Trigger on a View

**INSERT ON***view*

**REFERENCING NEW**

**AS**

*correlation*

**DELETE ON***view*

**REFERENCING OLD**

**AS**

*correlation*

**UPDATE ON***view*

**REFERENCING OLD**

**AS**

*correlation*

**NEW AS** *correlation*

**REFERENCING NEW**

**AS**

*correlation*

**OLD**

**AS**

*correlation*

**FOR EACH ROW**

INSTEAD OF Triggered Action<sup>229</sup>

| Element            | Description  | Restrictions   | Syntax                                  |
|--------------------|--|--|---|
| <i>correlation</i> | Name that you declare here to qualify an old or new column value (as <i>correlation.column</i> ) in a triggered action | Must be unique in this statement                           | <a href="#">Identifier on page 1456</a> |
| <i>trigger</i>     | Name declared here for the trigger   | Must be unique among the names of triggers in the database | <a href="#">Identifier on page 1456</a> |

229. See [The Action Clause of INSTEAD OF Triggers on page 442](#)

| Element     | Description  | Restrictions   | Syntax                                  |
|-------------|--|--|---|
| <i>view</i> | Name or synonym of the triggering view.<br>Can include <i>owner</i> . qualifier. | The view or synonym must exist in the current database | <a href="#">Identifier on page 1456</a> |

You can use the trigger action to update the tables underlying the view, in some cases updating an otherwise non-updatable view. You can also use INSTEAD OF triggers to substitute other actions when INSERT, DELETE, or UPDATE statements reference specific columns within the database.

In the optional REFERENCING clause of an INSTEAD OF UPDATE trigger, the *new* correlation name can appear before or after the *old* correlation name.

With Informix®, the same REFERENCING OLD and REFERENCING NEW syntax is supported in the CREATE FUNCTION and CREATE PROCEDURE statements for defining correlation names in trigger routines. A trigger routine can be invoked in the Action clause for INSTEAD OF triggers on the view that is specified in the FOR clause of the CREATE FUNCTION or CREATE PROCEDURE statement that defines the trigger routine.

The specified *view* is sometimes called the *triggering view*. The left-hand portion of this diagram (including the *view* specification) defines the *trigger event*. The rest of the diagram defines correlation names and the *trigger action*.

## Example

Suppose that **dept** and **emp** are tables that list departments and employees:

```
CREATE TABLE dept (
  deptno INTEGER PRIMARY KEY,
  deptname CHAR(20),
  manager_num INT
);
CREATE TABLE emp (
  empno INTEGER PRIMARY KEY,
  empname CHAR(20),
  deptno INTEGER REFERENCES dept(deptno),
  startdate DATE
);
ALTER TABLE dept ADD CONSTRAINT(FOREIGN KEY (manager_num)
  REFERENCES emp(empno));
```

The next statement defines **manager\_info**, a view of columns in the **dept** and **emp** tables that includes all the managers of each department:

```
CREATE VIEW manager_info AS
  SELECT d.deptno, d.deptname, e.empno, e.empname
  FROM emp e, dept d WHERE e.empno = d.manager_num;
```

The following CREATE TRIGGER statement creates **manager\_info\_insert**, an INSTEAD OF trigger that is designed to insert rows into the **dept** and **emp** tables through the **manager\_info** view:

```
CREATE TRIGGER manager_info_insert
  INSTEAD OF INSERT ON manager_info      --defines trigger event
  REFERENCING NEW AS n                  --new manager data
  FOR EACH ROW                          --defines trigger action
  (EXECUTE PROCEDURE instab(n.deptno, n.empno));

CREATE PROCEDURE instab (dno INT, eno INT)
  INSERT INTO dept(deptno, manager_num) VALUES(dno, eno);
```

```
INSERT INTO emp (empno, deptno) VALUES (eno, dno);
END PROCEDURE;
```

After the tables, view, trigger, and SPL routine have been created, the database server treats the following INSERT statement as a triggering event:

```
INSERT INTO manager_info(deptno, empno) VALUES (08, 4232);
```

This triggering INSERT statement is not executed, but this event causes the trigger action to be executed instead, invoking the `instab()` SPL routine. The INSERT statements in the SPL routine insert new values into both the **emp** and **dept** base tables of the **manager\_info** view.

## The Action Clause of INSTEAD OF Triggers

When the trigger event for the specified *view* is encountered, the SQL statements of the trigger action are executed, instead of the triggering statement. Triggers defined on a view support the following syntax in the action clause.

INSTEAD OF Triggered Action

```
(
,
INSERT Statement230
DELETE Statement231
UPDATE Statement232
EXECUTE PROCEDURE Statement233
EXECUTE FUNCTION Statement234
)
```

This is not identical to the syntax of the trigger action for a trigger on a table, as described in the section [Triggered Action on a Table on page 425](#). Because no *WHEN (condition)* is supported, the same trigger action is executed whenever the

230. See [INSERT statement on page 638](#)

231. See [DELETE statement on page 486](#)

232. See [UPDATE statement on page 1037](#)

233. See [EXECUTE PROCEDURE statement on page 557](#)

234. See [EXECUTE FUNCTION statement on page 549](#)

INSTEAD OF trigger event is encountered, and only one action list can be specified, rather than a separate list for each *condition*.

## Restrictions on INSTEAD OF Triggers on Views

You must be either the owner of the *view* or have the DBA status to create an INSTEAD OF trigger on a view. The owner of a simple view (based on only one table) has Insert, Update, and Delete privileges. For information about the relationship between the privileges of the trigger owner and the privileges of other users, see [Privileges to Execute Trigger Actions on page 435](#).

If multiple tables underlie a view, only the owner of the view can create a trigger, but that owner can grant DML privileges on the view to other users.

An INSTEAD OF trigger defined on a view cannot violate the [Restrictions on Triggers on page 409](#) and must observe the following additional rules:

- You can define an INSTEAD OF trigger only on a view, not on a table.
- The view must be local to the current database.
- The view cannot be an updatable view WITH CHECK OPTION.
- No SELECT event or WHEN clause is valid in an INSTEAD OF trigger.
- No BEFORE nor AFTER action is valid in an INSTEAD OF trigger.
- No OF *column* clause is valid in an INSTEAD OF UPDATE trigger.
- Every INSTEAD OF trigger must specify FOR EACH ROW.
- Trigger routines called by INSTEAD OF triggers cannot reference savepoints.

A view can have any number of INSTEAD OF triggers defined for each type of event (INSERT, DELETE, or UPDATE).

The ON EXCEPTION statement of SPL has no effect when it is issued from the Action clause of an INSTEAD OF trigger.

Just as with triggers on tables, an INSTEAD OF trigger whose triggered action inserts a new serial value into a BIGSERIAL, SERIAL, or SERIAL8 column cannot update the `sqlca.sqlerrd[1]` field of the SQL Communication Area structure. The triggered INSERT operation can successfully increment the serial counter for the column, but the value of the `sqlca.sqlerrd[1]` field remains zero, rather than being reset to the serial value. The `sqlca.sqlerrd[1]` field can show the new serial value that you insert directly through an updatable view, but that field cannot show the action of an INSTEAD OF Insert trigger on a serial column.

## Updating Views

INSERT, DELETE, or UPDATE statements can directly modify a view only if all of the following are true of the SELECT statement that defines the view:

- All of the columns in the view are from a single table.
- No columns in the projection list are aggregate values.
- No UNIQUE or DISTINCT keyword is in the SELECT projection list.

- No GROUP BY clause nor UNION operator is in the view definition.
- The query selects no calculated values and no literal values.

By using INSTEAD OF triggers, however, you can circumvent these restrictions on the view, if the trigger action modifies the base table.

## CREATE TRUSTED CONTEXT statement

Use the CREATE TRUSTED CONTEXT statement to define a newtrusted-context object. This statement is an extension to the ANSI/ISO standard for the SQL language.

You must hold the database security administrator (DBSECADM) role to run this statement.

### Syntax

**CREATE TRUSTED CONTEXT***context*

**USER**

**BASED UPON CONNECTION USING SYSTEM AUTHID**

*user*

<sup>235</sup>**ATTRIBUTES (**

,

**ADDRESS**'*address*'

)

<sup>235</sup>**WITH USE FOR**

, Authorized User Clause

<sup>235</sup>**NO DEFAULT ROLE**

**DEFAULT ROLE***role*

<sup>235</sup>**DISABLE ENABLE**

Authorized User Clause

*user*

**ROLE***role*

**PUBLIC**

**WITHOUT AUTHENTICATION WITH AUTHENTICATION**

| Element        | Description   | Restrictions  | Syntax                                     |
|----------------|---|---|--|
| <i>address</i> | Communication address of the client connection to the database server | Must be unique among communication addresses of clients for this trusted-context object. For additional <i>address</i> restrictions, see <b>ADDRESS attributes</b> below. | <a href="#">Quoted String on page 1424</a> |

235. Use path no more than once

| Element        | Description                                       | Restrictions   | Syntax                                  |
|----------------|---|--|---|
| <i>context</i> | Name declared here for the trusted-context object | Must be unique among the names of trusted-context objects of this database server instance, and cannot begin with the characters <code>sys</code>  | <a href="#">Identifier on page 1456</a> |
| <i>role</i>    | An existing user-defined or built-in role         | Must exist in the database, and must be unique among attributes of this trusted-context object   | <a href="#">Owner name on page 1488</a> |
| <i>user</i>    | Authorization identifier of a user                | Must be a valid authorization identifier. Cannot be longer than 32 bytes. Must not be the authorization ID of the user who issues this statement. Must not be specified more than once in the WITH USE FOR clause. | <a href="#">Owner name on page 1488</a> |

## Usage

The CREATE TRUSTED CONTEXT statement is used to create trusted-context objects, which can allow users to have trusted connections. Within the CREATE TRUSTED CONTEXT STATEMENT, each ATTRIBUTES, DEFAULT ROLE, ENABLE, and WITH USE clause can be specified no more than once, and each attribute name and corresponding value must be unique.

## USER clause

The USER clause specifies the system authorization ID that can establish the context created in this SQL statement.

## ADDRESS attributes

The ATTRIBUTES clause can specify one or more communication addresses for connections to the database server on which the trusted-context object is defined. The following restrictions apply to communication addresses that the ALTER TRUSTED CONTEXT or the CREATE TRUSTED CONTEXT statements reference:

- Each must be unique among communication addresses of clients for this trusted-context object.
- Each must conform to the TCP/IP protocol.
- Each must be an IPv4 address, an IPv6 address, or a secure domain name.
- An IPv4 address or IPv6 address must be a real host address (not a local host), and must not contain leading blank spaces.
- An IPv6 address, in addition, must not be an IPv4-mapped IPv6 address.
- A secure domain name must not be a Dynamic Host Configuration Protocol (DHCP) address.

If an *address* value is the name of a secure domain, that name is converted to an IP address by the domain-name server, where a resulting IPv4 or IPv6 address is determined. When a domain name is converted to an IP address, the result of this conversion might be a set of one or more IP addresses. In this case, the database server interprets an incoming connection request as matching the ADDRESS attribute of a trusted-context object if the IP address from which the connection originates matches any of the IP addresses to which the domain name was converted.

The ADDRESS attribute can be specified multiple times, but each *address* pair must be unique for the set of attributes.

**Attention:**

If you have an existing application that includes the `ENCRYPTION` or `WITH ENCRYPTION` options in the `ATTRIBUTES` clause, you can leave them without the database server issuing an SQL error. Except for `WITH ENCRYPTION 'NONE'` and `ENCRYPTION 'NONE'`, however, these encryption options of the `CREATE TRUSTED CONTEXT` statement are not supported for Informix® database servers.

**WITH USE FOR clause**

The `WITH USE FOR` clause specifies that the trusted connection can be used by the specified authorization identifier. The same *user* name cannot appear more than once in this clause, which allows access by both the list of specified users and by `PUBLIC`.

For example, assume that a trusted-context object is defined that allows access by both `PUBLIC WITH AUTHENTICATION` and `joe WITHOUT AUTHENTICATION`. If the trusted-context object is used by `joe`, authentication is not required. If the trusted-context object is used by `george`, however, who has access only as a member of `PUBLIC`, authentication is required.

The `WITH AUTHENTICATION` attribute specifies that switching the current user on a trusted connection based on this trusted-context object to this user requires authentication. The `WITHOUT AUTHENTICATION` attribute specifies that switching the current user does not require authentication. The specifications for a user override the specifications for `PUBLIC`.

These attributes also affect whether authentication is required during client sessions with ODBC, JDBC, or ESQL/C connections, in which the `SET SESSION AUTHORIZATION` statement attempts to switch to a different user ID after a trusted connection has been established.

**DEFAULT ROLE attributes**

A `ROLE` object specifies the user's role (and privileges) when using a trusted connection. A `DEFAULT ROLE` identifies a role that exists at the current server, and is used when a user does not have a user-specific role defined as part of the definition of the trusted-context object. The `NO DEFAULT ROLE` attribute will specify that the trusted-context object does not have a default role. The default is `NO DEFAULT ROLE`. The role explicitly specified for the user overrides any default role associated with the trusted-context object.

**ENABLE and DISABLE keywords**

The `ENABLE` keyword specifies that the trusted-context object is created in an enabled state.

The `DISABLE` keyword specifies that the new trusted-context object is created in a disabled state, and is not enabled for any new trusted connections that are established.

You cannot use the `SET Database Object Mode` statement of SQL to change the `ENABLE` or `DISABLE` attributes of trusted contexts. You must use the `ALTER TRUSTED CONTEXT` statement if you need to reset the `ENABLED` or `DISABLED` mode of a trusted-context.

**Examples of trusted-context definitions**

*Example 1:* Create a trusted-context object such that the current user on a trusted connection based on this trusted-context object can be switched to two different user IDs. When the current user of the connection is switched to `joe`, authentication

is not required. However, authentication is required when the current user of the connection is switched to `bob`. Note that the trusted-context object has a default role called `MANAGER`. This implies that users working within the confines of this trusted-context object inherit the discretionary access privileges associated with the `MANAGER` role.

```
CREATE TRUSTED CONTEXT appserver
  USER wrjaibi
  DEFAULT ROLE MANAGER
  ENABLE
  ATTRIBUTES (ADDRESS '9.26.113.204')
  WITH USE FOR joe WITHOUT AUTHENTICATION,
  bob WITH AUTHENTICATION;
```

*Example 2:* Create a trusted-context object such that the current user of a trusted connection based on this trusted-context object can be switched to any user ID without authentication.

```
CREATE TRUSTED CONTEXT securerole
  USER pbird
  ENABLE
  ATTRIBUTES (ADDRESS 'example.ibm.com')
  WITH USE FOR PUBLIC WITHOUT AUTHENTICATION;
```

## Usage

Only a DBSA can run the CREATE USER statement. With a non-root installation, the user who installs the server is the equivalent of the DBSA, unless the user delegates DBSA privileges to a different user.

The USERMAPPING configuration parameter must be set to a value that enables support for mapped users before users defined by the CREATE USER statement can connect to the database server. A DBSA can issue the CREATE USER statement to map users to properties that correspond to the appropriate level of authorization.

You must also enter values in the SYSUSERMAP table of the **sysusers** database to map users with the appropriate user properties so that the mapped user statements of SQL to work correctly.

Execution of the CREATE USER statement can be audited with the CRUR audit code.

## PASSWORD clause

For a root-privileged server, if an OS user is connecting and the USERMAPPING configuration parameter is unset, OS authentication occurs even though the user exists in the database. When the USERMAPPING parameter is set, internal user authentication takes precedence over OS authentication. Mapped users are authenticated internally or externally. When a user is created without a password, a mapped user is created. When a user is created with a password, an internally authenticated user is created with the properties from the operating system, unless an explicit PROPERTIES clause is also specified in the statement. When the CREATE USER statement contains both the PASSWORD clause and PROPERTIES clause, the user is an internally authenticated user, but has the surrogate properties that are specified in PROPERTIES clause. In this case, the surrogate user or group must also be listed in the `/etc/informix/allowed.surrogates` file.

## PROPERTIES clause

The PROPERTIES clause can define a new user, and can optionally associate that user with surrogate properties that can include a group and a home directory. CREATE DEFAULT USER is a special case of the CREATE USER statement. The CREATE DEFAULT USER statement defines the properties that are set for the default user. After you define default user properties, you can create new users who have default user properties by omitting the PROPERTIES clause. Mapped users can connect to the database server with the surrogate user properties if they authenticate with pluggable authentication module (PAM), single sign-on (SSO), or internal authentication. Property values are not applicable to non-root installations but must be

specified just like a root-privileged server. However, surrogate users and groups in non-root installations are not required in the `allowed.surrogates` file.

## AUTHORIZATION clause

The AUTHORIZATION clause grants a subset of administrative privileges. The USERMAPPING configuration parameter must be set to ADMIN to enable this clause.

### Note:

Use of this AUTHORIZATION clause (and of the AUTHORIZATION clause of the ALTER USER or GRANT ACCESS TO PROPERTIES statements) is not recommended. This syntax will not support role separation in a future release.

## HOME directory clause

Specifying a directory for the user files with the HOME keyword is optional, but in some cases it is highly desirable. If you do not specify a home directory, an externally authenticated user has the same home directory as the surrogate user account on the Informix® host computer. If the surrogate user identity that does not have a set home directory, then Informix® creates a directory for user files in `$INFORMIXDIR/users`. In the latter case, the directory name in `$INFORMIXDIR/users` takes the form `uid.ID_number` (for example, `uid.101`).

## ACCOUNT LOCK and ACCOUNT UNLOCK keywords

With the ACCOUNT LOCK and ACCOUNT UNLOCK keywords, the DBSA can toggle disabling and enabling the specified user's access to the database server.

### Example

### Examples

Example 1: Create a mapped user:

The following statement creates a mapped user named **joe**.

```
CREATE USER joe;
```

If the user **joe** is an OS user, **joe** has the operating system properties that are associated with his user name.

If the user **joe** is not an OS user and if default user properties are defined, **joe** has the surrogate properties of the default user.

If default user properties are not defined, an error is returned.

Example 2: Create an internally authenticated user:

The following statement creates an internally authenticated user named **joe** with a password of **joebar**:

```
CREATE USER joe WITH PASSWORD "joebar";
```

If the user **joe** is not an OS user and if default user properties are defined, **joe** has the surrogate properties of the default user.

If default user properties are not defined, an error is returned

Example 3: Create an internally authenticated user with a locked account:

The following statement creates an internally authenticated user named **phil** with a locked account:

```
CREATE USER phil WITH PASSWORD "joebar" ACCOUNT LOCK;
```

If the user **phil** is not an OS user and if default user properties are defined, **phil** has the surrogate properties of the default user. If default user properties are not defined, an error is returned

Example 4: Create an internally authenticated user with specific properties:

The following statement creates an internally authenticated user named **mary** with a UID, a group, and a home directory:

```
CREATE USER mary WITH PASSWORD "joebar" PROPERTIES UID 44567  
GROUP(1234) HOME "/home/pd/osuser";
```

Example 5: Create a mapped user with a surrogate user:

The following statement creates a mapped user named **bill** with a surrogate user name of **foo\_os**:

```
CREATE USER bill WITH PROPERTIES user "foo_os";
```

The user **bill** has the properties of the operating system user **foo\_os**.

Example 6: Create a default user:

The following statement creates a user, internally named PUBLIC, with the properties of the surrogate user **tmp**:

```
CREATE DEFAULT USER WITH PROPERTIES USER "tmp";
```

Other users created without surrogate properties will have these properties.

## CREATE VIEW statement

Use the CREATE VIEW statement to create a new view that is based on one or more existing tables and views that reside in the database, or in another database of the local database server or of a different database server.

**Syntax****CREATE VIEW** **IF NOT EXISTS** *viewowner*

```
(
, column
)
```

**OF TYPE** *row\_type***AS**Subset of SELECT Statement<sup>237</sup>**WITH CHECK OPTION**

| Element         | Description   | Restrictions   | Syntax                                  |
|-----------------|---|--|---|
| <i>column</i>   | Name that you declare here for a column in view. Default is a column name from Projection list of SELECT. | See <a href="#">Naming View Columns on page 456</a> .                          | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>    | Owner of the view. If omitted, default is the user ID that issues the statement.                          | To specify another user ID requires DBA access privilege.                      | <a href="#">Owner name on page 1488</a> |
| <i>row_type</i> | Named-row type for typed view   | Must already exist in the database   | <a href="#">Data Type on page 1163</a>  |
| <i>view</i>     | Name that you declare here for the view   | Must be unique among view, table, sequence, and synonym names in the database. | <a href="#">Identifier on page 1456</a> |

**Usage**

A *view* is a virtual table, defined by a SELECT statement. Except for the statements in the following list, you can specify the name or synonym of a view in any SQL statement where the name of a table is syntactically valid:

- ALTER FRAGMENT
- CREATE INDEX
- CREATE TABLE
- CREATE TRIGGER
- RENAME TABLE
- START VIOLATIONS TABLE
- STOP VIOLATIONS TABLE
- TRUNCATE
- UPDATE STATISTICS

You must specify the name of a view when you use the CREATE TRIGGER statement to define an INSTEAD OF trigger on a view, but the syntax and functionality are different from those of a trigger defined on a table.

237. See [Subset of SELECT syntax valid in view definitions on page 455](#)

[Updating Through Views on page 458](#) prohibits non-updatable views in INSERT, DELETE, or UPDATE statements (where other views are valid).

To create a view, you must have the Select privilege on all columns from which the view is derived. You can query a view as if it were a table, and in some cases, you can update it as if it were a table; but a view is not a table.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if a view of the specified name is already registered in the current database, or if the specified name is the identifier of a table, synonym, or sequence object in the current database.

The view consists of the set of rows and columns that the SELECT statement in the view definition returns each time you refer to the view in a query.

In some cases, the database server merges the SELECT statement of the user with the SELECT statement defining the view and executes the combined statements. In other cases, a query against a view might execute more slowly than expected, if the complexity of the view definition causes the database server to create a temporary table (referred to as a materialized view). For more information on materialized views, see the *Informix® Performance Guide*.

The view reflects changes to the underlying tables, but with two exceptions:

- If a SELECT \* specification defines the view, the view has only the columns that existed in the underlying tables when the view was defined by CREATE VIEW. Any new columns that are subsequently added to the underlying tables with the ALTER TABLE statement do not appear in the view.
- If a GRANT or REVOKE statement changes the discretionary access privileges on any table referenced in the view definition, the database server does not automatically apply those access privilege changes to the view.

To force modifications of the access privileges or schema of an underlying table to be applied to the view, you can use the DROP VIEW and CREATE VIEW statements of SQL to drop and recreate the view. You can also use the CREATE VIEW and CREATE TRIGGER statements to recreate, respectively, any dependent views or INSTEAD OF triggers that the DROP VIEW statement destroyed.

The view inherits the data types of the columns in the tables from which the view is derived. The database server determines data types of virtual columns from the nature of the expression.

The SELECT statement is stored in the **sysviews** system catalog table. When you subsequently refer to a view in another statement, the database server performs the defining SELECT statement while it executes the new statement.

In DB-Access, if you create a view outside the CREATE SCHEMA statement, you receive warnings if you use the **-ansi** flag or if you set the **DBANSIWARN** environment variable.

The following statement creates a view that is based on the **person** table. When you create a view like this, which has no OF TYPE clause, the view is referred to as an *untyped view*.

```
CREATE VIEW v1 AS SELECT * FROM person;
```

## Typed Views

You can create *typed views* if you have Usage privileges on the named-ROW type or if you are its owner or the DBA. If you omit the OF TYPE clause, rows in the view are considered untyped and default to an unnamed-ROW type.

Typed views, like typed tables, are based on a named-ROW type. Each column in the view corresponds to a field in the named-ROW type. The following statement creates a typed view that is based on the table **person**.

```
CREATE VIEW v2 OF TYPE person_t AS SELECT * FROM person;
```

To create a typed view, you must include an OF TYPE clause. When you create a typed view, the named-ROW type that you specify immediately after the OF TYPE keywords must already exist.

## Subset of SELECT syntax valid in view definitions

Most SELECT statement syntax is supported in view definitions, with certain exceptions.

- You cannot create a view on a temporary table. The FROM clause of the SELECT clause of the view definition cannot include the name of a temporary table.
- Table objects referenced by the SELECT clause in CREATE VIEW statements can be permanent database tables, views, or derived tables. The query can reference a single table object, or can join two or more. These can be in the current database, in other databases of the local database server, or in databases of remote server instances. The SELECT statement can define derived tables in the FROM clause, using uncorrelated or correlated table references. These derived table definitions can include the `LATERAL` keyword, and can include lateral table and column references.
- Table objects referenced by the SELECT clause in CREATE VIEW statements can be permanent database tables, views, or derived tables. The query can reference a single table object, or can join two or more. These can be in the current database, in other databases of the local database server, or in databases of remote server instances. The SELECT statement can define derived tables in the FROM clause, using uncorrelated or correlated table references. These derived table definitions can include the `LATERAL` keyword, and can include lateral table and column references.

- If Select privileges are revoked from a user for a table that is referenced in the SELECT statement defining a view that the same user owns, then that view is automatically dropped by the database server, unless the view also includes columns from tables in another database.
- You cannot create a view on a table that is part of a typed-table hierarchy, if that table resides in a database of a different database server instance.
- Do not use display labels in the Select list of the Projection clause in a view definition. Display labels in the Projection clause are interpreted as column names.
- Hardcoded values should not be used in a view definition, but only in the WHERE clause of subsequent SELECT statements that query the view. If the values are not hardcoded in the view, the query optimizer can then always exclude those literal values and can complete the query in less time. But if the same values are hardcoded in the view, the query optimizer still must evaluate each literal value.
- The SELECT clause in the CREATE VIEW statement cannot include the SKIP, FIRST, or LIMIT keywords, or the INTO TEMP clause.

For complete information about SELECT statement syntax and usage, see [SELECT statement on page 768](#).

## Union Views

A view that contains a UNION or UNION ALL operator in its SELECT statement is known as a *union view*. Certain restrictions apply to union views:

- If a CREATE VIEW statement defines a union view, or includes the INTERSECT, MINUS, or EXCEPT set operator, you cannot specify the WITH CHECK OPTION keywords in the CREATE VIEW statement.
- All restrictions that apply to UNION or UNION ALL set operations in stand-alone SELECT statements also apply to UNION and UNION ALL operations in the SELECT statement of a union view.
- Similarly, all other restrictions that apply to the INTERSECT, MINUS, or EXCEPT set operators in stand-alone SELECT statements also apply to those set operators in a combined SELECT statement that defines a view.

For a list of these restrictions, see [Restrictions on a Combined SELECT on page 837](#). For an example of a CREATE VIEW statement that defines a union view, see [Naming View Columns on page 456](#).

## Naming View Columns

The number of columns that you specify in the *column* list must match the number of columns returned by the SELECT statement that defines the view. If you do not specify a list of columns, the view inherits the column names of the underlying tables. In the following example, the view **herostock** has the same column names as the columns in Projection clause of the SELECT statement:

```
CREATE VIEW herostock AS
SELECT stock_num, description, unit_price, unit, unit_descr
FROM stock WHERE manu_code = 'HRO';
```

You must specify at least one column name in the following circumstances:

- If you provide names for some of the columns in a view, then you must provide names for all the columns. That is, the column list must contain an entry for every column that appears in the view.
- If the SELECT statement returns an expression, the corresponding column in the view is called a *virtual* column. You must provide a name for a virtual column. In the following example, the user must specify the column parameter because the select list of the Projection clause of the SELECT statement contains an aggregate expression:

```
CREATE VIEW newview (firstcol, secondcol) AS
    SELECT sum(col_a), col_b FROM oldtab;
```

- You must also specify column names in cases where any of the selected columns have duplicate column names without the table qualifiers. For example, if both **orders.order\_num** and **items.order\_num** appear in the SELECT statement, the CREATE VIEW statement, must provide two separate column names to label them:

```
CREATE VIEW someorders (custnum,ocustnum,newprice) AS
    SELECT orders.order_num,items.order_num,
           items.total_price*1.5
    FROM orders, items
    WHERE orders.order_num = items.order_num
    AND items.total_price > 100.00;
```

Here **custnum** and **ocustnum** replace the two identical column names.

- The CREATE VIEW statement must also provide column names in the column list when the SELECT statement includes a UNION or UNION ALL operator and the names of the corresponding columns in the SELECT statements are not identical.

For example, code in the following CREATE VIEW statement must specify the column list because the second column in the first SELECT statement has a different name from the second column in the second SELECT statement:

```
CREATE VIEW myview (col_a, col_b) AS
    SELECT col_x, col_y from firsttab
    UNION
    SELECT col_x, col_z from secondtab;
```

## Using a View in the SELECT Statement

You can define a view whose columns are based on other views, but you must abide by the restrictions on creating views that are discussed in the *Informix® Database Design and Implementation Guide*.

## WITH CHECK OPTION Keywords

The WITH CHECK OPTION keywords instruct the database server to ensure that all modifications that are made through the view to the underlying tables satisfy the definition of the view.

The following example creates a view that is named **palo\_alto**, which uses all the information in the **customer** table for customers in the city of Palo Alto. The database server checks any modifications made to the **customer** table through **palo\_alto** because the WITH CHECK OPTION keywords are specified.

```
CREATE VIEW palo_alto AS
    SELECT * FROM customer WHERE city = 'Palo Alto'
    WITH CHECK OPTION
```

You can insert into a view a row that does not satisfy the conditions of the view (that is, a row that is not visible through the view). You can also update a row of a view so that it no longer satisfies the conditions of the view. For example, if the view was created without the `WITH CHECK OPTION` keywords, you could insert a row through the view where the city is Los Altos, or you could update a row through the view by changing the city from Palo Alto to Los Altos.

To prevent such inserts and updates, you can add the `WITH CHECK OPTION` keywords when you create the view. These keywords ask the database server to test every inserted or updated row to ensure that it meets the conditions that are set by the `WHERE` clause of the view. The database server rejects the operation with an error if the row does not meet the conditions.

Even if the view was created with the `WITH CHECK OPTION` keywords, however, you can perform inserts and updates through the view to change columns that are not part of the view definition. A column is not part of the view definition if it does not appear in the `WHERE` clause of the `SELECT` statement that defines the view.

The `CREATE VIEW` statement fails with error -940 if you include the `WITH CHECK OPTION` keywords in a `CREATE VIEW` statement in which the `UNION`, `INTERSECT`, `MINUS`, or `EXCEPT` set operator combines two queries in the view definition.

## Updating Through Views

If a view is built on a single table, the view is *updatable* if the `SELECT` statement that defines the view does not contain any of the following elements:

- Columns in the projection list that are aggregate values
- Columns in the projection list that use the `UNIQUE` or `DISTINCT` keyword
- A `GROUP BY` clause
- A `UNION` operator
- A query that selects calculated or literal values.

You can `DELETE` from a view that selects calculated values from a single table, but `INSERT` and `UPDATE` operations are not valid on such views.

In an updatable view, you can update the values in the underlying table by inserting values into the view. If a view is built on a table that has a derived value for a column, however, that column is not updatable through the view. Other columns in the view, however, can be updated.

See also [Updating Views on page 443](#) for information about using `INSTEAD OF` triggers to update views that are based on more than one table or that include columns containing aggregates or other calculated values.

**Important:** You cannot update or insert rows in a remote table through views that were created using the `WITH CHECK OPTION` keywords.

## CREATE XADATASOURCE statement

Use the CREATE XADATASOURCE statement to create a new XA-compliant data source and create an entry for it in the **sysxdatasources** system catalog table. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

```
CREATE XADATASOURCE IF NOT EXISTS xa_source
USING xa_type
```

| Element          | Description   | Restrictions   | Syntax                                  |
|------------------|---|--|---|
| <i>xa_source</i> | Name that you declare here for the new XA data source | Must be unique among XA data source names in <b>sysxdatasources</b>                    | <a href="#">Identifier on page 1456</a> |
| <i>xa_type</i>   | Name of an existing XA data source type               | Must already exist in the database in the <b>sysxasourcetypes</b> system catalog table | <a href="#">Identifier on page 1456</a> |

### Usage

An XA-compliant data source is an external data source that complies with the X/Open DTP XA Standard for managing interactions between a transaction manager and a resource manager. To register XA-compliant data sources in the database requires two SQL statements:

- First create one or more XA-compliant data source types by using the CREATE XADATASOURCE TYPE statement.
- Then create one or more instances of XA-compliant data sources with the CREATE XADATASOURCE statement.

You can integrate transactions at the XA data source with the Informix® transaction, using a 2-phase commit protocol to ensure that transactions are uniformly committed or rolled back among multiple database servers, and manage multiple external XA data sources within the same global transaction.

The CREATE XADATASOURCE statement is not supported on secondary servers within a high-availability cluster.

Any user can create an XA data source, which follows standard owner-naming rules, according to the ANSI-compliance status of the database. Only a database that uses transaction logging can support the X/Open DTP XA Standard.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an XA data source of the specified name is already registered in the current database.

Both XA data source types and instances of XA data sources are specific to one database. To support distributed transactions, they must be created in each database that interacts with the external XA data source.

The following statement creates a new XA data source instance called **informix.NewYork** of type **informix.MQSeries**.

```
CREATE XADATASOURCE informix.NewYork USING informix.MQSeries;
```

SQL statements that are not valid in XA environments

The Informix® database server issues error -701 when you attempt to execute any of the following statements within an X/Open distributed transaction-processing environment:

- CLOSE DATABASE
- CREATE DATABASE
- DROP DATABASE
- SET LOG
- SAVEPOINT
- RELEASE SAVEPOINT
- ROLLBACK TO SAVEPOINT

Within an XA environment, you can execute a single DATABASE statement after an xa\_open call to specify a current database. After this database is selected, however, no subsequent DATABASE statement can be executed in the same session. If you attempt to execute a second DATABASE statement, the DATABASE statement fails with error -701.

---

[DROP XADATASOURCE statement on page 539](#)

[DROP XADATASOURCE TYPE statement on page 540](#)

## CREATE XADATASOURCE TYPE statement

Use the CREATE XADATASOURCE TYPE statement to create a new XA-compliant data source type and create an entry for it in the **sysxasourcetypes** system catalog table. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### CREATE

**XADATASOURCE TYPE**IF NOT EXISTS *xa\_type*

```
(
, Purpose Options238
)
```

| Element        | Description  | Restrictions   | Syntax                                  |
|----------------|--|--|---|
| <i>xa_type</i> | Name that you declare here for a new XA data source type | Must be unique among XA data source type names in the <b>sysxasourcetypes</b> system catalog table | <a href="#">Identifier on page 1456</a> |

### Usage

The CREATE XADATASOURCE TYPE statement adds an XA-compliant data source type to the database.

The CREATE XADATASOURCE TYPE statement is not supported on secondary servers within a high-availability cluster.

Any user can create an XA data source type, whose owner-naming rules depend on the ANSI-compliance status of the database. Only a database that uses transaction logging can support the X/Open DTP XA Standard.

238. See [Purpose Options on page 1493](#)

To create a data source type, you must declare its name and specify *purpose functions* and *purpose values* as attributes of the XA source type. Most of the purpose options that follow the source type name associate columns in the **sysxasourcetypes** system catalog table with the name of a UDR.

If you include the optional IF NOT EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if an XA data source type of the specified name is already registered in the current database.

Both XA data source types and instances of XA data sources are specific to one database. To support distributed transactions, they must be created in each database that interacts with the external XA data source.

The following statement creates a new XA data source type called **MQSeries®**, owned by user **informix**.

```
CREATE XADATASOURCE TYPE 'informix'.MQSeries(
    xa_flags      = 1,
    xa_version    = 0,
    xa_open       = informix.mqseries_open,
    xa_close      = informix.mqseries_close,
    xa_start      = informix.mqseries_start,
    xa_end        = informix.mqseries_end,
    xa_rollback   = informix.mqseries_rollback,
    xa_prepare    = informix.mqseries_prepare,
    xa_commit     = informix.mqseries_commit,
    xa_recover    = informix.mqseries_recover,
    xa_forget     = informix.mqseries_forget,
    xa_complete   = informix.mqseries_complete);
```

You need to provide one value or UDR name for each of the options listed above, but the sequence in which you list them is not critical. (The order of purpose options in this example corresponds to the order of column names in the **sysxasourcetypes** system catalog table.)

After this statement executes successfully, you can create instances of type **informix.MQSeries**. The following statement creates a new instance called **informix.MenloPark** of XA-compliant data source type **informix.MQSeries**:

```
CREATE XADATASOURCE informix.MenloPark USING informix.MQSeries;
```

---

#### Related reference

[CREATE XADATASOURCE statement on page 458](#)

[DROP XADATASOURCE statement on page 539](#)

[DROP XADATASOURCE TYPE statement on page 540](#)

[Purpose Options on page 1493](#)

## DATABASE statement

Use the DATABASE statement to open an accessible database as the current database. This statement is an extension to the ANSI/ISO standard for SQL.

## Syntax

**DATABASE***database***EXCLUSIVE**

| Element         | Description                            | Restrictions            | Syntax                                     |
|-----------------|--|-------------------------|--|
| <i>database</i> | Name of a database to which to connect | The database must exist | <a href="#">Database Name on page 1449</a> |

## Usage

You can use the **DATABASE** statement to select any database of your database server instance. To select a database on another database server, include the name of the database server with the database name:

```
DATABASE stores_demo@db_titinius;
```

You can also specify the database as a host variable that contains a valid database environment:

```
DATABASE db_varX;
```

Here the contents of **db\_varX** must correspond to one of the formats in the [Database Name on page 1449](#) syntax diagram.

If besides the name of the *database* you also provide the name of the current (or of another) database server instance, the database server name cannot include uppercase characters.

If the **DATABASE** statement specifies only a *database* name that corresponds to no database of the current server instance, the database server examines the **DBPATH** environment variable setting, and opens the specified database if a server is found. If no *database* is found, or if its server is offline, the **DATABASE** statement fails with an error. For more information, see the **CONNECT** statement topic [Only Database Specified on page 189](#).

Issuing the **DATABASE** statement when a database is already open closes the current database before opening the new one. Closing the current database releases any cursor resources that the database server holds, invalidating any cursors that you have declared up to that point. If the *user* specification was changed through a **SET SESSION AUTHORIZATION** statement, the original user name is restored when the new database is opened.

If a previous **CONNECT** statement has established an explicit connection to a database, and that connection is still your current connection, you cannot use the **DATABASE** statement (nor any SQL statement that creates an implicit connection) until after you use **DISCONNECT** to close the explicit connection.

The current user (or **PUBLIC**) must have the **Connect** privilege on the database that is specified in the **DATABASE** statement. The current user cannot have the same user name as an existing role in the database.

**DATABASE** is not a valid statement in multistatement **PREPARE** operations.

You can use the 'dbhostname' option to retrieve the host name of the database server to which a database client is connected. This option retrieves the physical computer name of the computer on which the database server is running. In the following example, the user enters the 'dbhostname' option of **DBINFO** in a **SELECT** statement to retrieve the host name of the database server instance to which **DB-Access** is connected:

```
SELECT DBINFO('dbhostname')
FROM systables
WHERE tabid = 1;
```

The following table shows the result of this query.

---

**(constant)**

---

rd\_lab1

---

[CONNECT statement on page 185](#)

## SQLCA.SQLWARN Settings Immediately after DATABASE Executes (ESQL/C)

Immediately after DATABASE executes, you can identify characteristics of the specified database by examining warning flags in the **sqlca** structure.

- If the first field of **sqlca.sqlwarn** is blank, then no warnings were issued.
- The second **sqlca.sqlwarn** field is set to the letter **w** if the *database* that was opened supports transaction logging.
- The third field is set to **w** if *database* is an ANSI-compliant database.
- The fourth field is set to **w**.
- The fifth field is set to **w** if *database* converts all floating-point data to DECIMAL format. (System lacks FLOAT and SMALLFLOAT support.)
- The seventh field is set to **w** if *database* is the secondary server (that is, running in read-only mode) in a data-replication pair.
- The eighth field is set to **w** if *database* has **DB\_LOCALE** set to a locale different from the **DB\_LOCALE** setting on the client system.

## EXCLUSIVE keyword

The EXCLUSIVE keyword opens the database in exclusive mode and prevents access by anyone but the current user. To allow others to access the database, you must first execute the CLOSE DATABASE statement and then reopen the database without the EXCLUSIVE keyword.

The following statement opens the **stores\_demo** database on the **training** database server in exclusive mode:

```
DATABASE stores_demo@training EXCLUSIVE;
```

If another user has already opened the specified database, exclusive access is denied, an error is returned, and no database is opened.

If you encounter this error, but you are unable to confirm that other users are connected to the database, your non-exclusive access might be caused by a sensor or task that is running in the Scheduler API. To temporarily disable the Scheduler, you can issue this SQL administration API command:

```
EXECUTE FUNCTION admin('scheduler shutdown');
```

After the admin('scheduler shutdown') routine has completed execution, retry the `DATABASE ... EXCLUSIVE` statement.

For more information on the Scheduler API commands, see your *Informix® Administrator's Guide*. For information about the privileges that you must hold to call SQL administration API functions, see your .

## DEALLOCATE COLLECTION statement

Use the DEALLOCATE COLLECTION statement to release memory for a collection variable that was previously allocated with the ALLOCATE COLLECTION statement.

This statement is an extension to the ANSI/ISO standard for SQL. Use this statement with ESQL/C.

### Syntax

#### DEALLOCATE COLLECTION

*:variable*

| Element         | Description  | Restrictions   | Syntax  |
|-----------------|--|--|---|
| <i>variable</i> | Name that identifies a typed or untyped collection variable for which to deallocate memory | Must be the name of the Informix® ESQL/C collection variable that has already been allocated | Name must conform to language-specific rules for names of variables |

### Usage

The DEALLOCATE COLLECTION statement frees all the memory that is associated with the Informix® ESQL/C collection variable that *variable* identifies. You must explicitly release memory resources for a collection variable with DEALLOCATE COLLECTION. Otherwise, deallocation occurs automatically at the end of the program.

The DEALLOCATE COLLECTION statement releases resources for both typed and untyped collection variables.

**Tip:** The DEALLOCATE COLLECTION statement deallocates memory for Informix® ESQL/C collection variables only. To deallocate memory for Informix® ESQL/C row variables, use the DEALLOCATE ROW statement.

If you deallocate nonexistent collection variables or variables that are not Informix® ESQL/C collection variables, you receive errors. After you deallocate a collection variable, you can use the ALLOCATE COLLECTION to reallocate resources and you can then reuse a collection variable.

This example shows how to deallocate resources with the DEALLOCATE COLLECTION statement for the untyped collection variable, `a_set`:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection a_set;
EXEC SQL END DECLARE SECTION;
. . .
EXEC SQL allocate collection :a_set;
. . .
EXEC SQL deallocate collection :a_set;
```

For a related example, see the related concept, [Inserting into a Collection Cursor](#).

#### Related reference

[ALLOCATE COLLECTION statement on page 16](#)

[DEALLOCATE ROW statement on page 466](#)

#### Related information

[Inserting into a Collection Cursor on page 705](#)

## DEALLOCATE DESCRIPTOR statement

Use the DEALLOCATE DESCRIPTOR statement to free a previously allocated, system-descriptor area. Use this statement with Informix® ESQL/C.

### Syntax

This statement is an extension to the ANSI/ISO standard for the SQL language.

#### DEALLOCATE DESCRIPTOR

*'descriptor' descriptor\_var*

| Element               | Description  | Restrictions   | Syntax                                       |
|-----------------------|--|--|--|
| <i>descriptor</i>     | Name of a system-descriptor area                                 | Use single quotation marks.<br>System-descriptor area must already be allocated                    | <a href="#">Quoted String on page 1424</a>   |
| <i>descriptor_var</i> | Host variable that contains the name of a system-descriptor area | System-descriptor area must already be allocated, and the variable must already have been declared | Name must conform to language-specific rules |

### Usage

The DEALLOCATE DESCRIPTOR statement frees all the memory that is associated with the system-descriptor area that *descriptor* or *descriptor\_var* identifies. It also frees all the item descriptors (including memory for data items in the item descriptors).

You can reuse a descriptor or descriptor variable after it is deallocated. Otherwise, deallocation occurs automatically at the end of the program.

If you deallocate a nonexistent descriptor or descriptor variable, an error results.

You cannot use the DEALLOCATE DESCRIPTOR statement to deallocate an **sqllda** structure. You can use it only to free the memory that is allocated for a system-descriptor area.

The following examples show valid DEALLOCATE DESCRIPTOR statements. The first line uses an embedded-variable name, and the second line uses a quoted string to identify the allocated system-descriptor area.

```
EXEC SQL deallocate descriptor :descname;

EXEC SQL deallocate descriptor 'desc1';
```

[PUT statement on page 700](#)

## DEALLOCATE ROW statement

Use the DEALLOCATE ROW statement to release memory for a ROW variable.

This statement is an extension to the ANSI/ISO standard for SQL. Use this statement with ESQL/C.

### Syntax

#### DEALLOCATE ROW

*:variable*

| Element         | Description                   | Restrictions                   | Syntax            |
|-----------------|-------------------------------|--------------------------------|-------------------|
| <i>variable</i> | Typed or untyped row variable | Must be declared and allocated | Language specific |

## Usage

DEALLOCATE ROW frees all the memory that is associated with the Informix® ESQL/C typed or untyped **row** variable that *variable* identifies. If you do not explicitly release memory resources with DEALLOCATE ROW, deallocation occurs automatically at the end of the program. To deallocate memory for the Informix® ESQL/C collection variable, use the DEALLOCATE COLLECTION statement.

After you deallocate a ROW variable, you can use the ALLOCATE ROW statement to reallocate resources, and you can then reuse a ROW variable. The following example shows how to deallocate resources for the ROW variable, **a\_row**, using the DEALLOCATE ROW statement:

```
EXEC SQL BEGIN DECLARE SECTION; row (a int, b int) a_row;
EXEC SQL END DECLARE SECTION;
. . .
EXEC SQL allocate row :a_row;
. . .
EXEC SQL deallocate row :a_row;
```

---

[ALLOCATE ROW statement on page 19](#)

## DECLARE statement

Use the DECLARE statement of dynamic SQL to declare a cursor and to associate it with an SQL statement that returns a set of rows to an SPL or Informix® ESQL/C or routine.

## Syntax

### DECLARE

*cursor\_id*

<sup>239</sup><sup>240</sup> *cursor\_id\_var*

### CURSOR

<sup>239</sup> **WITH HOLD**

**FOR**<sup>239</sup><sup>240</sup> Subset of INSERT Statement<sup>241</sup>

FOR UPDATE or FOR READ ONLY Select Options Other Select or Function Options

<sup>239</sup> <sup>240</sup> **SCROLL CURSOR**

### WITH HOLD

Other Select or Function Options

<sup>240</sup> **CURSOR FOR**

SELECT with Collection-Derived Table<sup>246</sup>

INSERT with Collection-Derived Table<sup>247</sup>

FOR UPDATE or FOR READ ONLY Select Options

<sup>240</sup>

Subset of SELECT Statement<sup>242</sup>

### FOR READ ONLY

<sup>239</sup> **FOR UPDATE**

### OF

, *column*

Other Select or Function Options

### FOR

<sup>240</sup> SELECT Statement<sup>243</sup>

*statement\_id*

<sup>239</sup>

<sup>240</sup> *statement\_id\_var*

EXECUTE PROCEDURE Statement<sup>244</sup>

<sup>240</sup> EXECUTE FUNCTION Statement<sup>245</sup>

| Element                 | Description                          | Restrictions  | Syntax                                  |
|-------------------------|--------------------------------------|---|---|
| <i>column</i>           | Column to update with cursor         | Must exist, but need not be listed in Select list of the Projection clause                              | <a href="#">Identifier on page 1456</a> |
| <i>cursor_id</i>        | Name declared here for cursor        | Must be unique in the routine among names of cursors and prepared objects (and in SPL, among variables) | <a href="#">Identifier on page 1456</a> |
| <i>cursor_id_var</i>    | Variable holding <i>cursor_id</i>    | Must have a character data type   | Language-specific                       |
| <i>statement_id</i>     | Name of prepared statement           | Must have been declared by a PREPARE statement  | <a href="#">Identifier on page 1456</a> |
| <i>statement_id_var</i> | Variable holding <i>statement_id</i> | Must have a character data type   | Language-specific                       |

## Usage

Except as noted, sections that follow describe how to use the DECLARE statement in Informix® ESQL/C routines. For information about the more restricted syntax and semantics of the DECLARE statement in SPL routines, see [Declaring a Dynamic Cursor in an SPL Routine on page 484](#).

A *cursor* is an identifier that you associate with an SQL statement that returns a group of rows. The DECLARE statement associates the cursor with one of the following database objects:

- With an SQL statement, such as SELECT, EXECUTE FUNCTION (or EXECUTE PROCEDURE), or INSERT.  
Each of these SQL statements creates a different type of cursor. For more information, see [Overview of Cursor Types on page 471](#).
- With the statement identifier (*statement id* or *statement id variable*) of a prepared statement  
You can prepare one of the previous SQL statements and associate the prepared statement with a cursor. For more information, see [Associating a Cursor with a Prepared Statement on page 480](#).
- With a collection variable in Informix® ESQL/C programs  
The name of the collection variable appears in the FROM clause of a SELECT or the INTO clause of an INSERT. For more information, see [Associating a Cursor with a Prepared Statement on page 480](#).

DECLARE assigns an identifier to the cursor, specifies its uses, and directs the Informix® ESQL/C preprocessor to allocate storage for it. DECLARE must precede any other statement that references the cursor during program execution.

The cursors and prepared objects that can exist concurrently in a single program are limited by available memory. To avoid exceeding the limit, use the FREE statement to release the resources of prepared statements or cursors that are no longer needed.

An ESQL/C program can consist of one or more source-code files. By default, the scope of reference of a cursor is global to a program, so a cursor that was declared in one source file can be referenced from a statement in another file. If you want to limit the scope of each cursor name to the file where it was declared, you must preprocess each file with the `-local` command-line option.

Multiple cursors can be declared for the same prepared statement identifier. For example, the following Informix® ESQL/C example does not return an error:

```
EXEC SQL prepare id1 from 'select * from customer';
EXEC SQL declare x cursor for id1;
EXEC SQL declare y scroll cursor for id1;
EXEC SQL declare z cursor with hold for id1;
```

If you include the **-ansi** compilation flag (or if **DBANSIWARN** is set), warnings are generated for statements that use dynamic cursor names, dynamic statement identifiers, or statements that use collection-derived tables. Some error checking is performed at runtime, such as these typical checks:

- Invalid use of sequential cursors as scroll cursors
- Use of undeclared cursors
- Invalid cursor names or statement names (empty)

Checks for multiple declarations of a cursor of the same name are performed at compile time only if the cursor or statement is specified as an identifier. The following example uses a host variable to store the cursor name:

```
EXEC SQL declare x cursor for select * from customer;
. . .
stcopy("x", s);
EXEC SQL declare :s cursor for select * from customer;
```

A cursor uses the collating order that was in effect when the cursor was declared, even if this is different from the collation of the session at run time.

## Overview of Cursor Types

Cursors are typically required for data manipulation language (DML) operations on more than one row of data (or on Informix® ESQL/C collection variables). You can declare the following types of cursors with the DECLARE statement:

- A *Select cursor* is a cursor associated with a SELECT statement.
- A *Function cursor* is a cursor associated with an EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement.
- An *Insert cursor* is a cursor associated with an INSERT statement.

Sections that follow describe each of these cursor types. Cursors can also have *sequential*, *scroll*, and *hold* characteristics (but an Insert cursor cannot be a scroll cursor). These characteristics determine the structure of the cursor; see [Cursor Characteristics on page 476](#). In addition, a Select or Function cursor can specify *read-only* or *update* mode. For more information, see [Select Cursor or Function Cursor on page 471](#).

**Tip:** Function cursors behave the same as Select cursors that are enabled as update cursors.

Besides associating a cursor directly with the text of an SQL statement, the FOR keyword of the DECLARE statement can be followed by the identifier of a prepared SQL statement, associating the cursor with the result set of an INSERT, SELECT, EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement that was prepared dynamically. This feature enables you to associate different SQL statements with the same cursor at different times. In this case, the type of cursor depends on the prepared SQL statement that the *statement\_id* or *statement\_id* variable specifies when the cursor is opened. (For more information, see [Associating a Cursor with a Prepared Statement on page 480](#).)

## Select Cursor or Function Cursor

When an SQL statement returns more than one group of values to the Informix® ESQL/C program, you must declare a cursor to save the multiple groups, or rows, of data and to access these rows one at a time. You must associate one of the following SQL statements with a cursor:

- If you associate a SELECT statement with a cursor, the cursor is called a *Select cursor*.

A Select cursor is a data structure that represents a specific location within the active set of rows that the SELECT statement retrieved.

- If you associate an EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement with a cursor, the cursor is called a *Function cursor*.

The Function cursor represents the columns or values that a user-defined function returns. Function cursors behave the same as Select cursors that are enabled as update cursors.

In Informix®, for compatibility with legacy applications, if an SPL function was created with the CREATE PROCEDURE statement, you can create a Function cursor with the EXECUTE PROCEDURE statement. With external functions, you must use the EXECUTE FUNCTION statement.

When you associate a SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement with a cursor, the statement can include an INTO clause. However, if you prepare the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement, you must omit the INTO clause in the PREPARE statement and use the INTO clause of the FETCH statement to retrieve the values from the Collection cursor.

A Select or Function cursor can scan returned rows of data and to move data row by row into a set of receiving variables, as the following steps describe:

1. DECLARE

Use DECLARE to define a cursor and associate it with a statement.

2. OPEN

Use OPEN to open the cursor. The database server processes the query until it locates or constructs the first row of the active set.

3. FETCH

Use FETCH to retrieve successive rows of data from the cursor.

4. CLOSE

Use CLOSE to close the cursor when its active set is no longer needed.

5. FREE

Use FREE to release the resources that are allocated for the cursor.

## Using the FOR READ ONLY Option

Use the FOR READ ONLY keywords to define a cursor as a read-only cursor. A cursor declared to be read-only cannot be used to update (or delete) any row that it fetches.

The need for the FOR READ ONLY keywords depends on whether your database is ANSI compliant or not ANSI compliant.

In a database that is not ANSI compliant, the cursor that the DECLARE statement defines is a read-only cursor by default, so you do not need to specify the FOR READ ONLY keywords if you want the cursor to be a read-only cursor. The only advantage of specifying the FOR READ ONLY keywords explicitly is for better program documentation.

In an ANSI-compliant database, the cursor associated with a SELECT statement through the DECLARE statement is an update cursor by default, provided that the SELECT statement conforms to all of the restrictions for update cursors listed in [Subset of SELECT statements associated with cursors on page 479](#). If you want a Select cursor to be read-only, you must use the FOR READ ONLY keywords when you declare the cursor.

The database server can use less stringent locking for a read-only cursor than for an update cursor.

The following example creates a read-only cursor:

```
EXEC SQL declare z_curs cursor for
select * from customer_ansi
for read only;
```

## Using the FOR UPDATE Option

Use the FOR UPDATE option to declare an update cursor. You can use the update cursor to modify (update or delete) the current row.

In an ANSI-compliant database, you can use a Select cursor to update or delete data if the cursor was not declared with the FOR READ ONLY keywords and it follows the restrictions on update cursors that are described in [Subset of SELECT statements associated with cursors on page 479](#). You do not need to use the FOR UPDATE keywords when you declare the cursor.

The following example declares an update cursor:

```
EXEC SQL declare new_curs cursor for
select * from customer_notansi
for update;
```

In an update cursor, you can update or delete rows in the active set. After you create an update cursor, you can update or delete the currently selected row by using an UPDATE or DELETE statement with the WHERE CURRENT OF clause. The words CURRENT OF refer to the row that was most recently fetched; they take the place of the usual test expressions in the WHERE clause.

An update cursor lets you perform updates that are not possible with the UPDATE statement because the decision to update and the values of the new data items can be based on the original contents of the row. Your program can evaluate or manipulate the selected data before it decides whether to update. The UPDATE statement cannot interrogate the table that is being updated.

You can specify particular columns that can be updated. The columns need not appear in the Select list of the Projection clause.

## Using FOR UPDATE with a List of Columns

When you declare an update cursor, you can limit the update to specific columns by including the OF keyword and a list of columns. You can modify only those named columns in subsequent UPDATE statements. The columns need not be in the select list of the SELECT clause.

The next example declares an update cursor and specifies that this cursor can update only the **fname** and **lname** columns in the **customer\_notansi** table:

```
EXEC SQL declare name_curs cursor for
  select * from customer_notansi
  for update of fname, lname;
```

By default, unless declared as FOR READ ONLY, a Select cursor in a database that is ANSI compliant is an update cursor, so the FOR UPDATE keywords are optional. If you want an update cursor to be able to modify only some of the columns in a table, however, you must specify these columns in the FOR UPDATE OF *column* list.

The principal advantage to specifying columns is documentation and preventing programming errors. (The database server refuses to update any other columns.) An additional advantage is improved performance, when the SELECT statement meets the following criteria:

- The SELECT statement can be processed using an index.
- The columns that are listed are not part of the index that is used to process the SELECT statement.

If the columns that you intend to update are part of the index that is used to process the SELECT statement, the database server keeps a list of each updated row, to ensure that no row is updated twice. If the OF keyword specifies which columns can be updated, the database server determines whether or not to keep the list of updated rows. If the database server determines that the work of keeping the list is unnecessary, performance improves. If you do not use the OF *column* list, the database server always maintains a list of updated rows, although the list might be unnecessary.

The following example contains Informix® ESQL/C code that uses an update cursor with a DELETE statement to delete the current row.

Whenever the row is deleted, the cursor remains between rows. After you delete data, you must use a FETCH statement to advance the cursor to the next row before you can refer to the cursor in a DELETE or UPDATE statement.

```
EXEC SQL declare q_curs cursor for
  select * from customer where lname matches :last_name for update;

EXEC SQL open q_curs;
for (;;)
{
  EXEC SQL fetch q_curs into :cust_rec;
  if (strncmp(SQLSTATE, "00", 2) != 0)
    break;

  /* Display customer values and prompt for answer */
  printf("\n%s %s", cust_rec.fname, cust_rec.lname);
  printf("\nDelete this customer? ");
  scanf("%s", answer);

  if (answer[0] == 'y')
    EXEC SQL delete from customer where current of q_curs;
  if (strncmp(SQLSTATE, "00", 2) != 0)
    break;
}
printf("\n");
EXEC SQL close q_curs;
```

## Locking with an Update Cursor

The FOR UPDATE keywords notify the database server that updating is possible and cause it to use more stringent locking than with a Select cursor. You declare an update cursor to let the database server know that the program might update (or delete) any row that it fetches as part of the SELECT statement. The update cursor employs *promotable* locks for rows that the program fetches. Other programs can read the locked row, but no other program can place a promotable lock (also called a *write lock*). Before the program modifies the row, the row lock is promoted to an exclusive lock.

It is possible to declare an update cursor with the WITH HOLD keywords, but the only reason to do so is to break a long series of updates into smaller transactions. You must fetch and update a particular row in the same transaction.

If an operation involves fetching and updating a large number of rows, the lock table that the database server maintains can overflow. The usual way to prevent this overflow is to lock the entire table that is being updated. If this action is impossible, an alternative is to update through a hold cursor and to execute COMMIT WORK at frequent intervals. You must plan such an application carefully, however, because COMMIT WORK releases all locks, even those that are placed through a hold cursor.

## Subset of INSERT Statement with a Sequential Cursor

As indicated in the diagram for [DECLARE statement on page 467](#), to create an Insert cursor, you associate a sequential cursor with a restricted form of the INSERT statement. The INSERT statement must include a VALUES clause; it cannot contain an embedded SELECT statement.

The following example contains Informix® ESQL/C code that declares an Insert cursor:

```
EXEC SQL declare ins_cur cursor for
  insert into stock values
  (:stock_no, :manu_code, :descr, :u_price, :unit, :u_desc);
```

The Insert cursor simply inserts rows of data; it cannot be used to fetch data. When an Insert cursor is opened, a buffer is created in memory. The buffer receives rows of data as the program executes PUT statements. The rows are written to disk only when the buffer is full. You can flush the buffer (that is, to write its contents into the database) when it is less than full, using the CLOSE, FLUSH, or COMMIT WORK statements. This topic is discussed further under the CLOSE, FLUSH, and PUT statements.

You must close an Insert cursor to insert any buffered rows into the database before the program ends. You can lose data if you do not close the cursor properly. For a complete description of INSERT syntax and usage, see [INSERT statement on page 638](#).

## Insert Cursor

### About this task

When you associate an INSERT statement with a cursor, the cursor is called an *Insert cursor*. An Insert cursor is a data structure that represents the rows that the INSERT statement is to add to the database. The Insert cursor simply inserts rows of data; it cannot be used to fetch data. To create an Insert cursor, you associate a cursor with a restricted form of the INSERT statement. The INSERT statement must include a VALUES clause; it cannot contain an embedded SELECT statement.

Create an Insert cursor if you want to add multiple rows to the database in an INSERT operation. An Insert cursor allows bulk insert data to be buffered in memory and written to disk when the buffer is full, as these steps describe:

1. Use DECLARE to define an Insert cursor for the INSERT statement.
2. Open the cursor with the OPEN statement. The database server creates the insert buffer in memory and positions the cursor at the first row of the insert buffer.
3. Copy successive rows of data into the insert buffer with the PUT statement.
4. The database server writes the rows to disk only when the buffer is full. You can use the CLOSE, FLUSH, or COMMIT WORK statement to flush the buffer when it is less than full. This topic is discussed further under the PUT and CLOSE statements.
5. Close the cursor with the CLOSE statement when the insert cursor is no longer needed. You must close an Insert cursor to insert any buffered rows into the database before the program ends. You can lose data if you do not close the cursor properly.
6. Free the cursor with the FREE statement. The FREE statement releases the resources that are allocated for an Insert cursor.

Using an Insert cursor is more efficient than embedding the INSERT statement directly. This process reduces communication between the program and the database server and also increases the speed of the insertions.

Insert cursors also have the sequential cursor characteristic. To create an Insert cursor, you associate a sequential cursor with a restricted form of the INSERT statement. (For more information, see [Insert Cursor on page 475.](#)) The following example contains Informix® ESQL/C code that declares a sequential Insert cursor:

```
EXEC SQL declare ins_cur cursor for
insert into stock values
(:stock_no, :manu_code, :descr, :u_price, :unit, :u_desc);
```

## Cursor Characteristics

You can declare a cursor as a *sequential* cursor (the default), a *scroll* cursor (by using the SCROLL keyword), or a *hold* cursor (by using the WITH HOLD keywords). The SCROLL and WITH HOLD keywords are not mutually exclusive. Sections that follow explain these structural characteristics.

A Select or Function cursor can be either a sequential or a scroll cursor. An Insert cursor can only be a sequential cursor. In ESQL/C routines, Select, Function, and Insert cursors can optionally be hold cursors. (In SPL routines, all cursors are sequential cursors, but only Select cursors can be hold cursors.)

## Creating a Sequential Cursor by Default

If you use only the CURSOR keyword, you create a sequential cursor, which can fetch only the next row in sequence from the active set. The sequential cursor can read through the active set only once each time it is opened.

If you are using a sequential cursor for a Select cursor, on each execution of the FETCH statement, the database server returns the contents of the current row and locates the next row in the active set.

The following example creates a read-only sequential cursor in a database that is not ANSI compliant and an update sequential cursor in an ANSI-compliant database:

```
EXEC SQL declare s_cur cursor for
  select fname, lname into :st_fname, :st_lname
  from orders where customer_num = 114;
```

Insert cursors also have the sequential cursor characteristic. To create a Insert cursor, you associate a sequential cursor with a restricted form of the INSERT statement. (For more information, see [Insert Cursor on page 475](#).) The following example declares an Insert cursor:

```
EXEC SQL declare ins_cur cursor for
  insert into stock values
  (:stock_no, :manu_code, :descr, :u_price, :unit, :u_desc);
```

## Using the SCROLL Keyword to Create a Scroll Cursor

Use the SCROLL keyword to create a scroll cursor, which can fetch rows of the active set in any sequence.

The database server retains the active set of the cursor as a temporary table until the cursor is closed. You can fetch the first, last, or any intermediate rows of the active set as well as fetch rows repeatedly without having to close and reopen the cursor. (See FETCH.)

On a multiuser system, the rows in the tables from which the active-set rows were derived might change after the cursor is opened and a copy is made in the temporary table. If you use a scroll cursor within a transaction, you can prevent copied rows from changing either by setting the isolation level to Repeatable Read or by locking the entire table in share mode during the transaction. (See SET ISOLATION and LOCK TABLE.)

The following example creates a scroll cursor for a SELECT statement:

```
DECLARE sc_cur SCROLL CURSOR FOR SELECT * FROM orders;
```

You can create scroll cursors as Select and Function cursors but *not* as Insert cursors. Scroll cursors cannot be declared as FOR UPDATE.

## Using the WITH HOLD keywords to create a hold cursor

Use the `WITH HOLD` keywords to create a *hold cursor*. A hold cursor allows uninterrupted access to a set of rows across multiple transactions.

Ordinarily, all cursors close at the end of a transaction. A hold cursor does not close; it remains open after a transaction ends.

A hold cursor can be either a sequential cursor or (in ESQL/C) a scroll cursor.

The `WITH HOLD` keywords are valid in SPL routines only for Select cursors. For the syntax of the DECLARE statement in SPL routines, see [Declaring a Dynamic Cursor in an SPL Routine on page 484](#).

In ESQL/C, you can use the `WITH HOLD` keywords to declare Select and Function cursors (with the sequential attribute or the scroll attribute) and also to declare Insert cursors. These keywords follow the `CURSOR` keyword in the DECLARE statement. The following example creates a sequential hold cursor for a SELECT statement:

```
DECLARE hld_cur CURSOR WITH HOLD FOR
  SELECT customer_num, lname, city FROM customer;
```

You can use a select hold cursor as the following Informix® ESQL/C code example shows. This code fragment uses a hold cursor as a *master* cursor to scan one set of records and a sequential cursor as a *detail* cursor to point to records that are located in a different table. The records that the master cursor scans are the basis for updating the records to which the detail cursor points. The COMMIT WORK statement at the end of each iteration of the first WHILE loop leaves the hold cursor **c\_master** open but closes the sequential cursor **c\_detail** and releases all locks. This technique minimizes the resources that the database server must devote to locks and unfinished transactions, and it gives other users immediate access to updated rows.

```
EXEC SQL BEGIN DECLARE SECTION;
  int p_custnum, int save_status; long p_orddate;
EXEC SQL END DECLARE SECTION;

EXEC SQL prepare st_1 from
  'select order_date from orders where customer_num = ? for update';
EXEC SQL declare c_detail cursor for st_1;
EXEC SQL declare c_master cursor with hold for
  select customer_num from customer where city = 'Pittsburgh';

EXEC SQL open c_master;
if(SQLCODE==0) /* the open worked */
  EXEC SQL fetch c_master into :p_custnum; /* discover first customer */
while(SQLCODE==0) /* while no errors and not end of pittsburgh customers */
  {
  EXEC SQL begin work; /* start transaction for customer p_custnum */
  EXEC SQL open c_detail using :p_custnum;
  if(SQLCODE==0) /* detail open succeeded */
    EXEC SQL fetch c_detail into :p_orddate; /* get first order */
  while(SQLCODE==0) /* while no errors and not end of orders */
    {
    EXEC SQL update orders set order_date = '08/15/94'
      where current of c_detail;
    if(status==0) /* update was ok */
      EXEC SQL fetch c_detail into :p_orddate; /* next order */
    }
  if(SQLCODE==SQLNOTFOUND) /* correctly updated all found orders */
    EXEC SQL commit work; /* make updates permanent, set status */
  else /* some failure in an update */
    {
    save_status = SQLCODE; /* save error for loop control */
    EXEC SQL rollback work;
    SQLCODE = save_status; /* force loop to end */
    }
  if(SQLCODE==0) /* all updates, and the commit, worked ok */
    EXEC SQL fetch c_master into :p_custnum; /* next customer? */
  }
EXEC SQL close c_master;
```

Use either the CLOSE statement to close the hold cursor explicitly or the CLOSE DATABASE or DISCONNECT statements to close it implicitly. The CLOSE DATABASE statement closes all cursors.

Releases earlier than Version 9.40 of Informix® do not support the PDQPRIORITY feature with cursors that were declared WITH HOLD.

## Using an Insert Cursor with Hold

If you associate a hold cursor with an INSERT statement, you can use transactions to break a long series of PUT statements into smaller sets of PUT statements. Instead of waiting for the PUT statements to fill the buffer and cause an automatic write to the database, you can execute a COMMIT WORK statement to flush the row buffer. With a hold cursor, COMMIT WORK commits the inserted rows but leaves the cursor open for further inserts. This method can be desirable when you are inserting a large number of rows, because pending uncommitted work consumes database server resources.

## Subset of SELECT statements associated with cursors

As indicated in the syntax diagram for the DECLARE statement, not all SELECT statements can be associated with a read-only or update cursor.

If the [DECLARE statement on page 467](#) includes the FOR READ ONLY or FOR UPDATE option, you must observe certain restrictions on the SELECT statement that is included in the DECLARE statement (either directly or as a prepared statement).

If the DECLARE statement includes the FOR READ ONLY option, the SELECT statement cannot have a FOR READ ONLY or FOR UPDATE option. (For a description of SELECT syntax and usage, see [SELECT statement on page 768](#).)

If the DECLARE statement includes the FOR UPDATE option, the SELECT statement must conform to the following restrictions:

- The statement can select data from only one table.
- The statement cannot include any aggregate functions.
- The statement cannot also include the FOR UPDATE keywords.
- The statement cannot include any of the following clauses or keywords: DISTINCT, EXCEPT, FOR READ ONLY, FOR UPDATE, GROUP BY, INTERSECT, INTO TEMP, MINUS, ORDER BY, UNION, or UNIQUE.

## Examples of Cursors in Non-ANSI Compliant Databases

In a database that is not ANSI compliant, a cursor associated with a SELECT statement is a read-only cursor by default. The following example declares a read-only cursor in a non-ANSI compliant database:

```
EXEC SQL declare cust_curs cursor for
select * from customer_notansi;
```

If you want to make it clear in the program code that this cursor is a read-only cursor, specify the FOR READ ONLY option as the following example shows:

```
EXEC SQL declare cust_curs cursor for
select * from customer_notansi for read only;
```

If you want this cursor to be an update cursor, specify the FOR UPDATE option in your DECLARE statement. This example declares an update cursor:

```
EXEC SQL declare new_curs cursor for
select * from customer_notansi for update;
```

If you want an update cursor to be able to modify only some columns in a table, you must specify those columns in the FOR UPDATE clause. The following example declares an update cursor that can update only the **fname** and **lname** columns in the **customer\_notansi** table:

```
EXEC SQL declare name_curs cursor for
select * from customer_notansi for update of fname, lname;
```

## Examples of Cursors in ANSI-Compliant Databases

In an ANSI-compliant database, a cursor associated with a SELECT statement is an update cursor by default.

The following example declares an update cursor in an ANSI-compliant database:

```
EXEC SQL declare x_curs cursor for select * from customer_ansi;
```

To make it clear in the program documentation that this cursor is an update cursor, you can specify the FOR UPDATE option as in this example:

```
EXEC SQL declare x_curs cursor for
select * from customer_ansi for update;
```

If you want an update cursor to be able to modify only some of the columns in a table, you must specify these columns in the FOR UPDATE option. The following example declares an update cursor and specifies that this cursor can update only the **fname** and **lname** columns in the **customer\_ansi** table:

```
EXEC SQL declare y_curs cursor for
select * from customer_ansi for update of fname, lname;
```

If you want a cursor to be a read-only cursor, you must override the default behavior of the DECLARE statement by specifying the FOR READ ONLY option in your DECLARE statement. The following example declares a read-only cursor:

```
EXEC SQL declare z_curs cursor for
select * from customer_ansi for read only;
```

## Associating a Cursor with a Prepared Statement

The PREPARE statement lets you assemble the text of an SQL statement at runtime and pass the statement text to the database server for execution. If you anticipate that a dynamically prepared SELECT, EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement that returns values could produce more than one row of data, the prepared statement must be associated with a cursor. (See PREPARE.)

The result of a PREPARE statement is a statement identifier (*statement id* or *id variable*), which is a data structure that represents the prepared statement text. To declare a cursor for the statement text, associate a cursor with the statement identifier.

You can associate a sequential cursor with any prepared SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement. You cannot associate a scroll cursor with a prepared INSERT statement or with a SELECT statement that was prepared to include a FOR UPDATE clause.

After a cursor is opened, used, and closed, a different statement can be prepared under the same statement identifier. In this way, it is possible to use a single cursor with different statements at different times. The cursor must be redeclared before you use it again.

The following example contains Informix® ESQL/C code that prepares a SELECT statement and declares a sequential cursor for the prepared statement text. The statement identifier **st\_1** is first prepared from a SELECT statement that returns values; then the cursor **c\_detail** is declared for **st\_1**.

```
EXEC SQL prepare st_1 from
  'select order_date
    from orders where customer_num = ?';
EXEC SQL declare c_detail cursor for st_1;
```

If you want to use a prepared SELECT statement to modify data, add a FOR UPDATE clause to the statement text that you want to prepare, as the following Informix® ESQL/C example shows:

```
EXEC SQL prepare sel_1 from
  'select * from customer for update';
EXEC SQL declare sel_curs cursor for sel_1;
```

DDL operations that change the schema of a table can invalidate a cursor whose associated prepared statement or associated routine references the modified table, unless the prepared objects are recompiled, or unless the routine is reoptimized. For more information, see the section [DDL Operations on Tables Referenced by Cursors on page 685](#).

The DECLARE statement allows you to declare a cursor for the Informix® ESQL/C collection variable. Such a cursor is called a *Collection cursor*. You use a collection variable to access the elements of a collection (SET, MULTISSET, LIST) column. Use a cursor when you want to access one or more elements in a collection variable.

The Collection-Derived Table segment identifies the collection variable for which to declare the cursor. For more information, see [Collection-Derived Table on page 1436](#).

## Select with a Collection-Derived Table

The diagram for [DECLARE statement on page 467](#) refers to this section.

To declare a Select cursor for a collection variable, include the Collection-Derived Table segment with the SELECT statement that you associate with the Collection cursor. A Select cursor allows you to select one or more elements *from* the collection variable. (For a description of SELECT syntax and usage, see [SELECT statement on page 768](#).)

When you declare a Select cursor for a collection variable, the DECLARE statement has the following restrictions:

- It cannot include the FOR READ ONLY keywords as cursor mode.
  - The Select cursor is an update cursor.
- It cannot include the SCROLL or WITH HOLD keywords.
  - The Select cursor must be a sequential cursor.

In addition, the SELECT statement that you associate with the collection cursor has the following restrictions:

- It cannot include the following clauses or options: WHERE, GROUP BY, ORDER BY, HAVING, INTO TEMP, and WITH REOPTIMIZATION.
- It cannot contain expressions in the projection list.
- If the collection contains elements of opaque, distinct, built-in, or other collection data types, the projection list must be an asterisk (\*).
- Column names in the projection list must be simple column names, without qualifiers.

These columns cannot use the following syntax:

```
database@server:table.column --INVALID SYNTAX
```

- It *must* specify the name of the collection variable in the FROM clause.

You cannot specify an input parameter (the question-mark (?) symbol) for the collection variable. Likewise, you cannot use the virtual table format of the Collection-Derived Table segment.

## Using a Select Cursor with a Collection Variable

### About this task

A Collection cursor that includes a SELECT statement with the Collection-Derived Table clause provides access to the elements in a collection variable.

To select more than one element:

1. Create a client collection variable in your Informix® ESQL/C program.
2. Declare the Collection cursor for the SELECT statement with the DECLARE statement.  
To modify elements of the collection variable, declare the Select cursor as an update cursor with the FOR UPDATE keywords. You can then use the WHERE CURRENT OF clause of the DELETE and UPDATE statements to delete or update elements of the collection.
3. Open this cursor with the OPEN statement.
4. Fetch the elements from the Collection cursor with the FETCH statement and the INTO clause.
5. If necessary, perform any updates or deletes on the fetched data and save the modified collection variable in the collection column.  
Once the collection variable contains the correct elements, use the UPDATE or INSERT statement to save the contents of the collection variable in the actual collection column (SET, MULTISET, or LIST).
6. Close the Collection cursor with the CLOSE statement.

### Results

This DECLARE statement declares a Select cursor for a collection variable:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection set(integer not null) a_set;
EXEC SQL END DECLARE SECTION;
...
EXEC SQL declare set_curs cursor for select * from table(:a_set);
```

For an extended code example that uses a Collection cursor for a SELECT statement, see [Fetching from a Collection Cursor on page 569](#).

## Insert with a Collection-Derived Table

### About this task

To declare an Insert cursor for a collection variable, include the Collection- Derived Table segment in the INSERT statement associated with the Collection cursor. An Insert cursor can insert one or more elements in the collection. For a description of INSERT syntax and usage, see [INSERT statement on page 638](#).

The Insert cursor must be a sequential cursor. That is, the DECLARE statement cannot specify the SCROLL keyword.

When you declare an Insert cursor for a collection variable, the Collection- Derived Table clause of the INSERT statement *must* contain the name of the collection variable. You cannot specify an input parameter (the question-mark ( ? ) symbol) for the collection variable. However, you can use an input parameter in the VALUES clause of the INSERT statement. This parameter indicates that the collection element is to be provided later by the FROM clause of the PUT statement.

A Collection cursor that includes an INSERT statement with the Collection- Derived Table clause allows you to insert more than one element into a collection variable.

To insert more than one element:

1. Create a client collection variable in your Informix® ESQL/C program.
2. Declare the Collection cursor for the INSERT statement with the DECLARE statement.
3. Open the cursor with the OPEN statement.
4. Put the elements into the Collection cursor with the PUT statement and the FROM clause.
5. Once the collection variable contains all the elements, use the UPDATE statement or the INSERT statement on a table name to save the contents of the collection variable in a collection column (SET, MULTISET, or LIST).
6. Close the Collection cursor with the CLOSE statement.

### Results

This example declares an Insert cursor for the **a\_set** collection variable:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection multiset(smallint not null) a_mset;
    int an_element;
EXEC SQL END DECLARE SECTION;
...
EXEC SQL declare mset_curs cursor for
    insert into table(:a_mset) values (?);
EXEC SQL open mset_curs;
while (1)
{
    ...
    EXEC SQL put mset_curs from :an_element;
    ...
}
```

To insert the elements into the collection variable, use the PUT statement with the FROM clause. For a code example that uses a Collection cursor for an INSERT statement, see [Inserting into a Collection Cursor on page 705](#).

## Using Cursors with Transactions

To roll back a modification, you must perform the modification within a transaction. A transaction in a database that is not ANSI compliant begins only when the `BEGIN WORK` statement is executed.

In an ANSI-compliant database, transactions are always in effect.

The database server enforces these guidelines for select and update cursors to ensure that modifications can be committed or rolled back properly:

- Open an insert or update cursor within a transaction.
- Include `PUT` and `FLUSH` statements within one transaction.
- Modify data (update, insert, or delete) within one transaction.

The database server lets you open and close a hold cursor for an update outside a transaction; however, you should fetch all the rows that pertain to a given modification and then perform the modification all within a single transaction. You cannot open and close a hold cursor or an update cursor outside a transaction.

The following example uses an update cursor within a transaction:

```
EXEC SQL declare q_curs cursor for
  select customer_num, fname, lname from customer
  where lname matches :last_name for update;
EXEC SQL open q_curs;
EXEC SQL begin work;
EXEC SQL fetch q_curs into :cust_rec; /* fetch after begin */
EXEC SQL update customer set lname = 'Smith'
  where current of q_curs;
/* no error */
EXEC SQL commit work;
```

When you update a row within a transaction, the row remains locked until the cursor is closed or the transaction is committed or rolled back. If you update a row when no transaction is in effect, the row lock is released when the modified row is written to disk. If you update or delete a row outside a transaction, you cannot roll back the operation.

In a database that uses transactions, you cannot open an Insert cursor outside a transaction unless it was also declared with the `WITH HOLD` keywords.

## Declaring a Dynamic Cursor in an SPL Routine

Use the `DECLARE` statement in an SPL routine to declare the name of a dynamic cursor, and to associate that cursor with the statement identifier of a prepared statement that the `PREPARE` statement has declared in the same SPL routine.

Dynamic cursors that the `DECLARE` statement of SQL can create in SPL routines are distinct from the direct sequential cursors that the `FOREACH` statement of SPL can create in SPL routines. (For the syntax and usage of direct sequential cursors, see [FOREACH on page 1107](#).)

### Syntax

The syntax of the `DECLARE` statement in SPL routines is a subset of the syntax that `DECLARE` supports in Informix® ESQL/C routines.

**DECLARE** *cursor\_id*

<sup>248</sup> **WITH HOLD**

**FOR** *statement\_id*

| Element             | Description                                   | Restrictions   | Syntax                                  |
|---------------------|---|--|---|
| <i>cursor_id</i>    | Name declared here for a new dynamic cursor   | Must be unique among names of cursors, prepared statements, and SPL variables in the routine | <a href="#">Identifier on page 1456</a> |
| <i>statement_id</i> | Identifier of a single prepared SQL statement | Must have been declared in a PREPARE statement of the same SPL routine                       | <a href="#">Identifier on page 1456</a> |

### Usage

In UDRs written in the SPL language, the *statement\_id* associated with the cursor must have been declared earlier in the same UDR by a PREPARE statement from the text of a single SQL statement of one of these statement types:

- EXECUTE FUNCTION
- EXECUTE PROCEDURE
- SELECT.

This prepared statement text that *statement\_id* specifies can include question mark ( ? ) symbols as placeholders for values that the user supplies at runtime, but these placeholders in the PREPARE statement can represent only data values, not SQL identifiers.

Dynamic cursors that the DECLARE statement can define in SPL routines resemble ESQL/C Select cursors or Function cursors in their functionality, but with these restrictions:

- Cursors that DECLARE defines in an SPL routine can be Select cursors or Function cursors, but they cannot be Insert cursors nor Collection cursors.
- The identifier of the cursor or of the prepared statement cannot be specified as an SPL variable, because in SPL, the identifiers of variables, cursors, and prepared objects all share the same namespace.
- By default, dynamic cursors of SPL are sequential. They cannot be scroll cursors.
- The semantics of dynamic cursors that you create with the WITH HOLD keywords are the same as for hold cursors that the FOREACH statement declares.
- The WITH HOLD keywords are valid in SPL routines only for Select cursors. If *statement\_id* references the prepared text of an EXECUTE FUNCTION or EXECUTE PROCEDURE statement, the DECLARE statement fails with error -26056.
- The FOR UPDATE and FOR READ ONLY keywords that ESQL/C supports in DECLARE statements are not supported in SPL routines. Use the FOREACH statement of SPL to declare direct cursors that can emulate the functionality of ESQL/C update cursors. (But queries associated with direct cursors are defined when the UDR is compiled, rather than at runtime.)

- The DECLARE statement in SPL routines does not support SELECT operations on collection-derived tables.
- Syntax errors in DECLARE statements of SPL routines are reported at runtime, unlike syntax errors of ESQL/C, which are reported when the routine is compiled.

The names of the dynamic cursors that the DECLARE statement associates with a prepared statement in SPL routines can be referenced by the OPEN, CLOSE, FETCH, and FREE statements of dynamic SQL in the same SPL routine.

In the following program fragment, a cursor called **equi\_noctis** is declared, opened, closed, and freed.

```
CREATE FUNCTION lente
  DEFINE first, last VARCHAR(30);
  . . .
  DATABASE stores_demo;
  LET first = "SELECT * FROM state";
  LET lsst = "WHERE code < ?";
  PREPARE stmt_1 FROM first || last;
  DECLARE equi_noctis FOR stmt_1;
  OPEN equi_noctis
  . . .
  CLOSE equi_noctis;
  FREE equi_noctis;
  FREE stmt_1;
  . . .
  END FUNCTION;
```

## DELETE statement

Use the DELETE statement to delete one or more rows from a table, or to delete one or more elements from a collection variable of SPL or of Informix® ESQL/C.

**Syntax****DELETE**

249

Optimizer Directives<sup>253</sup>**FROM**

249

*table view synonym***AS** *alias*<sup>251</sup>

249

**ONLY(***table synonym*)<sup>250</sup>Collection-Derived Table<sup>254</sup>

249

**WHERE***condition*<sup>255</sup>

252

**WHERE CURRENT OF** *cursor\_id*

256

| Element                     | Description   | Restrictions  | Syntax  |
|-----------------------------|---|---|---|
| <i>alias</i>                | Temporary name declared here for a table, view, or synonym. | The AS keyword must precede <i>alias</i> if WHERE is the identifier of <i>alias</i>                     | <a href="#">Identifier on page 1456</a>           |
| <i>condition</i>            | Logical criteria that deleted rows must satisfy             | Cannot be a UDR nor a correlated subquery   | <a href="#">Condition on page 1144</a>            |
| <i>cursor_id</i>            | Previously declared cursor                                  | Must have been declared FOR UPDATE  | <a href="#">Identifier on page 1456</a>           |
| <i>synonym, table, view</i> | Synonym, table, or updatable view with rows to be deleted   | The <i>table</i> or <i>view</i> (or <i>synonym</i> and the table or view to which it points) must exist | <a href="#">Database Object Name on page 1450</a> |

**Usage**

Use the DELETE statement to remove any of the following types of database objects or program objects:

249. Informix® extension

250. See [Using the ONLY keyword with typed tables on page 489](#)

251. See [Declaring an alias for the table on page 492](#)

252. ESQL/C and Stored Procedure Language only

253. See [Optimizer Directives on page 1472](#)

254. See [Collection-Derived Table on page 1436](#)

255. See [Using the WHERE Keyword to Specify a Condition on page 491](#)

256. See [Using the WHERE CURRENT OF Keywords \(ESQL/C, SPL\) on page 492](#)

- A row in a table or in a view: a single row, a group of rows, or all rows
- An element in a column of a collection data type
- In a column of a named or unnamed ROW data type, a field, or all fields.

You can also use this statement to remove the values in one or more elements in Informix® ESQL/C or SPL collection variables or ROW variables.

To execute the DELETE statement, you must hold the DBA access privilege on the database, or the Delete access privilege on the table.

If you specify a *view* name, the view must be updatable. For an explanation of an updatable view, see [Updating Through Views on page 458](#).

The DELETE statement cannot reference table objects that the CREATE EXTERNAL TABLE statement defined.

In a database with explicit transaction logging, any DELETE statement that you execute outside a transaction is treated as a single transaction.

In an ANSI-compliant database, data manipulation language (DML) statements are always in a transaction. You cannot execute a DELETE statement outside a transaction.

## FROM clause

The `FROM` keyword that precedes the name of the target table is optional. To delete rows from a table named `from`, you can set the `DELIMIT` environment variable and use double quotation marks ( `"` ) to delimit `"from"`:

```
DELETE "from";
```

Alternatively, you can qualify the name of the `from` table with the name of its owner:

```
DELETE zelaine.from;
```

Your SQL code will be easier for humans to read and to maintain, however, if you avoid declaring SQL keywords as identifiers of tables, views, or other database objects.

## WHERE clause

If you use DELETE without a WHERE clause (to specify either a condition or the active set of the cursor), all rows in the table are deleted:

```
DELETE FROM tableZ;
```

It is typically more efficient, however, to use the TRUNCATE statement, rather than the DELETE statement, to remove all rows from a table.

In DB-Access, if you omit the WHERE clause while working at the SQL menu, DB-Access prompts you to verify that you want to delete all rows from a table. You do not receive a prompt if you execute DELETE within a command file.

## Locking considerations

The database server locks each row affected by a DELETE statement within a transaction for the duration of the transaction. The locking granularity of the table can be PAGE level or ROW level.

Features that determine the locking granularity have this ascending order of precedence:

- The DEF\_TABLE\_LOCKMODE configuration parameter can set the default granularity for table locks to PAGE or to ROW.
- If the IFX\_TABLE\_LOCKMODE environment variable is set to PAGE or ROW, its setting overrides any DEF\_TABLE\_LOCKMODE default.
- The LOCK MODE clause of the CREATE TABLE statement overrides any default locking granularity for the new table.
- The LOCK MODE clause of the ALTER TABLE statement can reset the locking granularity to PAGE or to ROW for a table, overriding any of the settings above.
- The LOCK TABLE statement always locks the entire table, overriding any locking granularity specification listed above for the specified table.

When the locking granularity of the table is ROW, the database server acquires one lock for each row affected by the DELETE statement.

If the number of rows affected is very large, and the lock mode is ROW, you might exceed the limits that your operating system places on the maximum number of simultaneous locks. If this occurs, you can either reduce the scope of the DELETE statement, or you can use LOCK TABLE statement to lock the table in exclusive mode before you execute the DELETE statement.

## Using the ONLY keyword with typed tables

When the DELETE statement specifies a supertable, any qualifying rows that satisfy the WHERE clause are also deleted, by default, from all the subtables of the supertable within the table hierarchy. To restrict the scope of DELETE to the supertable, you must specify the `ONLY` keyword before the name or synonym of the supertable.

In the following example, any rows whose name column has the value **johnson** will be deleted from the **super\_tab** supertable. Any rows with **johnson** in their name column will persist, however, in the subtables of **super\_tab**, because the `ONLY ( )` clause restricts the DELETE operation to that supertable:

```
DELETE FROM ONLY(super_tab) -- scope excludes child tables
WHERE name = "johnson";
```

**Warning:** If you use the DELETE statement on a supertable and omit the ONLY keyword and the WHERE clause, all rows of the supertable and of all its subtables are deleted, as in the following example.

```
DELETE FROM super_tab; -- deletes all rows in the hierarchy
```

You cannot specify the ONLY keyword if you plan to use the WHERE CURRENT OF clause to delete the current row of the active set of a cursor.

## Considerations When Tables Have Cascading Deletes

When you use the ON DELETE CASCADE option of the REFERENCES clause of either the CREATE TABLE or ALTER TABLE statement, you specify that you want deletes to cascade from one table to another. For example, in the **stores\_demo** database, the **stock** table contains the column **stock\_num** as a primary key. The **catalog** and **items** tables each contain the column **stock\_num** as foreign keys with the ON DELETE CASCADE option specified. When a delete is performed from the **stock** table, rows are also deleted in the **catalog** and **items** tables, which are referenced through the foreign keys.

To have DELETE actions cascade to a table that has a referential constraint on a parent table, you need the Delete privilege only on the parent table that you reference in the DELETE statement.

If a DELETE operation with no WHERE clause is performed on a table that one or more child tables reference with cascading deletes, Informix® deletes all rows from that table and from any affected child tables. (This resembles the effect of the TRUNCATE statement, but Informix® does not support TRUNCATE operations on any table that has a child table referencing it.)

For an example of how to create a referential constraint that uses cascading deletes, see [Using the ON DELETE CASCADE Option on page 360](#).

## Restrictions on DELETE When Tables Have Cascading Deletes

You cannot use a child table in a correlated subquery to delete a row from a parent table. If two child tables reference the same parent table, and one child specifies cascading deletes but the other child does not, then if you attempt to delete a row that applies to both child tables from the parent table, the delete fails, and no rows are deleted from the parent or child tables.

## Locking and Logging Implications of Cascading Deletes

During deletes, the database server places locks on all qualifying rows of the referenced and referencing tables.

Informix® requires transaction logging for cascading deletes. If logging is turned off in a database that is not ANSI-compliant, even temporarily, deletes do not cascade, because you cannot roll back any actions. For example, if a parent row

is deleted, but the system fails before the child rows are deleted, the database will have dangling child records, in violation of referential integrity. After logging is turned back on, however, subsequent deletes cascade.

## Using the WHERE Keyword to Specify a Condition

Use the WHERE *condition* clause to specify which rows you want to delete from the table. The *condition* after the WHERE keyword is equivalent to the *condition* in the SELECT or UPDATE statement. For example, the next statement deletes all the rows of the **items** table where the order number is less than 1034:

```
DELETE FROM items WHERE order_num < 1034;
```

In DB-Access, if you include a WHERE clause that selects all rows in the table, DB-Access gives no prompt and deletes all rows.

If you are deleting from a supertable in a table hierarchy, a subquery in the WHERE clause cannot reference a subtable.

When deleting from a subtable, a subquery in the WHERE clause can reference the supertable only in SELECT FROM ONLY (*supertable*)... syntax.

## Subqueries in the WHERE Clause of DELETE

The FROM clause of a subquery in the WHERE clause of the DELETE statement can specify as a data source the same table or view that the FROM clause of the DELETE statement specifies. DELETE operations with subqueries that reference the same table object are supported only if all of the following conditions are true:

- The subquery either returns a single row, or else has no correlated column references.
- The subquery is in the DELETE statement WHERE clause, using Condition with Subquery syntax.
- Any SPL routines within the subquery cannot reference the table that is being modified.

Unless all of these conditions are satisfied, DELETE statements that include subqueries that reference the same table or view that the DELETE statement modifies return error -360.

The following example deletes from the **orders** table a subset of rows whose **paid\_date** column value satisfies the condition in the WHERE clause. The WHERE clause specifies which rows to delete by applying the IN operator to the rows returned by a subquery that selects only the rows of the **orders** table where the **paid\_date** value is earlier than the current date:

```
DELETE FROM orders WHERE paid_date IN
(SELECT paid_date FROM orders WHERE paid_date < CURRENT );
```

This subquery includes only uncorrelated column references, because its only referenced column is in a table specified in its FROM clause. The requirements listed above are in effect, because the data source of the subquery is the same orders table that the FROM clause of the outer UPDATE statement specifies. The previous example illustrates Informix® support for uncorrelated subqueries in the WHERE clause of the DELETE statement. rather than how to write short SQL statements. The next example achieves the same result with simpler syntax:

```
DELETE orders WHERE paid_date < CURRENT;
```

The following example deletes from the **stock** table the row (or rows) with the largest **unit\_price** value. The WHERE clause identifies which **unit\_price** value is the largest by applying the equality operator to the result of a subquery that calls the built-in **MAX** aggregate function for the **unit\_price** column values:

```
DELETE FROM stock WHERE unit_price =
(SELECT MAX(unit_price) FROM stock );
```

If an enabled Select trigger is defined on a table that is the data source of a subquery in the WHERE clause of a DELETE statement that modifies the same table, executing that subquery within the DELETE statement does not activate the trigger.

A subquery in the DELETE statement can include the UNION or UNION ALL operators.

If the table that the outer DELETE statement modifies a typed table within a table hierarchy, Informix® supports all of the following operations that use valid subqueries in the WHERE clause of DELETE:

- DELETE from parent table with subquery ( SELECT from parent table )
- DELETE from parent table with subquery ( SELECT from child table )
- DELETE from child table with subquery ( SELECT from parent table )
- DELETE from child table with subquery ( SELECT from child table ).

See the [Condition with Subquery on page 1158](#) topic for more information about the syntax of subqueries to return multiple rows as predicates in the WHERE clause of the DELETE statement.

## Declaring an alias for the table

You can declare an alias for the table. The alias can reference the fully-qualified database object name of a local or remote table, view, or synonym.

The alias is a temporary name that is not registered in the system catalog of the database, and that persists only while the DELETE statement is running.

If the name that you declare as the alias is the keyword WHERE, you must use the AS keyword to clarify the syntax:

```
DELETE stock AS where
WHERE manu_code =
(SELECT manu_code FROM where WHERE manu_code MATCHES 'H*');
```

Because **where** is a keyword of both the DELETE and SELECT statements, the previous example is not easy to read. The following example accesses a remote table without declaring an alias for the table:

```
DELETE overstock@cleveland:stock AS ocs
WHERE manu_code =
(SELECT manu_code FROM overstock@cleveland:stock
WHERE manu_code MATCHES 'H*');
;
```

The next example is logically equivalent to the previous DELETE statement, but simplifies the notation by declaring **ocs** as alias that references the same table in the subquery"

```
DELETE overstock@cleveland:stock AS ocs
WHERE manu_code =
(SELECT manu_code FROM ocs WHERE manu_code MATCHES 'H*');
;
```

## Using the WHERE CURRENT OF Keywords (ESQL/C, SPL)

The WHERE CURRENT OF clause deletes the current row of the active set of a cursor. When you include this clause, the DELETE statement removes the row of the active set at the current position of the cursor. After the deletion, no current row exists; you cannot use the cursor to delete or update a row until you reposition the cursor with a FETCH statement (in ESQL/C routines) or with a FOREACH statement (in SPL routines).

You access the current row of the active set of a cursor with an update cursor. Before you can use the WHERE CURRENT OF clause, you must first create an update cursor by using the FOREACH statement (in SPL) or the DECLARE statement with the FOR UPDATE clause (in Informix® ESQL/C). The *cursor\_id* that follows the OF keyword cannot be declared, however, by the DECLARE statement in an SPL routine

Unless they are declared with the FOR READ ONLY keywords, all Select cursors are potentially update cursors in an ANSI-compliant database. You can use the WHERE CURRENT OF clause with any Select cursor that was not declared with the FOR READ ONLY keywords.

You cannot use WHERE CURRENT OF if you are selecting from only one table in a table hierarchy. That is, this clause is not valid with the ONLY keyword.

The WHERE CURRENT OF clause can be used to delete an element from a collection by deleting the current row of the collection-derived table that a collection variable holds. For more information, see [Collection-Derived Table on page 1436](#).

## Deleting Rows That Contain Opaque Data Types

Some opaque data types require special processing when they are deleted. For example, if an opaque data type contains spatial or multirepresentational data, it might provide a choice of how to store the data: inside the internal structure or, for large objects, in a smart large object.

To accomplish this process, call a user-defined support function called **destroy()**. When you use DELETE to remove a row that contains one of these opaque types, the database server automatically invokes **destroy()** for the opaque type. This function decides how to remove the data, regardless of where it is stored. For more information on the **destroy()** support function, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Deleting Rows That Contain Collection Data Types

When a row contains a column that is a collection data type (LIST, MULTISSET, or SET), you can search for a particular element in the collection, and delete the row or rows in which the element is found.

For example, the following statement deletes any rows from the **new\_tab** table in which the **set\_col** column contains the element `jimmy smith`:

```
DELETE FROM new_tab WHERE 'jimmy smith' IN set_col;
```

You can also use a collection variable to delete values in a collection column by deleting one or more individual elements in a collection. For more information, see [Collection-Derived Table on page 1436](#) and the examples in [Database Name on page 1449](#) and [Example of Deleting from a Collection on page 1446](#).

## Data Types in Distributed DELETE Operations

Distributed DELETE operations across tables in databases of different server instances can return only a subset of the data types that distributed DELETE operations can return from tables that are all in databases of the same Informix® instance.

A DELETE statement (or any other SQL data-manipulation language statement) that accesses a database of another Informix® instance can reference only the following data types:

- Built-in data types that are not opaque or complex
- BOOLEAN
- BSON
- JSON
- LVARCHAR
- DISTINCT of built-in types that are not opaque
- DISTINCT of BOOLEAN
- DISTINCT of BSON
- DISTINCT of JSON
- DISTINCT of LVARCHAR
- DISTINCT of the DISTINCT types in this list.

Cross-server distributed DELETE operations can support these DISTINCT types only if the DISTINCT types are cast explicitly to built-in types, and all of the DISTINCT types, their data type hierarchies, and their casts are defined exactly the same way in each participating database.

Cross-server DML operations cannot reference a column or expression of a complex, large-object, nor user-defined opaque data type (UDT), nor of an unsupported DISTINCT type or built-in opaque type. For additional information about the data types that Informix® supports in cross-server DML operations, see [Data Types in Cross-Server Transactions on page 781](#).

Distributed operations that access other databases of the local Informix® instance, however, can access the same data types that are listed above for cross-server operations, and also the following additional data types:

- Most of the *built-in opaque data types*, as listed in [Data Types in Cross-Database Transactions on page 779](#)
- DISTINCT of the built-in types that are referenced in the line above
- DISTINCT of any of the data types that are listed in either of the two lines above
- Opaque user-defined data types (UDTs) that can be cast explicitly to built-in data types.

Cross-database DELETE operations can support these DISTINCT and opaque UDTs only if all the opaque and DISTINCT UDTs are cast explicitly to built-in types, and all of the opaque UDTs, DISTINCT types, data type hierarchies, and casts are defined exactly the same way in each of the participating databases.

Distributed DELETE statements cannot access a database of another Informix® instance unless both server instances support either a TCP/IP or an IPCSTR connection, as defined in their DBSERVERNAME or DBSERVERALIASES configuration parameters and in the **sqlhosts** information. This connection-type requirement applies to any communication between Informix® instances, even if both database servers reside on the same computer.

## SQLSTATE Values in an ANSI-Compliant Database

If no rows satisfy the WHERE clause of a DELETE operation on a table in an ANSI-compliant database, the database server issues a warning. You can detect this warning condition in either of the following ways:

- The GET DIAGNOSTICS statement sets the **RETURNED\_SQLSTATE** field to the value `02000`. In an SQL API application, the **SQLSTATE** variable contains this same value.
- In an SQL API application, the **sqlca.sqlcode** and **SQLCODE** variables contain the value `100`.

The database server also sets **SQLSTATE** and **SQLCODE** to these values if the DELETE . . . WHERE statement is part of a multistatement prepared object, and the database server returns no rows.

## SQLSTATE Values in a Database That Is Not ANSI-Compliant

In a database that is not ANSI compliant, the database server does not return a warning when it finds no rows satisfying the WHERE clause of a DELETE statement. In this case, the **SQLSTATE** code is `00000` and the **SQLCODE** code is zero (0). If the DELETE . . . WHERE is part of a multistatement prepared object, however, and no rows are returned, the database server does issue a warning. It sets **SQLSTATE** to `02000` and sets the **SQLCODE** value to `100`.

For information on the ANSI/ISO-compliance status of values returned to the **SQLSTATE** variable, see the section [SQLSTATE Support for the ANSI/ISO Standard for SQL on page 582](#).

## DESCRIBE statement

Use the DESCRIBE statement to obtain information about output parameters and other features of a prepared object before you execute it.

Use this statement with Informix® ESQL/C. (See also [DESCRIBE INPUT statement on page 500](#).)

### Syntax

#### DESCRIBE

#### OUTPUT

*statement\_id\_var statement\_id*

#### USING SQL DESCRIPTOR

*descriptor\_var 'descriptor'*

#### INTO

#### SQL DESCRIPTOR

*descriptor\_var 'descriptor'*

*sqlda\_pointer*

| Element           | Description                      | Restrictions                                     | Syntax                                     |
|-------------------|----------------------------------|--|--|
| <i>descriptor</i> | Name of a system-descriptor area | System-descriptor area must already be allocated | <a href="#">Quoted String on page 1424</a> |

| Element                 | Description  | Restrictions   | Syntax  |
|-------------------------|--|--|---|
| <i>descriptor_var</i>   | Host variable specifying a system-descriptor area            | Must contain the name of an allocated system-descriptor area   | Language-specific rules for names   |
| <i>sqlda_pointer</i>    | Pointer to an <b>sqlda</b> structure                         | Cannot begin with dollar ( \$ ) sign or colon ( : ). An <b>sqlda</b> structure is required if dynamic SQL is used. | See the <b>sqlda</b> structure in the <i>Informix® ESQL/C Programmer's Manual</i>       |
| <i>statement_id</i>     | Statement identifier for a prepared SQL statement            | Must be defined in a previous PREPARE statement  | <a href="#">PREPARE statement on page 687</a> ; <a href="#">Identifier on page 1456</a> |
| <i>statement_id_var</i> | Host variable that contains the value of <i>statement_id</i> | Must be declared in a previous PREPARE statement   | Language-specific rules for names   |

## Usage

DESCRIBE can provide information at runtime about a prepared statement:

- The type of SQL statement that was prepared
- Whether an UPDATE or DELETE statement contains a WHERE clause
- For an EXECUTE, EXECUTE FUNCTION, EXECUTE PROCEDURE, INSERT, SELECT, or UPDATE statement, the DESCRIBE statement also returns the number, data types, and size of the output parameter values.
- For a SELECT statement, DESCRIBE also returns the name of the column or expression that the query returns.

With this information, you can write code to allocate memory to hold retrieved values and display or process them after they are fetched.

## The OUTPUT Keyword

The OUTPUT keyword specifies that only information about output parameters of the prepared statement are stored in the **sqllda** descriptor area. If you omit this keyword, DESCRIBE can return input parameters, but only for INSERT statements (and for UPDATE, if the **IFX\_UPDDESC** environment variable is set in the environment where the database server is initialized).

## Describing the Statement Type

The DESCRIBE statement takes a statement identifier from a PREPARE statement as input. When the DESCRIBE statement executes, the database server sets the value of the SQLCODE field of the **sqlca** to indicate the statement type (that is, the keyword with which the statement begins). If the prepared statement text contains more than one SQL statement, the DESCRIBE statement returns the type of the first statement in the text.

SQLCODE is set to zero to indicate a SELECT statement *without* an INTO TEMP clause. This situation is the most common. For any other SQL statement, SQLCODE is set to a positive integer. You can test the number against the constant names that are defined. In Informix® ESQL/C, the constant names are defined in the **sqlstypes.h** header file.

The DESCRIBE statement (and the DESCRIBE INPUT statement) use the SQLCODE field differently from any other statement, possibly returning a nonzero value when it executes successfully. You can revise standard error-checking routines to accommodate this behavior, if desired.

## Checking for the Existence of a WHERE Clause

If the DESCRIBE statement detects that a prepared statement contains an UPDATE or DELETE statement without a WHERE clause, the DESCRIBE statement sets the **sqlca.sqlwarn.sqlwarn4** variable to **w**.

When you do not specify a WHERE clause in either a DELETE or UPDATE statement, the database server performs the delete or update operation on the entire table. Check the **sqlca.sqlwarn.sqlwarn4** variable to avoid unintended global changes to your table.

## Describing a Statement with Runtime Parameters

If the prepared statement contains parameters for which the number of parameters or parameter data types is to be supplied at runtime, you can describe these input values. If the prepared statement text includes one of the following statements, the DESCRIBE statement returns a description of each column or expression that is included in the list:

- EXECUTE FUNCTION (or EXECUTE PROCEDURE)
- INSERT
- SELECT (without an INTO TEMP clause)

- UPDATE

In Informix®, the **IFX\_UPDDESC** environment variable, as described in the *Informix® Guide to SQL: Reference*, must be set before you can use DESCRIBE to obtain information about an UPDATE statement.

The description includes the following information:

- The data type of the column, as defined in the table
- The length of the column, in bytes
- The name of the column or expression

For a prepared INSERT or UPDATE statement, DESCRIBE returns only the dynamic parameters (those expressed with a question mark (?) symbol). Using the OUTPUT keyword, however, prevents these from being returned.

You can specify a destination for the returned information as a new or existing system-descriptor area, or as a pointer to an **sqlda** structure.

A system-descriptor area conforms to the X/Open standards.

---

## Using the SQL DESCRIPTOR Keywords

Use the USING SQL DESCRIPTOR clause to store the description of a prepared statement list in a previously allocated system-descriptor area.

Use the INTO SQL DESCRIPTOR clause to create a new system-descriptor structure and store the description of a statement list in that structure.

To describe one of the previously mentioned statements into a system-descriptor area, DESCRIBE updates the system-descriptor area in these ways:

- It sets the COUNT field in the system-descriptor area to the number of values in the statement list. An error results if COUNT is greater than the number of item descriptors in the system-descriptor area.
- It sets the TYPE, LENGTH, NAME, SCALE, PRECISION, and NULLABLE fields in the system-descriptor area.

If the column has an opaque data type, the database server sets the EXTTYPEID, EXTYPENAME, EXTYPELENGTH, EXTTYPEOWNERLENGTH, and EXTTYPEOWNERNAME fields of the item descriptor.

- It allocates memory for the DATA field for each item descriptor, based on the TYPE and LENGTH information.

After a DESCRIBE statement is executed, the SCALE and PRECISION fields contain the scale and precision of the column, respectively. If SCALE and PRECISION are set in the SET DESCRIPTOR statement, and TYPE is set to DECIMAL or MONEY, the LENGTH field is modified to adjust for the scale and precision of the decimal value. If TYPE is not set to DECIMAL or MONEY, the values for SCALE and PRECISION are not set, and LENGTH is unaffected.

You must modify system-descriptor-area information with SET DESCRIPTOR statements to show the address in memory that is to receive the described value. You can change the data type to another compatible type. This change causes data conversion to take place when data values are fetched.

You can use the system-descriptor area in prepared statements that support a USING SQL DESCRIPTOR clause, such as EXECUTE, FETCH, OPEN, and PUT.

The following examples show the use of a system descriptor in a DESCRIBE statement. In the first example, the system descriptor is a quoted string; in the second example, it is an embedded variable name.

```
main()
{
  . . .
  EXEC SQL allocate descriptor 'desc1' with max 3;
  EXEC SQL prepare curs1 FROM 'select * from tab';
  EXEC SQL describe curs1 using sql descriptor 'desc1';
}
EXEC SQL describe curs1 using sql descriptor :desc1var;
```

## Using the INTO sqllda Pointer Clause

Use the INTO *sqllda\_pointer* clause to allocate memory for an **sqllda** structure and store its address in an **sqllda** pointer. The DESCRIBE statement fills in the allocated memory with descriptive information. Unlike the USING clause, the INTO clause creates new **sqllda** structures to store the output from DESCRIBE.

The DESCRIBE statement sets the **sqllda.sqlld** field to the number of values in the statement list. The **sqllda** structure also contains an array of data descriptors (**sqlvar** structures), one for each value in the statement list. After a DESCRIBE statement is executed, the **sqllda.sqlvar** structure has the **sqltype**, **sqllen**, and **sqlname** fields set.

If the column has an opaque data type, DESCRIBE...INTO sets the **sqlxid**, **sqltypename**, **sqltypelen**, **sqlownerlen**, and **sqlownername** fields of the item descriptor.

The DESCRIBE statement allocates memory for an **sqllda** pointer once it is declared in a program. The application program, however, must designate the storage area of the **sqllda.sqlvar.sqldata** fields.

## Describing a Collection Variable

The DESCRIBE statement can provide information about a collection variable when you use the USING SQL DESCRIPTOR or INTO clause. You must issue the DESCRIBE statement *after* you open the Select or Insert cursor, because the OPEN...USING statement specifies the name of the collection variable to use.

The next Informix® ESQL/C code fragment dynamically selects the elements of the **:a\_set** collection variable into a system-descriptor area called **desc1**:

```
EXEC SQL BEGIN DECLARE SECTION;
  client collection a_set;
  int i, set_count;
  int element_type, element_value;
EXEC SQL END DECLARE SECTION;

EXEC SQL allocate collection :a_set;
EXEC SQL allocate descriptor 'desc1';
EXEC SQL select set_col into :a_set from table1;
EXEC SQL prepare set_id from 'select * from table(?)'

EXEC SQL declare set_curs cursor for set_id;
```

```

EXEC SQL open set_curs using :a_set;
EXEC SQL describe set_id using sql descriptor 'desc1';

do
{
    EXEC SQL fetch set_curs using sql descriptor 'desc1';
    ...
    EXEC SQL get descriptor 'desc1' :set_count = count;
    for (i = 1; i <= set_count; i++)
    {
        EXEC SQL get descriptor 'desc1' value :i
            :element_type = TYPE;
        switch
        {
            case SQLINTEGER:
                EXEC SQL get descriptor 'desc1' value :i
                    :element_value = data;
                ...
            } /* end switch */
        } /* end for */
    } while (SQLCODE == 0);

EXEC SQL close set_curs;
EXEC SQL free set_curs;
EXEC SQL free set_id;
EXEC SQL deallocate collection :a_set;
EXEC SQL deallocate descriptor 'desc1';

```

## DESCRIBE INPUT statement

Use the DESCRIBE INPUT statement to return input parameter information before a prepared statement is executed.

Use this statement with ESQL/C.

### Syntax

#### DESCRIBE INPUT

*statement\_var statement\_id*

#### USINGSQL DESCRIPTOR

*'descriptor' descriptor\_var*

#### INTO

#### SQL DESCRIPTOR

*'descriptor' descriptor\_var*

<sup>257</sup> *sqlda\_pointer*

| Element           | Description                      | Restrictions                                     | Syntax                                     |
|-------------------|----------------------------------|--|--|

257. Informix® extension

| Element               | Description  | Restrictions   | Syntax  |
|-----------------------|--|--|---|
| <i>descriptor_var</i> | Host variable specifying a system-descriptor area            | Must contain the name of an allocated system-descriptor area   | Language-specific rules for names   |
| <i>sqlda_pointer</i>  | Pointer to an <b>sqlda</b> structure                         | Cannot begin with dollar ( \$ ) sign or colon ( : ). An <b>sqlda</b> structure is required if dynamic SQL is used. | See the <b>sqlda</b> structure in the <i>Informix® ESQ/C Programmer's Manual</i> .  |
| <i>statement_id</i>   | Statement identifier for a prepared SQL statement            | Must be defined in a previously executed PREPARE statement   | <a href="#">PREPARE statement on page 687</a> ; <a href="#">PREPARE statement on page 687</a> ; <a href="#">Identifier on page 1456</a> |
| <i>statement_var</i>  | Host variable that contains the value of <i>statement_id</i> | Variable and <i>statement_id</i> both must be declared   | Language-specific rules for names   |

## Usage

The DESCRIBE INPUT and the DESCRIBE OUTPUT statements can return information about a prepared statement to an SQL Descriptor Area (**sqlda**):

- For a SELECT, EXECUTE FUNCTION (or PROCEDURE), INSERT, or UPDATE statement, the DESCRIBE statement (with no INPUT keyword) returns the number, data types, and size of the returned values, and the name of the column or expression.
- For a SELECT, EXECUTE FUNCTION, EXECUTE PROCEDURE, DELETE, INSERT, or UPDATE statement, the DESCRIBE INPUT statement returns all the input parameters of a prepared statement.

**Tip:** Informix® versions earlier than 9.40 do not support the *INPUT* keyword. For compatibility with legacy applications, *DESCRIBE* without *INPUT* is supported. In new applications, you should use DESCRIBE INPUT statements to provide information about dynamic parameters in the WHERE clause, in subqueries, and in other syntactic contexts where the old form of DESCRIBE cannot provide information.

With this information, you can write code to allocate memory to hold retrieved values that you can display or process after they are fetched.

The **IFX\_UPDDESC** environment variable does not need to be set before you can use DESCRIBE INPUT to obtain information about an UPDATE statement.

## Describing the Statement Type

This statement takes a statement identifier from a PREPARE statement as input. After DESCRIBE INPUT executes, the SQLCODE field of the **sqlca** indicates the statement type (that is, the keyword with which the statement begins). If a prepared object contains more than one SQL statement, DESCRIBE INPUT returns the type of the first statement in the prepared text.

SQLCODE is set to zero to indicate a SELECT statement *without* an INTO TEMP clause. This situation is the most common. For any other SQL statement, SQLCODE is set to a positive integer. You can compare the number with the named constants that are defined in the **sqlstypes.h** header file.

The DESCRIBE and DESCRIBE INPUT statements use SQLCODE differently from other statements, under some circumstances returning a nonzero value after successful execution. You can revise standard error-checking routines to accommodate this behavior, if desired.

## Checking for Existence of a WHERE Clause

If the DESCRIBE INPUT statement detects that a prepared object contains an UPDATE or DELETE statement without a WHERE clause, the database server sets the **sqlca.sqlwarn.sqlwarn4** variable to **w**.

When you do not specify a WHERE clause in either a DELETE or UPDATE statement, the database server performs the delete or update action on the entire table. Check the **sqlca.sqlwarn.sqlwarn4** variable after DESCRIBE INPUT executes to avoid unintended global changes to your table.

## Describing a Statement with Dynamic Runtime Parameters

If the prepared statement specifies a set of parameters whose cardinality or data types must be supplied at runtime, you can describe these input values. If the prepared statement text includes one of the following statements, the DESCRIBE INPUT statement returns a description of each column or expression that is included in the list:

- EXECUTE FUNCTION (or EXECUTE PROCEDURE)
- INSERT or SELECT
- UPDATE or DELETE

The description includes the following information:

- The data type of the column, as defined in the table
- The length of the column, in bytes
- The name of the column or expression
- Information about *dynamic parameters* (parameters that are expressed as question ( ? ) mark symbols within the prepared statement)

If the database server cannot infer the data type of an expression parameter, the DESCRIBE INPUT statement returns SQLUNKNOWN as the data type.

You can specify a destination for the returned information as a new or existing system-descriptor area, or as a pointer to an **sqlda** structure.

## Using the SQL DESCRIPTOR Keywords

Specify INTO SQL DESCRIPTOR to create a new system-descriptor structure and store the description of a prepared statement list in that structure.

Use the USING SQL DESCRIPTOR clause to store the description of a prepared statement list in a previously allocated system-descriptor area. Executing the DESCRIBE INPUT . . . USING SQL DESCRIPTOR statement updates an existing system-descriptor area in the following ways:

- It allocates memory for the DATA field for each item descriptor, based on the TYPE and LENGTH information.
- It sets the COUNT field in the system-descriptor area to the number of values in the statement list. An error results if COUNT is greater than the number of item descriptors in the system-descriptor area.
- It sets the TYPE, LENGTH, NAME, SCALE, PRECISION, and NULLABLE fields in the system-descriptor area.

For columns of opaque data types, the DESCRIBE INPUT statement sets the EXTTYPEID, EXTYPENAME, EXTYPELENGTH, EXTYPEOWNERLENGTH, and EXTYPEOWNERNAME fields of the item descriptor.

After a DESCRIBE INPUT statement executes, the SCALE and PRECISION fields contain the scale and precision of the column, respectively. If SCALE and PRECISION are set in the SET DESCRIPTOR statement, and TYPE is set to DECIMAL or MONEY, the LENGTH field is modified to adjust for the decimal scale and precision. If TYPE is not set to DECIMAL or MONEY, the values for SCALE and PRECISION are not set, and LENGTH is unaffected.

You must modify the system-descriptor-area information with the SET DESCRIPTOR statement to specify the address in memory that is to receive the described value. You can change the data type to another compatible type. This causes data conversion to take place when the data values are fetched.

You can also use the system-descriptor area in other statements that support a USING SQL DESCRIPTOR clause, such as EXECUTE, FETCH, OPEN, and PUT.

The following examples show the use of a system descriptor in a DESCRIBE statement. In the first example, the system descriptor is a quoted string; in the second example, it is an embedded variable name.

```
main()
{
. . .
EXEC SQL allocate descriptor 'desc1' with max 3;
```

```
EXEC SQL prepare curs1 FROM 'select * from tab';
EXEC SQL describe curs1 using sql descriptor 'desc1';
}
EXEC SQL describe curs1 using sql descriptor :desc1var;
```

A system-descriptor area conforms to the X/Open standards.

## Using the INTO sqllda Pointer Clause

The INTO *sqllda\_pointer* clause allocates memory for an **sqllda** structure and store its address in an **sqllda** pointer. The DESCRIBE INPUT statement fills in the allocated memory with descriptive information.

The DESCRIBE INPUT statement sets the **sqllda.sqlld** field to the number of values in the statement list. The **sqllda** structure also contains an array of data descriptors (**sqlvar** structures), one for each value in the statement list. After a DESCRIBE statement is executed, the **sqllda.sqlvar** structure has the **sqltype**, **sqllen**, and **sqlname** fields set.

If the column has an opaque data type, DESCRIBE INPUT . . . INTO sets the **sqlxid**, **sqltypename**, **sqltypelen**, **sqlownerlen**, and **sqlownername** fields of the item descriptor.

The DESCRIBE INPUT statement allocates memory for an **sqllda** pointer once it is declared in a program. The application program, however, must designate the storage area of the **sqllda.sqlvar.sqlldata** fields.

## Describing a Collection Variable

The DESCRIBE INPUT statement can provide information about a collection variable if you use the INTO or USING SQL DESCRIPTOR clause.

You must execute the DESCRIBE INPUT statement *after* you open the Select or Insert cursor. Otherwise, DESCRIBE INPUT cannot get information about the collection variable because it is the OPEN . . . USING statement that specifies the name of the collection variable to use.

The next Informix® ESQL/C program fragment dynamically selects the elements of the **:a\_set** collection variable into a system-descriptor area called **desc1**:

```
EXEC SQL BEGIN DECLARE SECTION;
    client collection a_set;
    int i, set_count;
    int element_type, element_value;
EXEC SQL END DECLARE SECTION;

EXEC SQL allocate collection :a_set;
EXEC SQL allocate descriptor 'desc1';
EXEC SQL select set_col into :a_set from table1;
EXEC SQL prepare set_id from
    'select * from table(?)';

EXEC SQL declare set_curs cursor for set_id;
EXEC SQL open set_curs using :a_set;
EXEC SQL describe set_id using sql descriptor 'desc1';do
{
    EXEC SQL fetch set_curs using sql descriptor 'desc1';
    ...
}
```

```

EXEC SQL get descriptor 'desc1' :set_count = count;
for (i = 1; i <= set_count; i++)
{
    EXEC SQL get descriptor 'desc1' value :i
        :element_type = TYPE;
    switch
    {
        case SQLINTEGER:
            EXEC SQL get descriptor 'desc1' value :i
                :element_value = data;
            ...
        } /* end switch */
    } /* end for */
} while (SQLCODE == 0);

EXEC SQL close set_curs;
EXEC SQL free set_curs;
EXEC SQL free set_id;
EXEC SQL deallocate collection :a_set;
EXEC SQL deallocate descriptor 'desc1';

```

## DISCONNECT statement

Use the DISCONNECT statement to terminate a connection between an application and a database server.

### Syntax

#### DISCONNECT

#### CURRENT

258

#### ALL DEFAULT

*'connection' connection\_var*

| Element               | Description                                       | Restrictions  | Syntax                                     |
|-----------------------|---|---|--|
| <i>connection</i>     | String that specifies a connection to terminate   | Connection name that the CONNECT statement assigned | <a href="#">Quoted String on page 1424</a> |
| <i>connection_var</i> | Host variable that holds the name of a connection | Must be a fixed-length character data type          | Language specific                          |

### Usage

DISCONNECT terminates a connection to a database server. If a database is open, it closes before the connection drops. Even if you made a connection to a specific database only, the connection to the database server is terminated by DISCONNECT. If DISCONNECT does not terminate the current connection, the connection context of the current environment is not changed.

DISCONNECT is not valid as statement text in a PREPARE statement.

258. ESQL/C only

In ESQL/C, if you disconnect with *connection* or *connection\_var*, DISCONNECT generates an error if the specified connection is not a current or dormant connection.

---

#### Related reference

[DROP DATABASE statement on page 510](#)

[CONNECT statement on page 185](#)

[DATABASE statement on page 461](#)

[SET CONNECTION statement on page 865](#)

[CLOSE DATABASE statement on page 182](#)

## DEFAULT Option

DISCONNECT DEFAULT disconnects the default connection.

The *default connection* is one of the following connections:

- A connection established by the CONNECT TO DEFAULT statement
- An implicit default connection established by the DATABASE or CREATE DATABASE statement

You can use DISCONNECT to drop the default connection. If the DATABASE statement does not specify a database server, as in the following example, the default connection is made to the default database server:

```
EXEC SQL database 'stores_demo';  
. . .  
EXEC SQL disconnect default;
```

If the DATABASE statement specifies a database server, as the following example shows, the default connection is made to that database server:

```
EXEC SQL database 'stores_demo@mydbsrvr';  
. . .  
EXEC SQL disconnect default;
```

In either case, the DEFAULT option of DISCONNECT disconnects this default connection. For more information, see [The DEFAULT Connection Specification on page 191](#).

## Specifying the CURRENT Keyword

The DISCONNECT CURRENT statement terminates the current connection. For example, the DISCONNECT statement in the following program fragment terminates the current connection to the database server **mydbsrvr**:

```
CONNECT TO 'stores_demo@mydbsrvr';  
. . .  
DISCONNECT CURRENT;
```

## When a Transaction is Active

DISCONNECT generates an error during a transaction. The transaction remains active, and the application must explicitly commit it or roll it back. If an application terminates without issuing DISCONNECT (because of a system failure or program error, for example), active transactions are rolled back.

In an ANSI-compliant database, however, if no error is encountered while you exit from DB-Access in non-interactive mode without issuing the CLOSE DATABASE, COMMIT WORK, or DISCONNECT statement, the database server automatically commits any open transaction.

## Disconnecting in a Thread-Safe Environment

If you issue the DISCONNECT statement in a thread-safe Informix® ESQL/C application, keep in mind that an active connection can be disconnected only from within the thread in which it is active. Therefore, one thread cannot disconnect the active connection of another thread. The DISCONNECT statement generates an error if such an attempt is made.

Once a connection becomes dormant, however, any other thread can disconnect it unless an ongoing transaction is associated with the dormant connection that was established with the WITH CONCURRENT TRANSACTION clause of CONNECT. If the dormant connection was not established with the WITH CONCURRENT TRANSACTION clause, DISCONNECT generates an error when it tries to disconnect the connection.

For an explanation of connections in a thread-safe Informix® ESQL/C application, see [SET CONNECTION statement on page 865](#).

## Specifying the ALL Option

Use the keyword ALL to terminate all connections established by the application up to that time. For example, the following DISCONNECT statement disconnects the current connection as well as all dormant connections:

```
DISCONNECT ALL;
```

In Informix® ESQL/C, the ALL keyword has the same effect on multithreaded applications that it has on single-threaded applications. Execution of the DISCONNECT ALL statement causes all connections in all threads to be terminated. However, the DISCONNECT ALL statement fails if any of the connections is in use or has an ongoing transaction associated with it. If either of these conditions is true, none of the connections is disconnected.

## DROP ACCESS\_METHOD statement

Use the DROP ACCESS\_METHOD statement to remove a previously defined primary or secondary access method from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP****ACCESS\_METHODIF EXISTS***access\_method***RESTRICT**

| Element              | Description                   | Restrictions   | Syntax                                  |
|----------------------|-------------------------------|--|---|
| <i>access_method</i> | Name of access method to drop | Must be registered in <b>sysams</b> system catalog table; cannot be a built-in access method | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>         | Owner of the access method    | Must own the access method   | <a href="#">Owner name on page 1488</a> |

**Usage**

The RESTRICT keyword is required. You cannot drop an access method if virtual tables or indexes exist that use the access method. You must be the owner of the access method or have DBA privileges to drop an access method.

If a transaction is in progress, the database server waits to drop the access method until the transaction is committed or rolled back. No other users can execute the access method until the transaction has completed.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no access method of the specified name is registered in the current database.

**Example**

For this example, suppose that an access method was created by this statement:

```
CREATE SECONDARY ACCESS_METHOD T_tree
(
  am_getnext = ttree_getnext,
  am_unique,
  am_cluster,
  am_sptype = 'S'
);
```

The following statement drops this access method:

```
DROP ACCESS_METHOD T_tree RESTRICT;
```

Details of existing access methods can be found in the **sysams** system catalog table with the following query:

```
SELECT am_name FROM informix.sysams;
```

**Related reference**

[ALTER ACCESS\\_METHOD statement on page 20](#)

[CREATE ACCESS\\_METHOD statement on page 193](#)

[GRANT statement on page 592](#)

**Related information**

[Specifying RESTRICT Mode on page 533](#)

**DROP AGGREGATE statement**

Use the DROP AGGREGATE statement to drop a user-defined aggregate that you created with the CREATE AGGREGATE statement.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP AGGREGATEIF EXISTS**

*owner* .

*aggregate*

| Element          | Description                                      | Restrictions  | Syntax                                  |
|------------------|--|---|---|
| <i>aggregate</i> | Name of the user-defined aggregate to be dropped | Must have been previously created with the CREATE AGGREGATE statement | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>     | Owner of the aggregate                           | Must own the aggregate  | <a href="#">Owner name on page 1488</a> |

**Usage**

Dropping a user-defined aggregate does not drop the support functions that you defined for the aggregate in the CREATE AGGREGATE statement. The database server does not track dependency of SQL statements on user-defined aggregates that you use in the statements. For example, you can drop a user-defined aggregate that is used in an SPL routine.

The following example drops the user-defined aggregate named **my\_avg**:

```
DROP AGGREGATE my_avg;
```

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no aggregate with the specified name is registered in the current database.

**Related reference**

[CREATE AGGREGATE statement on page 195](#)

**DROP CAST statement**

Use the DROP CAST statement to remove an existing cast from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

## Syntax

### DROP CAST IF EXISTS

(*source\_type* AS *target\_type* )

| Element            | Description                              | Restrictions | Syntax   |
|--------------------|--|--------------|--|
| <i>source_type</i> | Data type that the cast accepts as input | Must exist   | <a href="#">Identifier on page 1456</a> ; <a href="#">Data Type on page 1163</a> |
| <i>target_type</i> | Data type returned by the cast           | Must exist   | <a href="#">Identifier on page 1456</a> ; <a href="#">Data Type on page 1163</a> |

## Usage

You must be owner of the cast or have the DBA privilege to use DROP CAST. Dropping a cast removes its definition from the **syscasts** system catalog table, so the cast cannot be invoked explicitly or implicitly. Dropping a cast has no effect on the user-defined function associated with the cast. Use the DROP FUNCTION statement to remove the user-defined function from the database.

**Warning:** Do not drop built-in casts, which user **informix** owns. These are required for automatic conversions between built-in data types.

A cast defined on a given data type can also be used on any DISTINCT types created from that source type. If you drop the cast, you can no longer invoke it for the DISTINCT types, but dropping a cast that is defined for a DISTINCT type has no effect on casts for its source type. When you create a DISTINCT type, the database server automatically defines an explicit cast from the DISTINCT type to its source type and another explicit cast from the source type to the DISTINCT type. When you drop the DISTINCT type, the database server automatically drops these two casts.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an error to the application) if no cast between the two specified data types is registered in the current database.

## Example

A cast (like this one in the **superstores\_demo** database) can be dropped with the DROP CAST statement:

```
DROP CAST (decimal(5,5) AS percent);
```

Details of existing casts can be found in the **syscasts** system catalog table the following SQL:

```
SELECT routine_name, class, argument_type, result_type FROM Syscasts;
```

### Related reference

[CREATE CAST statement on page 198](#)

[DROP FUNCTION statement on page 512](#)

## DROP DATABASE statement

Use the DROP DATABASE statement to delete an entire database, including all system catalog tables, objects, and data.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP DATABASE IF EXISTS

Database Name<sup>259</sup>

### Usage

The DROP DATABASE statement is an extension to the ANSI/ISO standard, which does not provide syntax for the destruction of a database.

The following statement drops the **stores\_demo** database:

```
DROP DATABASE IF EXISTS stores_demo;
```

You must have the DBA privilege or be user **informix** to run the DROP DATABASE statement successfully. Otherwise, the database server issues an error message and does not drop the database.

### Restrictions on the DROP DATABASE statement

You cannot drop the current database or a database that is currently being used by another user. All the current users of the database must first execute the CLOSE DATABASE statement before DROP DATABASE can be successful.

You cannot drop a tenant database with the DROP DATABASE statement. You must drop a tenant database by running the admin() or task() SQL administration API function with the tenant drop argument.

The DROP DATABASE statement attempts to create an implicit connection to the database that you intend to drop. If a previous CONNECT statement has established an explicit connection to another database, and that connection is still your current connection, the DROP DATABASE statement fails with error -1811. In this case, you must first use the DISCONNECT statement to close the explicit connection before you can execute the DROP DATABASE statement.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than returning an error to the application) if no database of the specified name is managed by the database server instance to which you are connected.

The DROP DATABASE statement cannot appear in a multistatement PREPARE statement, nor within an SPL routine.

In a DROP DATABASE operation, the database server acquires a lock on each table in the database and holds the locks until the entire operation is complete. Configure your database server with enough locks to accommodate this fact.

For example, if the database to be dropped has 2500 tables, but fewer than 2500 locks were configured for your database server, the DROP DATABASE statement fails. For more information on how to configure the number of locks available to the database server, see the discussion of the LOCKS configuration parameter in your .

In DB-Access, use the DROP DATABASE statement with caution. DB-Access does not prompt you to verify that you want to delete the entire database.

259. See [Database Name](#) on page 1449

In ESQL/C, you can use an unqualified database name in a program or host variable, or you can specify the fully-qualified *database@server* format. For example, the following statement drops the **stores\_demo** database of a database server called **gibson95**:

```
EXEC SQL DROP DATABASE stores_demo@gibson95;
```

If this statement executes successfully, the **gibson95** database server instance continues to exist, but the **stores\_demo** database of that database server no longer exists. For more information, see [Database Name on page 1449](#).

[CONNECT statement on page 185](#)

[DATABASE statement on page 461](#)

[DISCONNECT statement on page 505](#)

[DROP TABLE statement on page 531](#)

## DROP FUNCTION statement

Use the DROP FUNCTION statement to remove a user-defined function from the database. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP FUNCTIONIF EXISTS

*owner* .

*function*

(  
 , *parameter\_type*  
 )

#### SPECIFIC FUNCTIONIF EXISTS

Specific Name<sup>260</sup>

| Element               | Description                                     | Restrictions  | Syntax                                  |
|-----------------------|---|---|---|
| <i>function</i>       | Name of the user-defined function to be dropped | Must exist (that is, be registered) in the database. If the name does not uniquely identify a function, you must enter one or more appropriate values for <i>parameter_type</i> . | <a href="#">Identifier on page 1456</a> |
| <i>parameter_type</i> | Data type of the parameter                      | The data type (or list of data types) must be the same data types (and specified in the same order) as in the   | <a href="#">Data Type on page 1163</a>  |

260. See [Specific Name on page 1521](#)

| Element | Description | Restrictions   | Syntax |
|---------|-------------|--|--------|
|         |             | CREATE FUNCTION statement that registered the function |        |

## Usage

Dropping a user-defined function removes the text and executable versions of the function from the database. (Make sure to keep a copy of the function text somewhere outside the database, in case you need to re-create a function after it is dropped.)

If you do not know whether a UDR is a function or a procedure, you can drop it by using the DROP ROUTINE statement.

To use the DROP FUNCTION statement, you must be the owner of the user-defined function (and hold the Resource privilege on the database) or have the DBA privilege. You must also hold the Usage privilege on the programming language in which the UDR is written. To drop an external user-defined function, see also [Dropping an External Routine on page 524](#).

You cannot use the DROP ROUTINE, DROP FUNCTION, or DROP PROCEDURE statement to drop a protected routine. For more information about protected routines, see the description of the **sysprocedures** system catalog table in the *Informix® Guide to SQL: Reference*.

You cannot drop an SPL function from within the same SPL function.

Informix® can resolve a function by its *specific name*, if the function definition declared a specific name. If you use the specific name in this statement, you must also use the keyword SPECIFIC, as in the following example:

```
DROP SPECIFIC FUNCTION compare_point;
```

Otherwise, if the *function* name is not unique within the database, you must specify enough *parameter\_type* information to disambiguate the name. If you use parameter data types to identify a user-defined function, they follow the function name, as in the following example:

```
DROP FUNCTION compare (int, int);
```

But the database server returns an error if it cannot resolve an ambiguous function name whose signature differs from that of another function only in an unnamed ROW-type parameter. (This error cannot be anticipated by the database server when the ambiguous *function* is defined.)

If you include the optional IF EXISTS keywords, the database server takes no action (rather than issue an error) if the database server cannot find in the current database any function that matches what your DROP FUNCTION statement specifies.

## Determine whether a function exists

Before you attempt to drop a user-defined function, you can check for its existence in the database by querying the system catalog. In the following example, the SELECT statement retrieves from the **sysprocedures** table any routines whose identifier is `MyFunction`:

```
SELECT * FROM sysprocedures WHERE procname = MyFunction;
```

If this query returns a single row, then a UDR called `MyFunction` is registered in the current database.

If this query returns no rows, you do not need to issue the DROP FUNCTION statement, but you might wish to verify that the WHERE clause specified the correct name, and that you are connected to the correct database.

If the query returns more than one row, then the routine name `MyFunction` is overloaded in the current database, and you need to examine the attributes of the `MyFunction` routines to determine which of them, if any, need to be unregistered by the `DROP FUNCTION` statement.

## Examples

Most functions can be dropped using SQL statements similar to the following:

```
DROP FUNCTION best_month;
```

If you have more than one function with the same name, however, by using function overloading, the `DROP FUNCTION` statement must either specify the specific name of the function (if it has one), or the parameter list to uniquely identify it. For example, the **superstores\_demo** database has two **last\_contact** functions that were created with the following arguments:

```
CREATE FUNCTION last_contact(cust_name name_t) ...
```

and

```
CREATE FUNCTION last_contact(c_num INT) ...
```

To drop the second of these functions, use the following:

```
DROP FUNCTION last_contact(INT);
```

If the above functions had been created with the specific names **last\_cname\_contact** and **last\_cnum\_contact**, then to drop the second of these, issue the following statement:

```
DROP SPECIFIC FUNCTION last_cnum_contact;
```

Details of existing functions can be found in the **sysprocedures** system catalog table using SQL queries like the following:

```
SELECT procname, specificname, paramtypes
       FROM sysprocedures ;
```

## Dropping External Functions

A user-defined function (UDF) written in C language or in the Java™ language is called an *external function*. External functions must include the External Routine Reference clause that specifies a shared-object filename. By default, only users to whom the DBSA has granted the built-in EXTEND role can create or drop an external function. You must also hold the Usage privilege on the external programming language in which the UDF is written. See the section [Granting the EXTEND Role on page 612](#) for additional information about the EXTEND role security feature. See the section [Language-Level Privileges on page 607](#) for the syntax of the USAGE ON LANGUAGE clause for the C language or for the Java™ language.

To remove the executable version of a C language routine from shared memory, call the **IFX\_UNLOAD\_MODULE** function. To replace the executable version of a C routine with another routine, call the **IFX\_REPLACE\_MODULE** function. Both of these built-in functions are described in UDR Definition Routines.

## DROP INDEX statement

Use the DROP INDEX statement to remove an index.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP INDEX IF EXISTS

*owner* .

*index*

**ONLINE**

| Element      | Description                     | Restrictions               | Syntax                                  |
|--------------|---------------------------------|----------------------------|---|
| <i>index</i> | Name of the index to be dropped | Must exist in the database | <a href="#">Identifier on page 1456</a> |
| <i>owner</i> | Name of index owner             | Must own the index         | <a href="#">Owner name on page 1488</a> |

### Usage

In a typical online transaction processing (OLTP) environment, concurrent applications are connected to the database server to perform DML operations. For every query, the optimizer chooses a plan that is based on existing indexes, distribution statistics, and directives. After numerous OLTP transactions, however, the chosen plan might no longer be the best plan for query execution. In this case, dropping an inefficient index can sometimes improve performance.

You must be the owner of the *index* or have the DBA privilege to use the DROP INDEX statement. The following example drops the index **o\_num\_ix** that **joed** owns. The **stores\_demo** database must be the current database:

```
DROP INDEX stores_demo:joed.o_num_ix;
```

You cannot use the DROP INDEX statement to drop a unique constraint, nor to drop an index that supports a constraint; you must use the ALTER TABLE . . . DROP CONSTRAINT statement to drop the constraint. When you drop the constraint, the database server automatically drops any index that exists solely to support that constraint. If you attempt to use

DROP INDEX to drop an index that is shared by a unique constraint, the database server renames the specified index in the **sysindexes** system catalog table, declaring a new name in this format:

```
[space]<tabid>_<constraint_id>
```

Here *tabid* and *constraint\_id* are from the **sysindexes** and **sysconstraints** system catalog tables, respectively. The **sysconstraints.idxname** column is then updated to something like: " 121\_13" (where quotation marks show the leading blank space). If this index is a unique index with only referential constraints sharing it, the index is downgraded to a duplicate index after it is renamed.

In some contexts, an alternative to the DROP INDEX statement is the SET Database Object Mode statement, which can disable a specified index without removing it from the system catalog. For more information about this SQL statement, which can also enable an index that is currently disabled, see [SET Database Object Mode statement on page 871](#).

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no index of the specified name is registered in the current database.

## Example

An index such as the one found in the *stores\_demo* database can be dropped with:

```
DROP INDEX zip_ix;
```

If necessary, you can specify the index name as the fully qualified four-part object name (*database@instance:owner.indexname*), as in the following:

```
DROP INDEX stores_demo@prod:"informix".zip_ix ;
```

Details of existing functions can be found in the *sysprocedures* system catalog table, as in the following:

```
SELECT idxname FROM sysindexes ;
```

---

[DROP OPCLASS statement on page 517](#)

## The ONLINE keyword of DROP INDEX

For indexes that were not defined with the IN TABLE keyword option, the DBA can reduce the risk of nonexclusive access errors, and can increase the availability of the indexed table, by including the ONLINE keyword as the last specification of the DROP INDEX statement. The ONLINE keyword instructs the database server to drop the index while minimizing the duration of an exclusive lock, so that the index can be dropped while concurrent users are accessing the table.

By default, DROP INDEX attempts to place an exclusive lock on the indexed table to prevent all other users from accessing the table while the index is being dropped. The DROP INDEX statement fails if another user already has a lock on the table, or is currently accessing the table at the Dirty Read isolation level.

After you issue the DROP INDEX ONLINE statement, the query optimizer does not consider using the specified index in subsequent query plans or cost estimates, and the database server does not support any other DDL operations on the indexed table, until after the specified index has been dropped. Query operations that were initiated prior to the DROP INDEX ONLINE statement, however, can continue to access the index until the queries are completed.

When no other users are accessing the index, the database server drops the index, and the DROP INDEX ONLINE statement terminates execution.

By default, the DROP INDEX ONLINE statement does not wait indefinitely for locks to be released. If one or more concurrent sessions hold locks on the table, the statement might fail with error -216 or -113 unless you first issue the SET LOCK MODE TO WAIT statement to specify an indefinite wait. Otherwise, DROP INDEX ONLINE uses the waiting period for locks that the DEADLOCK\_TIMEOUT configuration parameter specifies, or that a previous SET LOCK MODE statement specified. To avoid locking errors, execute SET LOCK MODE TO WAIT (with no specified limit) before you attempt to drop an index online.

You cannot use the CREATE INDEX statement to declare a new index that has the same identifier until after the specified index has been dropped. No more than one CREATE INDEX ONLINE or DROP INDEX ONLINE statement can concurrently reference indexes on the same table.

The indexed table in a DROP INDEX ONLINE statement can be permanent or temporary, logged or unlogged, and fragmented or non-fragmented. You cannot specify the ONLINE keyword, however, when you are dropping an index that has any of the following attributes:

- a functional index
- a clustered index
- a virtual index
- an R-tree index.

The following statement instructs the database server to drop online an index called **idx\_01**:

```
DROP INDEX IF EXISTS idx_01 ONLINE;
```

For indexes defined with the IN TABLE keyword option, however, the indexed table remains locked for the duration of the DROP INDEX ONLINE operation. While the in-table index is being dropped, attempted access by other sessions to the locked table would fail with one or more of these errors:

```
107: ISAM error: record is locked.
211: Cannot read system catalog (systables).
710: Table (table.tix) has been dropped, altered or renamed.
```

## DROP OPCLASS statement

Use the DROP OPCLASS statement to remove an existing operator class from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP OPCLASSIF EXISTS***owner* .*opclass***RESTRICT**

| Element        | Description                          | Restrictions  | Syntax                                  |
|----------------|--------------------------------------|---|---|
| <i>opclass</i> | Name of operator class to be dropped | Must have been created by a previous CREATE OPCLASS statement | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>   | Name of opclass owner                | Must own the operator class                                   | <a href="#">Owner name on page 1488</a> |

**Usage**

You must be the owner of the operator class or have the DBA privilege to use the DROP OPCLASS statement.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no operator class of the specified name is registered in the current database.

The RESTRICT keyword causes DROP OPCLASS to fail if the database contains indexes defined on the operator class that you plan to drop. Therefore, before you drop the operator class, you must use the DROP INDEX statement to drop any dependent indexes.

The following DROP OPCLASS statement drops an operator class called **abs\_btree\_ops**:

```
DROP OPCLASS abs_btree_ops RESTRICT
```

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no function of the specified name (or of the specified specific name, if you include the SPECIFIC keyword) is registered in the current database.

**Related reference**

[CREATE OPCLASS statement on page 286](#)

[DROP INDEX statement on page 515](#)

**DROP PROCEDURE statement**

Use the DROP PROCEDURE statement to drop a user-defined procedure from the database. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP****PROCEDUREIF EXISTS***owner* .*procedure*<sup>261</sup>*function*

(

, *parameter\_type*

)

**SPECIFIC PROCEDUREIF EXISTS**Specific Name<sup>262</sup>

| Element               | Description                                 | Restrictions   | Syntax   |
|-----------------------|---|--|--|
| <i>function</i>       | Name of a procedure or SPL function to drop | Must exist (that is, be registered) in the database  | <a href="#">Identifier on page 1456</a>  |
| <i>owner</i>          | Name of UDR owner                           | Must own the procedure or SPL function   | <a href="#">Owner name on page 1488</a>  |
| <i>parameter_type</i> | The data type of the parameter              | The data type (or list of data types) must be the same types (and in the same order) as those specified when the procedure was created | <a href="#">Identifier on page 1456;</a><br><a href="#">Data Type on page 1163</a> |
| <i>procedure</i>      | Name of user-defined procedure to drop      | Must exist (that is, be registered) in the database  | <a href="#">Database Object Name on page 1450</a>                                  |

**Usage**

Dropping a user-defined procedure removes the text and executable version of the procedure from the database. You cannot drop an SPL procedure within the same SPL procedure.

You cannot use the DROP ROUTINE, DROP FUNCTION, or DROP PROCEDURE statement to drop a protected routine. For more information about protected routines, see the description of the **sysprocedures** system catalog table in the *Informix® Guide to SQL: Reference*.

To use the DROP PROCEDURE statement, you must be the owner of the procedure and also hold the Resource privilege on the database, or have the DBA privilege. You must also hold the Usage privilege on the programming language in which the UDR is written. To drop an external user-defined procedure, see also [Dropping an External Procedure on page 520](#).

If the *function* or *procedure* name is not unique within the database, you must specify enough *parameter\_type* information to disambiguate the name. If the database server cannot resolve an ambiguous UDR name whose signature differs from that of

261. Informix®-SPL language only

262. See [Specific Name on page 1521](#)

another UDR only in an unnamed ROW type parameter, an error is returned. (This error cannot be anticipated by the database server when the ambiguous *function* or *procedure* is defined.)

If you do not know whether a UDR is a user-defined procedure or a user-defined function, you can use the DROP ROUTINE statement. For more information, see [DROP ROUTINE statement on page 522](#).

For compatibility with earlier Informix® versions, you can use this statement to drop an SPL function that CREATE PROCEDURE created. You can include parameter data types after the name of the procedure to identify the procedure:

```
DROP PROCEDURE compare(int, int);
```

If you use the specific name for the user-defined procedure, you must also use the keyword SPECIFIC, as in the following example:

```
DROP SPECIFIC PROCEDURE compare_point;
```

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no procedure of the specified name is registered in the current database.

### Determine whether a procedure exists

Before you attempt to drop a user-defined procedure, you can check for its existence in the database by querying the system catalog. In the following example, the SELECT statement retrieves from the **sysprocedures** table any routines whose identifier is `MyProcedure`:

```
SELECT * FROM sysprocedures WHERE procname = MyProcedure;
```

If this query returns a single row, then a UDR called `MyProcedure` is registered in the current database.

If this query returns no rows, you do not need to issue the DROP PROCEDURE statement, but you might wish to verify that the WHERE clause specified the correct name, and that you are connected to the correct database.

If the query returns more than one row, then the routine name `MyProcedure` is overloaded in the current database, and you need to examine the attributes of the `MyProcedure` routines to determine which of them, if any, need to be unregistered by the DROP PROCEDURE statement.

## Dropping an External Procedure

A user-defined procedure (UDP) written in C language or in the Java™ language is called an *external routine*. External routines must include the External Routine Reference clause that specifies a shared-object filename. By default, only users to whom the DBSA has granted the built-in EXTEND role can create or drop an external routine. You must also hold the Usage privilege on the external programming language in which the UDP is written. See the section [Granting the EXTEND Role on page 612](#) for additional information about the EXTEND role security feature. See the section [Language-Level Privileges on page 607](#) for the syntax of the USAGE ON LANGUAGE clause for the C language or for the Java™ language.

To remove the executable version of a C language procedure from shared memory, call the **IFX\_UNLOAD\_MODULE** function. To replace the executable version of a C routine with another routine, call the **IFX\_REPLACE\_MODULE** function. Both of these built-in functions are described in UDR Definition Routines.

## DROP ROLE statement

Use the DROP ROLE statement to remove a user-defined role from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP ROLE IF EXISTS

*role* 'role'

| Element     | Description                    | Restrictions  | Syntax                                  |
|-------------|--------------------------------|---|---|
| <i>role</i> | Name of the role to be dropped | Must be registered in the local database. When a <i>role</i> name is enclosed in quotation marks, it is case sensitive. | <a href="#">Owner name on page 1488</a> |

### Usage

Either the DBA or a user to whom the role was granted with the WITH GRANT OPTION keywords can issue the DROP ROLE statement. (Like a *user* name, a *role* is an authorization identifier, not a database object, so a *role* has no owner.)

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no role of the specified name is registered in the current database.

After you drop a role, no user can grant or enable the dropped role, and any user who had been assigned the role loses its privileges (such as table-level privileges or routine-level privileges) when the role is dropped, unless the same privileges were granted to PUBLIC or to the user individually. If the dropped role was the default role of a user, the default role for that user becomes NULL.

The following statement drops the role **engineer**:

```
DROP ROLE engineer;
```

You cannot use the DROP ROLE statement to drop a built-in role, such as the EXTEND or DBSECADM roles of Informix®.

**Related reference**[SET ROLE statement on page 994](#)[CREATE ROLE statement on page 303](#)[GRANT statement on page 592](#)[REVOKE statement on page 727](#)

## DROP ROUTINE statement

Use the DROP ROUTINE statement to remove a user-defined routine (UDR) from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP****ROUTINEIF EXISTS***owner* .*routine*

(

, *parameter\_type*

)

**SPECIFIC ROUTINEIF EXISTS**Specific Name<sup>263</sup>

| Element               | Description                                | Restrictions   | Syntax   |
|-----------------------|--|--|--|
| <i>owner</i>          | Name of UDR owner                          | Must own the UDR   | <a href="#">Owner name on page 1488</a>  |
| <i>parameter_type</i> | Data type of a parameter of <i>routine</i> | The data type (or list of data types) must be the same type (and specified in the same order) as in the UDR definition | <a href="#">Identifier on page 1456;</a><br><a href="#">Data Type on page 1163</a> |
| <i>routine</i>        | Name of the UDR to drop                    | The UDR must exist (that is, be registered) in the database  | <a href="#">Identifier on page 1456</a>  |

**Usage**

Dropping a UDR removes the text and executable versions of the UDR from the database. If you do not know whether a UDR is a user-defined function or a user-defined procedure, this statement instructs the database server to drop the specified user-defined function or user-defined procedure.

263. See [Specific Name on page 1521](#)

To use the DROP ROUTINE statement, you must be the owner of the UDR (and also hold the Resource privilege on the database), or you must have the DBA privilege. You must also hold the Usage privilege on the programming language in which the UDR is written. To drop an external user-defined routine, see also [Dropping an External Routine on page 524](#).

---

[ALTER ROUTINE statement on page 88](#)

[ALTER PROCEDURE statement on page 86](#)

#### Related information

[Overloading the Name of a Function on page 247](#)

## Restrictions

You cannot drop an SPL routine from within the same SPL routine.

You cannot use the DROP ROUTINE, DROP FUNCTION, or DROP PROCEDURE statement to drop a protected routine. For more information about protected routines, see the description of the **sysprocedures** system catalog table in the *Informix® Guide to SQL: Reference*.

To use the DROP ROUTINE statement to unregister a UDR, the type of UDR cannot be ambiguous. The name of the UDR that you specify must refer to either a user-defined function or a user-defined procedure. If either of the following conditions exist, the database server returns an error:

- The name (and parameters) that you specify apply to both a user-defined procedure and a user-defined function,
- The *specific* name that you specify applies to both a user-defined procedure and a user-defined function.

If the *routine* name is not unique within the database, you must specify enough *parameter\_type* information to disambiguate the name. If the database server cannot resolve an ambiguous routine name whose signature differs from that of another routine only in an unnamed ROW type parameter, an error is returned. (This error cannot be anticipated by the database server when the ambiguous *routine* is defined.)

If you use parameter data types to identify a UDR, they follow the UDR name, as in the following example:

```
DROP ROUTINE compare(INT, INT);
```

If you use the specific name for the UDR, you must also include the keyword SPECIFIC, as in the following example:

```
DROP SPECIFIC ROUTINE compare_point;
```

If you include the optional IF EXISTS keywords, the database server takes no action (rather than issues an error) if the database server cannot find in the current database any routine that matches what your DROP ROUTINE statement specifies.

### Determining Whether a Routine Exists

Before you attempt to drop a user-defined routine, you can check for its existence in the database by querying the system catalog. In the following example, the SELECT statement retrieves from the **sysprocedures** table any routines whose identifier is **MyRoutine**:

```
SELECT * FROM sysprocedures WHERE procname = MyRoutine;
```

If this query returns a single row, then a UDR called **MyRoutine** is registered in the current database.

If this query returns no rows, you do not need to issue the DROP ROUTINE statement, but you might wish to verify that the WHERE clause specified the correct name, and that you are connected to the correct database.

If the query returns more than one row, then the routine name **MyRoutine** is overloaded in the current database, and you need to examine the attributes of the **MyRoutine** routines to determine which of them, if any, need to be unregistered by the DROP ROUTINE statement.

---

## Dropping an External Routine

### About this task

A user-defined routine (UDR) written in C language or in the Java™ language is called an *external routine*. External routines must include the External Routine Reference clause that specifies a shared-object filename. By default, only users to whom the DBSA has granted the built-in EXTEND role can create or drop an external routine. You must also hold the Usage privilege on the external programming language in which the UDR is written. See the section [Granting the EXTEND Role on page 612](#) for additional information about the EXTEND security feature. See the section [Language-Level Privileges on page 607](#) for the syntax of the USAGE ON LANGUAGE clause for the C language or for the Java™ language.

To remove the executable version of a C language procedure from shared memory, call the **IFX\_UNLOAD\_MODULE** function. To replace the executable version of a C routine with another routine, call the **IFX\_REPLACE\_MODULE** function. Both of these built-in functions are described in UDR Definition Routines.

## DROP ROW TYPE statement

Use the DROP ROW TYPE statement to remove an existing named ROW data type from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP ROW TYPE IF EXISTS***owner* .*row\_type***RESTRICT**

| Element         | Description  | Restrictions  | Syntax  |
|-----------------|--|---|---|
| <i>owner</i>    | Authorization identifier of the owner of <i>row_type</i> | Must own <i>row_type</i>                                    | <a href="#">Owner name on page 1488</a>   |
| <i>row_type</i> | Name of an existing named ROW data type to be dropped    | Must exist. See also the <b>Usage</b> section that follows. | <a href="#">Identifier on page 1456</a> ;<br><a href="#">Data Type on page 1163</a> |

**Usage**

The DROP ROW TYPE statement removes the entry for the specified *row\_type* from the **sysxdtypes** system catalog table. You must be the owner of the specified named ROW data type or have the DBA privilege to execute the DROP ROW TYPE statement.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no named ROW data type of the specified name is registered in the current database.

You cannot drop a named ROW data type if its name is in use in the database. The DROP ROW TYPE statement fails to destroy the specified ROW data type when any of the following conditions are true in the database:

- Any existing tables or columns are using the named ROW data type.
- The named ROW data type is a supertype in an inheritance hierarchy.
- A view is defined on a column of the named ROW data type.

**Example of dropping a named ROW type**

If the named ROW type **postal\_t** is registered in the system catalog of the database, but none of the restrictions listed above apply, then the following statement destroys the ROW data type whose name is **postal\_t**:

```
DROP ROW TYPE postal_t RESTRICT;
```

If this DROP ROW TYPE statement succeeds, the row in the system catalog where the named ROW type **postal\_t** is registered is deleted from the **sysxdtypes** table.

To drop a named ROW-type column from the schema of a table without removing the corresponding ROW type database object from the system catalog, use the ALTER TABLE . . . DROP COLUMN statement.

The DROP ROW TYPE statement cannot drop unnamed ROW data types.

**Related reference**[CREATE ROW TYPE statement on page 307](#)[CREATE DISTINCT TYPE statement on page 210](#)[DROP TYPE statement on page 536](#)

## The RESTRICT Keyword

The RESTRICT keyword is required with the DROP ROW TYPE statement. RESTRICT causes DROP ROW TYPE to fail if dependencies on *row\_type* exist.

The DROP ROW TYPE statement fails and returns an error message if any of the following conditions is true:

- The named ROW data type is used for an existing table or column.

Check the **sysables** and **syscolumns** system catalog tables to find out whether any tables or data types use the named ROW data type.

- The named ROW data type is the supertype in an inheritance hierarchy.

Look in the **sysinherits** system catalog table to see which named ROW data types have child types.

The following statement drops the named ROW data type **employee\_t**:

```
DROP ROW TYPE employee_t RESTRICT
```

## DROP SECURITY statement

Use the DROP SECURITY statement to remove an existing security object from the current database. The object can be a security policy, security label, or a security label component.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP SECURITY****LABEL IF EXISTS***policy.label***LABEL COMPONENT IF EXISTS***component***RESTRICT****POLICY IF EXISTS***policy***RESTRICT CASCADE**

| Element          | Description                      | Restrictions               | Syntax                                  |
|------------------|----------------------------------|----------------------------|---|
| <i>component</i> | Security label component to drop | Must exist in the database | <a href="#">Identifier on page 1456</a> |

| Element       | Description             | Restrictions   | Syntax                                  |
|---------------|-------------------------|--|---|
| <i>label</i>  | Security label to drop  | Must exist in the database as a label of the specified <i>policy</i> | <a href="#">Identifier on page 1456</a> |
| <i>policy</i> | Security policy to drop | Must exist in the database   | <a href="#">Identifier on page 1456</a> |

## Usage

Only DBSECADM can issue this statement. When the DROP SECURITY statement executes successfully, the database server deletes any rows that reference the name or the numeric identifier of the specified object from the tables of the system catalog, including these tables:

- **sysecpolicies** for security policies
- **sysseclabels** for security labels
- **sysseclabelcomponents** for security label components.

The keyword or keywords that follow the SECURITY keyword identify the type of security object that is being dropped.

- SECURITY POLICY *policy* specifies a security policy
- SECURITY LABEL *policy.label* specifies a security label
- SECURITY LABEL COMPONENT *component* specifies a security label component.

There is no SQL statement that selectively drops some elements of a security label component without destroying the entire component object. To remove only a subset of the elements of a security label component from the database, DBSECADM can use the DROP SECURITY LABEL COMPONENT statement to drop the component, and then redefine the dropped component, using the CREATE SECURITY LABEL COMPONENT statement, but without including any elements that are no longer needed. (An alternative is to drop all the security labels that include the deprecated elements, and then use the CREATE SECURITY LABEL statement to redefine new labels with the same components as the dropped labels, but without those elements. In this case, the deprecated elements persist in the database, but no security label uses them as values for their component.)

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no security object of the specified security object type and of the specified name is registered in the current database.

## Examples

The following statement instructs the database server to drop the security label **witty**:

```
DROP SECURITY LABEL witty;
```

The statement fails if any column is protected by the **witty** label, or if any user holds this label.

The next example instructs the database server to drop the security label component **adhesive** from the database:

```
DROP SECURITY LABEL COMPONENT adhesive;
```

The statement fails if any security policy depends on the **adhesive** security label component.

The following example instructs the database server to drop the **best** security policy in CASCADE mode:

```
DROP SECURITY POLICY best CASCADE;
```

This statement fails if that policy is currently protecting any table. If this statement succeeds, however, it has the following additional effects because of the CASCADE specification:

- All security labels associated with the **best** security policy are also dropped.
- All exemptions from the **best** security policy are revoked.
- All security labels that were dropped because the **best** security policy was dropped are revoked from all users who hold those labels.

## Dropping security objects in RESTRICT mode or in CASCADE mode

By default, the RESTRICT keyword is in effect when any security object is dropped. Only a security *policy* can be dropped in CASCADE mode. DBSECADM cannot drop a security policy in RESTRICT mode if any of the following conditions are true:

- A table is protected by that security policy
- A security label depends on that security policy
- A user has been granted an exemption from a rule of that security policy.

A security policy cannot be dropped in CASCADE mode if the policy is protecting any table. When a security policy is successfully dropped in CASCADE mode, the following security objects are also dropped or revoked:

- All the security labels that are associated with the dropped security policy
- All the security labels that were dropped are also revoked from the users who hold those labels
- All the exemptions from the dropped security policy are revoked.

A security label cannot be dropped in RESTRICT mode, which is the only supported mode for dropping labels, if any of the following conditions are true:

- A column is protected by that security label
- A user holds that security label.

A security label component cannot be dropped in RESTRICT mode, which is the only supported mode for dropping components, if any security policy depends on that security label component.

## DROP SEQUENCE statement

Use the DROP SEQUENCE statement to remove a sequence object from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP SEQUENCEIF EXISTS

```
owner .
sequence
```

| Element         | Description            | Restrictions                       | Syntax                                  |
|-----------------|------------------------|------------------------------------|---|
| <i>owner</i>    | Name of sequence owner | Must own the sequence object       | <a href="#">Owner name on page 1488</a> |
| <i>sequence</i> | Name of a sequence     | Must exist in the current database | <a href="#">Identifier on page 1456</a> |

### Usage

This statement removes the *sequence* entry from the **syssequences** system catalog table. To drop a sequence, you must be its owner or have the DBA privilege on the database. In an ANSI-compliant database, you must qualify the name of the sequence with the name of its owner (*owner.sequence*) if you are not the owner.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no sequence object of the specified name is registered in the current database.

If you drop a sequence, any synonyms for the name of the sequence are also dropped automatically by the database server.

You cannot use a synonym to specify the identifier of the *sequence* in the DROP SEQUENCE statement.

### Examples

Suppose you had a sequence created with something code similar to the following:

```
CREATE SEQUENCE Invoice_Numbers
START 10000 INCREMENT 1 NOCYCLE ;
```

Such a sequence can be dropped using the following:

```
DROP SEQUENCE Invoice_Numbers;
```

Details of existing sequences can be found by joining the *syssequences* and *systables* system catalog tables as in the following:

```
SELECT t.tabname SeqName
FROM Syssequences s, Systables t
```

```
WHERE t.tabid = s.tabid ;
```

### Related reference

[SELECT statement on page 768](#)

[UPDATE statement on page 1037](#)

## DROP SYNONYM statement

Use the DROP SYNONYM statement to unregister an existing synonym.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP SYNONYMIF EXISTS

*owner* .

*synonym*

| Element        | Description             | Restrictions                                    | Syntax                                  |
|----------------|-------------------------|---|---|
| <i>owner</i>   | Owner of <i>synonym</i> | Must own <i>synonym</i>                         | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> | Synonym to be dropped   | The synonym must exist in the current database. | <a href="#">Identifier on page 1456</a> |

### Usage

This removes the entries for the *synonym* from the **sytables** and **syssytable** system catalog tables. You must own the *synonym* or have the DBA privilege to execute the DROP SYNONYM statement. Dropping a synonym has no effect on the table, view, or sequence object to which the synonym points.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no synonym of the specified name is registered in the current database.

The following statement drops the synonym **nj\_cust**, that user **cathyg** owns:

```
DROP SYNONYM cathyg.nj_cust;
```

DROP SYNONYM is not the only DDL operation that can unregister a synonym. If a table, view, or sequence is dropped, any synonyms that exist in the same database and that refer to that table, view, or sequence object are also dropped.

If a synonym in the current database refers to a dropped table or view in another database, however, that synonym remains registered in the system catalog until you explicitly drop it by using the DROP SYNONYM statement. You can create in the same database another table or view, and declare as its identifier the name of the dropped table or view. (If that is not the name of any table object in the current database, you can instead create a table, view, or sequence object in the current database, and declare as its name the identifier of the table or view that was dropped in the other database.) In either case, the old synonym now refers to the new table object. For a more complete discussion of synonym chaining, see the topic [Chaining Synonyms on page 334](#) in the CREATE SYNONYM statement description.

---

#### Related reference

[ALTER SEQUENCE statement on page 95](#)

[CREATE SEQUENCE statement on page 326](#)

[CREATE SYNONYM statement on page 330](#)

[RENAME SEQUENCE statement on page 716](#)

## DROP TABLE statement

Use the DROP TABLE statement to remove a table with its associated indexes and data. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP TABLE IF EXISTS

*owner* .

*table synonym*

#### CASCADE RESTRICT

| Element        | Description                                     | Restrictions  | Syntax                                  |
|----------------|---|---|---|
| <i>owner</i>   | Name of table owner                             | Must own the table  | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> | Local synonym for a table that is to be dropped | The synonym and its table must exist, and <b>USETABLENAME</b> must not be set to 1    | <a href="#">Identifier on page 1456</a> |
| <i>table</i>   | Name of a table to drop                         | Must be registered in the <b>systables</b> system catalog table of the local database | <a href="#">Identifier on page 1456</a> |

### Usage

You must be the owner of the table or have the DBA privilege to use the DROP TABLE statement.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no table of the specified name is registered in the current database.

If DROP TABLE statement is used with a synonym name, both the synonym and the table identified by the synonym are dropped along with any other synonyms that reference the same table.

You can prevent users from specifying a synonym in DROP table statements by setting the USETABLENAME environment variable. If USETABLENAME is set, an error results if any user attempts to specify DROP TABLE *synonym*.

You cannot drop a system catalog table.

If you issue a DROP TABLE statement, DB-Access does not prompt you to verify that you want to delete an entire table.

---

#### Related reference

[CREATE TABLE statement on page 335](#)

[CREATE TEMP TABLE statement on page 397](#)

[RENAME TABLE statement on page 717](#)

[ADD TYPE Clause on page 132](#)

[TRUNCATE statement on page 1025](#)

[DROP DATABASE statement on page 510](#)

[DROP VIEW statement on page 538](#)

[DROP XADATASOURCE statement on page 539](#)

[DROP TRIGGER statement on page 534](#)

## Effects of the DROP TABLE Statement

Use the DROP TABLE statement with caution. When you remove a table, you also delete the data stored in it, the indexes or constraints on the columns (including all the referential constraints placed on its columns), any local synonyms assigned to it, any triggers created on it, and any access privileges granted on the table. You also drop all views based on the table and any violations and diagnostics tables associated with the table.

DROP TABLE does not remove any synonyms for the table that were created in an external database. To remove external synonyms for the dropped table, you must do so explicitly with the DROP SYNONYM statement.

If DROP TABLE statement is used with a synonym name, both the synonym and the table identified by the synonym are dropped along with any other synonyms that reference the same table.

You can prevent users from specifying a synonym in DROP TABLE statements by setting the **USETABLENAME** environment variable. If **USETABLENAME** is set, an error results if any user attempts to specify DROP TABLE *synonym*.

## Specifying CASCADE Mode

The CASCADE keyword in DROP TABLE removes related database objects, including referential constraints built on the table, views defined on the table, and any violations and diagnostics tables associated with the table.

If the table is the supertable in an inheritance hierarchy, CASCADE drops all of the subtables as well as the supertable.

The CASCADE mode is the default mode of the DROP TABLE statement. You can also specify this mode explicitly with the CASCADE keyword.

## Specifying RESTRICT Mode

The RESTRICT keyword can control the drop operation for supertables, for tables that have referential constraints and views defined on them, or for tables that have violations and diagnostics tables associated them. Using the RESTRICT option causes the drop operation to fail and an error message to be returned if any of the following conditions are true:

- Existing referential constraints reference *table*.
- Existing views are defined on *table*.
- Any violations tables or diagnostics tables are associated with *table*.
- The *table* is the supertable in an inheritance hierarchy.

---

[DROP XADATASOURCE TYPE statement on page 540](#)

## Dropping a Table That Contains Opaque Data Types

Some opaque data types require special processing when they are deleted. For example, if an opaque type contains spatial or multi-representational data, it might provide a choice of how to store the data: inside the internal structure or, for large objects, in a smart large object.

The database server removes opaque types by calling a user-defined support function called **destroy()**. When you execute the DROP TABLE statement on a table whose rows contain an opaque type, the database server automatically invokes the **destroy()** function for the type. The **destroy()** function can perform certain operations on columns of the opaque data type before the table is dropped. For more information about the **destroy()** support function, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Tables That Cannot Be Dropped

Restrictions exist on the types of tables that you can drop.

- You cannot drop any system catalog table.
- You cannot drop a table that is not in the current database.

- You cannot drop a violations table or a diagnostics table.

Before you can drop such a table, you must first issue a `STOP VIOLATIONS TABLE` statement on the base table with which the violations and diagnostics tables are associated.

The following example removes two tables in the current database. Both are owned by **joed**, the current user. Neither table has an associated violations or diagnostics table, nor a referential constraint or view defined on it.

```
DROP TABLE customer;
DROP TABLE stores_demo@accntg:joed.state;
```

## DROP TRIGGER statement

Use the `DROP TRIGGER` statement to remove a trigger definition from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP TRIGGER IF EXISTS

*owner* .

*trigger*

| Element        | Description                      | Restrictions                                 | Syntax                                  |
|----------------|----------------------------------|--|---|
| <i>owner</i>   | Name of the owner of the trigger | Must own the trigger                         | <a href="#">Owner name on page 1488</a> |
| <i>trigger</i> | Name of the trigger to drop      | The trigger must exist in the local database | <a href="#">Identifier on page 1456</a> |

### Usage

You must be the owner of the trigger or have the DBA privilege to drop the trigger. Dropping a trigger removes the text of the trigger definition and the executable trigger from the database. The row describing the specified trigger is deleted from the **systriggers** system catalog table.

If you include the optional `IF EXISTS` keywords, the database server takes no action (rather than sending an exception to the application) if no trigger of the specified name is registered in the current database.

Dropping an `INSTEAD OF` trigger on a complex view (a view with columns from more than one table) revokes any privileges on the view that the owner of the trigger received automatically when creating the trigger, and also revokes any privileges that the owner of the trigger granted to other users. (Dropping a trigger on a simple view does not revoke any privileges.)

The following statement drops the **items\_pct** trigger:

```
DROP TRIGGER items_pct;
```

If a `DROP TRIGGER` statement appears inside an SPL routine that is called by a data manipulation (DML) statement, the database server returns an error.

When multiple triggers are defined on the same table or view for the same triggering event, the order in which the triggers execute is not guaranteed. If you have a preferred sequence of execution, but the triggers are executing in some other sequence, you might wish to drop all of the triggers except the one that you want to run first, and then re-create the other triggers in the relative order in which you want them to execute, so that they are listed in the system catalog in the intended order of execution.

[INSTEAD OF Triggers on Views on page 439](#)

[CREATE TRIGGER statement on page 405](#)

## DROP TRUSTED CONTEXT statement

Use the DROP TRUSTED CONTEXT statement to destroy a trusted-context object.

This statement is the Informix® extension to the ANSI/ISO standard for SQL. You must hold the database security administrator (DBSECADM) role to drop a trusted context.

### Syntax

#### DROP TRUSTED CONTEXT

*context*

| Element        | Description                        | Restrictions  | Syntax                                  |
|----------------|------------------------------------|---|---|
| <i>context</i> | Trusted-context object to destroy. | Must exist on the current Informix® database server instance. | <a href="#">Identifier on page 1456</a> |

### Usage

When the DROP TRUSTED CONTEXT statement executes successfully, the specified trusted context object is destroyed. All references to the *context* will be deleted from these tables in the **sysuser** database of the Informix® database server instance:

- **systrustedcontext**
- **systcxattributes**
- **systcxusers**.

If you drop the trusted context while trusted connections for this context are active, those connections remain trusted until they terminate, or until the next reuse attempt. If an attempt is made to switch the user on these trusted connections, however, an error is returned.

The following example of a DROP TRUSTED CONTEXT statement destroys the cntx1 trusted-context object:

```
DROP TRUSTED CONTEXT cntx1;
```

This example fails if cntx1 is not the name of a trusted-context object of the current database server instance.

---

[RENAME TRUSTED CONTEXT statement on page 719](#)

## DROP TYPE statement

Use the DROP TYPE statement to remove a user-defined distinct or opaque data type from the database. (You cannot use this statement to remove a built-in data type or a ROW data type.)

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP TYPEIF EXISTS

*owner* .

*data\_type*

**RESTRICT**

| Element          | Description  | Restrictions  | Syntax                                  |
|------------------|--|---|---|
| <i>data_type</i> | Name of distinct or opaque data type to be removed     | Must be an existing user-defined DISTINCT or OPAQUE type in the local database. Cannot be a built-in data type. | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>     | Authorization identifier of the <i>data type</i> owner | Must own <i>data type</i>   | <a href="#">Owner name on page 1488</a> |

### Usage

To drop a distinct or opaque data type with the DROP TYPE statement, you must be the owner of the data type or have the DBA privilege. When you use this statement, you remove the data type definition from the database (in the **sysxdtypes** system catalog table). In general, this statement does not remove any definitions of casts or of support functions associated with that data type.

**Important:** When you drop a distinct type, the database server automatically drops the two explicit casts between the distinct type and the type on which it is based.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no user-defined distinct or opaque data type of the specified name is registered in the current database.

The DROP TYPE statement fails with an error if you attempt to drop a built-in data type, such as the built-in opaque BOOLEAN or LVARCHAR type, or the built-in distinct IDSECURITYLABEL type.

Do not confuse the DROP TYPE statement with the [DROP ROW TYPE statement on page 524](#), which can only destroy named ROW types, including ROW types within data type hierarchies.

You cannot drop a distinct or opaque type if the database contains any casts, columns, or user-defined functions whose definitions reference the data type.

The following statement destroys the **new\_type** data type:

```
DROP TYPE new_type RESTRICT;
```

[CREATE TABLE statement on page 335](#)

## DROP USER statement (UNIX™, Linux™)

Use the DROP USER statement to remove an internal user.

This statement is an extension to the ANSI/ISO standard for the SQL language.

### Syntax

**DROP USER***user*

| Element     | Description  | Restrictions                                 | Syntax                                  |
|-------------|--|--|---|
| <i>user</i> | Authorization identifier of a specific user that you are dropping. | Must be an existing authorization identifier | <a href="#">Owner name on page 1488</a> |

### Usage

Only a DBSA can run the DROP USER statement. With a non-root installation, the user who installs the server is the equivalent of the DBSA, unless the user delegates DBSA privileges to a different user.

It is recommended that you do not run the DROP USER statement while the specified user is active on a connection. Execution of the DROP USER statement can be audited with the DRUR audit code.

### Example

### Example

The following statement drops the user **bill**:

```
DROP USER bill;
```

#### Related reference

[ALTER USER statement \(UNIX, Linux\) on page 172](#)

## DROP VIEW statement

Use the DROP VIEW statement to remove a view from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP VIEWIF EXISTS

*owner* .

*view synonym*

#### CASCADE RESTRICT

| Element        | Description                                  | Restrictions  | Syntax                                  |
|----------------|--|---|---|
| <i>owner</i>   | Name of view owner                           | Must own the view   | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> | Synonym for a view that this statement drops | The <i>synonym</i> and the view to which it points must exist in the local database | <a href="#">Identifier on page 1456</a> |
| <i>view</i>    | Name of a view to drop                       | Must exist in <b>systables</b>  | <a href="#">Identifier on page 1456</a> |

### Usage

To drop a view, you must be the owner or have the DBA privilege.

When you drop a view, you also drop any other views and INSTEAD OF triggers whose definitions depend on that view. (You can also specify this default behavior explicitly with the CASCADE keyword.)

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no view of the specified name is registered in the current database.

When you include the **RESTRICT** keyword in the **DROP VIEW** statement, the drop operation fails if any other existing views are defined on *view*; otherwise, these dependent views would be unregistered by the **DROP VIEW** operation.

You can query the **sysdepend** system catalog table to determine which views, if any, depend on another view.

The following statement drops the view that is named **cust1**:

```
DROP VIEW cust1
```

[DROP TABLE statement on page 531](#)

## DROP XADATASOURCE statement

Use the **DROP XADATASOURCE** statement to drop a previously defined XA-compliant data source from the system catalog of the database.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### DROP

#### XADATASOURCEIF EXISTS

*xa\_source*

#### RESTRICT

| Element          | Description                          | Restrictions   | Syntax                                  |
|------------------|--------------------------------------|--|---|
| <i>xa_source</i> | The XA-compliant data source to drop | Must be present in the <b>sysxdatasources</b> system catalog table | <a href="#">Identifier on page 1456</a> |

### Usage

The **RESTRICT** keyword is required. You must be the owner of the XA data source or hold DBA privileges to drop an access method.

The **DROP XADATASOURCE** statement is not supported on secondary servers within a high-availability cluster.

If you include the optional **IF EXISTS** keywords, the database server takes no action (rather than sending an exception to the application) if no XA data source of the specified name is registered in the current database.

The following statement drops the XA data source instance called **NewYork** that is owned by user **informix**.

```
DROP XADATASOURCE informix.NewYork RESTRICT;
```

You cannot drop an access method if it is being used in a transaction that is currently open. If an XA data source has been registered with a transaction that is not complete, you can drop the data source only after the database is closed or the session ends.

**Related reference**[CREATE XADATASOURCE TYPE statement on page 460](#)[CREATE XADATASOURCE statement on page 458](#)[DROP TABLE statement on page 531](#)[DROP XADATASOURCE TYPE statement on page 540](#)**Related information**[Specifying RESTRICT Mode on page 533](#)

## DROP XADATASOURCE TYPE statement

Use the DROP XADATASOURCE TYPE statement to drop a previously defined XA-compliant data source type from the database.

This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****DROP****XADATASOURCE TYPE IF EXISTS***xa\_type***RESTRICT**

| Element        | Description                                   | Restrictions  | Syntax                                  |
|----------------|---|---|---|
| <i>xa_type</i> | Name of the XA data source type to be dropped | Must be present in the <b>sysxasourcetypes</b> system catalog table | <a href="#">Identifier on page 1456</a> |

**Usage**

The RESTRICT keyword is required. You cannot unregister an XA data source type if virtual tables or indexes exist that use the data source. You must be user **informix** or have DBA privileges to drop an XA data source type.

The DROP XADATASOURCE TYPE statement is not supported on secondary servers within a high-availability cluster.

The following statement drops an XA data source type called **MQSeries®** owned by user **informix**:

```
DROP XADATASOURCE TYPE informix.MQSeries RESTRICT;
```

You cannot drop an XA data source type until after all the XA data source instances that use that data source type have been dropped.

If you include the optional IF EXISTS keywords, the database server takes no action (rather than sending an exception to the application) if no XA data source type of the specified name is registered in the current database.

**Related reference**[CREATE XADATASOURCE TYPE statement on page 460](#)[CREATE XADATASOURCE statement on page 458](#)[DROP XADATASOURCE statement on page 539](#)**Related information**[Specifying RESTRICT Mode on page 533](#)

## EXECUTE statement

Use the EXECUTE statement to run a previously prepared statement or a multiple-statement prepared object.

Use this statement with Informix® ESQL/C.

**Syntax****EXECUTE**

*stmt\_id stmt\_id\_var*

INTO Clause <sup>264</sup>

USING Clause <sup>265</sup>

| Element            | Description   | Restrictions  | Syntax  |
|--------------------|---|---|---|
| <i>stmt_id</i>     | Identifier of a prepared SQL statement                          | Must have been declared in a previous PREPARE statement   | <a href="#">Identifier on page 1456</a>       |
| <i>stmt_id_var</i> | Host variable containing the identifier of a prepared statement | Must exist and must contain a statement identifier that a previous PREPARE statement declared, and must be of a character data type | <a href="#">PREPARE statement on page 687</a> |

**Usage**

The EXECUTE statement passes a prepared SQL statement to the database server for execution. The following example shows an EXECUTE statement within the Informix® ESQL/C program:

```
EXEC SQL PREPARE del_1 FROM
  'DELETE FROM customer WHERE customer_num = 119';
EXEC SQL EXECUTE del_1;
```

Once prepared, an SQL statement can be executed as often as needed.

After you release the database server resources (using a FREE statement), you cannot use the statement identifier with a DECLARE cursor or with the EXECUTE statement until you prepare the statement again.

If the statement contained question mark ( ? ) placeholders, use the USING clause to provide specific values for them before execution. For more information, see the [USING Clause on page 547](#).

264. See [INTO Clause on page 543](#)

265. See [USING Clause on page 547](#)

You can execute any prepared statement except those in the following list:

- A prepared SELECT statement that returns more than one row

When you use a prepared SELECT statement to return multiple rows of data, you must use a cursor to retrieve the data rows. As an alternative, you can EXECUTE a prepared SELECT INTO TEMP statement to achieve the same result.

For more information on cursors, see [DECLARE statement on page 467](#).

- A prepared EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement for an SPL function that returns more than one row

When you prepare an EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement to invoke an SPL function that returns multiple rows, you must use a cursor to retrieve the data rows.

For more information on how to execute a SELECT or an EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement, see [PREPARE statement on page 687](#).

If you create or drop a trigger after you prepare a triggering INSERT, DELETE, or UPDATE statement, the prepared statement returns an error when you execute it.

## Scope of Statement Identifiers

A program can consist of one or more source-code files. By default, the scope of reference of a statement identifier is global to the program. A statement identifier created in one file can be referenced from another file.

In a multiple-file program, if you want to limit the scope of reference of a statement identifier to the file in which it is executed, you can preprocess all the files with the **-local** command-line option.

### INTO Clause

Use the INTO clause to save the returned values of these SQL statements:

- A prepared singleton SELECT statement that returns only one row of column values for the columns in the select list
- A prepared EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement for an SPL function that returns only one set of values

The INTO clause of the EXECUTE statement has the following syntax:

INTO Clause

#### INTO

*, output\_var*  
266.

#### INDICATOR

*indicator\_var*

#### SQL DESCRIPTOR

*descriptor\_var 'descriptor'*

#### DESCRIPTOR *sqlda\_pointer*

| Element               | Description   | Restrictions   | Syntax   |
|-----------------------|---|--|--|
| <i>descriptor</i>     | Quoted string that identifies a system-descriptor area  | Must already be allocated. Use single ( ' ) quotation marks  | <a href="#">Quoted String on page 1424</a>           |
| <i>descriptor_var</i> | Host variable that identifies a system-descriptor area  | System-descriptor area must already be allocated   | Language specific                                    |
| <i>indicator_var</i>  | Host variable that receives a return code if corresponding <i>parameter_var</i> is NULL value, or if truncation occurs                                      | Cannot be DATETIME or INTERVAL data type   | Language specific                                    |
| <i>output_var</i>     | Host variable whose contents replace a question-mark ( ? ) placeholder in a prepared statement  | Must be a character data type  | Language specific                                    |
| <i>sqlda_pointer</i>  | Pointer to an <b>sqlda</b> structure that defines data type and memory location of values to replace a question-mark ( ? ) placeholder in a prepared object | Cannot begin with a dollar sign ( \$ ) or a colon ( : ) symbol. An <b>sqlda</b> structure is required with dynamic SQL | <a href="#">DESCRIBE INPUT statement on page 500</a> |

266. Informix® extension

This closely resembles the syntax of the [USING Clause on page 547](#).

The INTO clause provides a concise and efficient alternative to more complicated and lengthy syntax. In addition, by placing values into variables that can be displayed, the INTO clause simplifies and enhances your ability to retrieve and display data values. For example, if you use the INTO clause, you do not need to use a cursor to retrieve values from a table.

You can store the returned values in output variables, in output SQL descriptors, or in output **sqllda** pointers.

## Restrictions with the INTO Clause

If you execute a prepared SELECT statement that returns more than one row, or execute a prepared EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement for an SPL function that returns more than one group of return values, you receive an error message. In addition, if you prepare and declare a statement and then attempt to execute that statement, you receive an error message.

You cannot select a NULL value from a table column and place that value into an output variable. If you know in advance that a table column contains a NULL value, after you select the data, check the indicator variable that is associated with the column to determine if the value is NULL.

To use the INTO clause with the EXECUTE statement:

1. Declare the output variables that the EXECUTE statement uses.
2. Use PREPARE to prepare your SELECT statement or to prepare your EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement.
3. Use the EXECUTE statement, with the INTO clause, to execute your SELECT statement or to execute your EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement.

## Replacing Placeholders with Parameters

You can specify any of the following items to replace the question-mark placeholders in a prepared statement before you execute it:

- A host variable name (if the number and data type of the parameters are known at compile time)
- A system descriptor that identifies a system descriptor area
- A descriptor that is a pointer to an **sqllda** structure

Sections that follow describe each of these options for specifying parameters.

## Saving Values In Host or Program Variables

If you know the number of return values to be supplied at runtime and their data types, you can define the values that the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement returns as host variables in your program. Use these host variables with the INTO keyword, followed by the names of the variables. These variables are matched with the return values in a one-to-one correspondence, from left to right.

You must supply one variable name for each value that the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) returns. The data type of each variable must be compatible with the corresponding returned value from the prepared statement.

## Saving Values in a System-Descriptor Area

If you do not know the number of return values to be supplied at runtime or their data types, you can associate output values with a system-descriptor area. A system-descriptor area describes the data type and memory location of one or more values.

A system-descriptor area conforms to the X/Open standards.

To specify a system-descriptor area as the location of output values, use the INTO SQL DESCRIPTOR clause of the EXECUTE statement. Each time that the EXECUTE statement is run, the values that the system-descriptor area describes are stored in the system-descriptor area.

The following example shows how to use the system-descriptor area to execute prepared statements in Informix® ESQL/C:

```
EXEC SQL allocate descriptor 'desc1';
...
sprintf(sel_stmt, "%s %s %s",
    "select fname, lname from customer",
    "where customer_num =",
    cust_num);
EXEC SQL prepare sel1 from :sel_stmt;
EXEC SQL execute sel1 into sql descriptor 'desc1';
```

The COUNT field corresponds to the number of values that the prepared statement returns. The value of COUNT must be less than or equal to the value of the occurrences that were specified when the system-descriptor area was allocated with the ALLOCATE DESCRIPTOR statement.

You can obtain the value of a field with the GET DESCRIPTOR statement and set the value with the SET DESCRIPTOR statement.

For more information, refer to the discussion of the system-descriptor area in the *Informix® ESQL/C Programmer's Manual*.

## Saving Values in an sqllda Structure (ESQL/C)

If you do not know the number of output values to be returned at runtime or their data types, you can associate output values from an **sqllda** structure. An **sqllda** structure lists the data type and memory location of one or more return values. To specify an **sqllda** structure as the location of return values, use the INTO DESCRIPTOR clause of the EXECUTE statement. Each time the EXECUTE statement is run, the database server places the returns values that the **sqllda** structure describes into the **sqllda** structure.

The next example uses an **sqllda** structure to execute a prepared statement:

```
struct sqllda *pointer2;
...
sprintf(sel_stmt, "%s %s %s",
    "select fname, lname from customer",
    "where customer_num =",
    cust_num);
```

```
EXEC SQL prepare sel1 from :sel_stmt;
EXEC SQL describe sel1 into pointer2;
EXEC SQL execute sel1 into descriptor pointer2;
```

The **sqlda.sqlid** value specifies the number of output values that are described in occurrences of **sqlvar**. This number must correspond to the number of values that the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement returns.

For more information, refer to the **sqlda** discussion in the *Informix® ESQL/C Programmer's Manual*.

This example uses the INTO clause with an EXECUTE statement in Informix® ESQL/C:

```
EXEC SQL prepare sel1 from 'select fname, lname from customer
where customer_num =123';
EXEC SQL execute sel1 into :fname, :lname using :cust_num;
```

The next example uses the INTO clause to return multiple rows of data:

```
EXEC SQL BEGIN DECLARE SECTION;
int customer_num =100;
char fname[25];
EXEC SQL END DECLARE SECTION;

EXEC SQL prepare sel1 from 'select fname from customer
where customer_num=?';
for ( ;customer_num < 200; customer_num++)
{
EXEC SQL execute sel1 into :fname using customer_num;
printf("Customer number is %d\n", customer_num);
printf("Customer first name is %s\n", fname);
}
```

## The sqlca Record and EXECUTE

After an EXECUTE statement, the **sqlca** can reflect two results:

- The **sqlca** can reflect an error within the EXECUTE statement.

For example, when an UPDATE WHERE statement in a prepared statement processes zero rows, the database server sets **sqlca** to 100.

- The **sqlca** can reflect the success or failure of the executed statement.

## Returned SQLCODE Values with EXECUTE

If a prepared statement fails to access any rows when it executes, the database server returns the **SQLCODE** value of zero (0).

For a multistatement prepared object, however, if any statement in the following list fails to access rows, the returned **SQLCODE** value is `SQLNOTFOUND` (= 100):

- INSERT INTO *table* SELECT WHERE
- SELECTWHERE INTO TEMP

- DELETE WHERE
- UPDATE WHERE

In an ANSI-compliant database, if you prepare and execute any of the statements in the preceding list, and no rows are returned, the returned **SQLCODE** value is `SQLNOTFOUND ( = 100)`.

### USING Clause

Use the USING clause to specify the values that are to replace question-mark ( ? ) placeholders in the prepared statement. Providing values in the EXECUTE statement that replace the question-mark ( ? ) placeholders in the prepared statement is sometimes called *parameterizing* the prepared statement.

USING Clause

#### USING

```
, parameter_var
267 :
```

#### INDICATOR

```
indicator_var
```

#### SQL DESCRIPTOR

```
descriptor_var 'descriptor'
```

```
DESCRIPTOR sqlda_pointer
```

| Element               | Description  | Restrictions  | Syntax   |
|-----------------------|--|---|--|
| <i>descriptor</i>     | Quoted string that identifies a system-descriptor area   | System-descriptor area must already be allocated. Use single ( ' ) quotation marks.                             | <a href="#">Quoted String on page 1424</a>           |
| <i>descriptor_var</i> | Host variable that identifies a system-descriptor area   | System-descriptor area must already be allocated  | Language specific                                    |
| <i>indicator_var</i>  | Host variable that receives a return code if corresponding <i>parameter_var</i> is NULL value, or if truncation occurs                             | Cannot be DATETIME or INTERVAL data type  | Language specific                                    |
| <i>parameter_var</i>  | Host variable whose contents replace a question-mark ( ? ) placeholder in a prepared statement   | Must be a character data type   | Language specific                                    |
| <i>sqlda_pointer</i>  | Pointer to an sqlda structure that defines data type and memory location of values to replace question-mark ( ? ) placeholder in a prepared object | Cannot begin with a dollar sign ( \$ ) or a colon ( : ). An <b>sqlda</b> structure is required with dynamic SQL | <a href="#">DESCRIBE INPUT statement on page 500</a> |

This closely resembles the syntax of the [INTO Clause on page 543](#).

267. Informix® extension

If you know the number of parameters to be supplied at runtime and their data types, you can define the parameters that are needed by the EXECUTE statement as host variables in your program.

If you do not know the number of parameters to be supplied at runtime or their data types, you can associate input values from a system-descriptor area or an **sqlda** structure. Both of these descriptor structures describe the data type and memory location of one or more values to replace question-mark ( ? ) placeholders.

## Supplying Parameters Through Host or Program Variables

You pass parameters to the database server by opening the cursor with the USING keyword, followed by the names of the variables. These variables are matched with prepared statement question-mark ( ? ) placeholders in a one-to-one correspondence, from left to right. You must supply one storage- parameter variable for each placeholder. The data type of each variable must be compatible with the corresponding value that the prepared statement requires.

The following example executes the prepared UPDATE statement in Informix® ESQL/C:

```
stcopy ("update orders set order_date = ?
      where po_num = ?", stm1);
EXEC SQL prepare statement_1 from :stm1;
EXEC SQL execute statement_1 using :order_date, :po_num;
```

## Supplying Parameters Through a System Descriptor

You can create a system-descriptor area that describes the data type and memory location of one or more values and then specify the descriptor in the USING SQL DESCRIPTOR clause of the EXECUTE statement.

Each time that the EXECUTE statement is run, the values that the system-descriptor area describes are used to replace question-mark ( ? ) placeholders in the PREPARE statement.

The COUNT field corresponds to the number of dynamic parameters in the prepared statement. The value of COUNT must be less than or equal to the number of item descriptors that were specified when the system-descriptor area was allocated with the ALLOCATE DESCRIPTOR statement.

The following example shows how to use system descriptors to execute a prepared statement in Informix® ESQL/C:

```
EXEC SQL execute prep_stmt using sql descriptor 'desc1';
```

## Supplying Parameters Through an sqlda Structure (ESQL/C)

You can specify the **sqlda** pointer in the USING DESCRIPTOR clause of the EXECUTE statement.

Each time the EXECUTE statement is run, the values that the descriptor structure describes are used to replace question-mark ( ? ) placeholders in the PREPARE statement.

The **sqlda.sqlld** value specifies the number of input values that are described in occurrences of **sqlvar**. This number must correspond to the number of dynamic parameters in the prepared statement.

The following example shows how to use an **sqlda** structure to execute a prepared statement in Informix® ESQL/C:

```
EXEC SQL execute prep_stmt using descriptor pointer2;
```

## EXECUTE FUNCTION statement

Use the EXECUTE FUNCTION statement to invoke a user-defined function or a built-in routine that returns a value.

This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### EXECUTE FUNCTION

*function*

<sup>268</sup>*SPL\_var*

(

, Argument<sup>272</sup>

)

<sup>268</sup><sup>269</sup> INTO Clause<sup>273</sup>

<sup>270</sup> WITH TRIGGER REFERENCES<sup>271</sup>

| Element         | Description  | Restrictions  | Syntax  |
|-----------------|--|---|---|
| <i>function</i> | Name of a user-defined function to execute                       | Must be registered in the database  | <a href="#">Database Object Name on page 1450</a> |
| <i>SPL_var</i>  | Variable that contains the name of an SPL routine to be executed | Must be a CHAR, VARCHAR, NCHAR, or NVARCHAR data type that contains the non-NULL name of an existing SPL function | <a href="#">Identifier on page 1456</a>           |

### Usage

The EXECUTE FUNCTION statement invokes a user-defined function (UDF), with arguments, and specifies where the results are to be returned.

An external C or Java™ language function returns exactly one value.

An SPL function can return one or more values.

You cannot use the EXECUTE FUNCTION statement to invoke any type of user-defined procedure that returns no value. Instead, use the EXECUTE PROCEDURE or EXECUTE ROUTINE statement to execute procedures.

You must have the Execute privilege on the user-defined function.

For more information, see [GRANT statement on page 592](#).

268. Stored Procedure Language only

269. ESQL/C only

270. Trigger functions only

271. See [The WITH TRIGGER REFERENCES Keywords on page 560](#)

272. See [Arguments on page 1433](#)

273. See [INTO Clause on page 551](#)

In ANSI/ISO-compliant databases that support implicit transactions, the EXECUTE FUNCTION statement does not, by default, begin a new transaction. SQL statements within the invoked function, however, can begin a new transaction.

**Related information**

[Overloading the Name of a Function on page 247](#)

## Negator Functions and Their Companions

If a UDF that returns a BOOLEAN value has a companion function, any user who executes the function must have the Execute privilege on both the function and on its companion. For example, if a function has a negator function, any user who executes the function must have the Execute privilege on both the function and its negator. In addition, the companion function must have the same owner as its negator function.

For information on how to designate a UDF as the companion to its negator function, see [NEGATOR on page 1510](#).

## How the EXECUTE FUNCTION Statement Works

For a user-defined function (UDF) to be executed with the EXECUTE FUNCTION statement, the following conditions must exist:

- The qualified function name or the function signature (the function name with its parameter list) must be unique within the name space or database.
- The function must exist in the current database.

If EXECUTE FUNCTION specifies fewer arguments than the user-defined function expects, the unspecified arguments are said to be *missing*. Missing arguments are initialized to their corresponding parameter default values, if these were defined. The syntax of specifying default values for parameters is described in [Routine Parameter List on page 1514](#).

EXECUTE FUNCTION returns an error under the following conditions:

- EXECUTE FUNCTION specifies more arguments than the UDF expects.
- One or more arguments are missing and do not have default values.
- The fully qualified function name or the function signature is not unique.
- No function with the specified name or signature that you specify is found.
- EXECUTE FUNCTION attempts to invoke a user-defined procedure.
- In a distributed transaction, a UDR that is running on a subordinate participating server calls a remote function on a database of another server instance.

If the *function* name is not unique within the database, you must specify enough *parameter\_type* information to disambiguate the name. See the section [Arguments on page 1433](#) for more information about how to specify parameters when invoking a function.

The *specific name* of an external UDR is valid in some DDL statements, but is not valid in contexts where you invoke the function.

If Informix® cannot resolve an ambiguous function name whose signature differs from the signature of another routine only in an unnamed-ROW type parameter, an error is returned. (This error cannot be anticipated by the database server when the ambiguous function is defined.)

## INTO Clause

INTO Clause

### INTO

,  
*data\_var*  
 274

:  
 275§

### INDICATOR

*indicator\_var*  
*data\_structure*

| Element               | Description  | Restrictions   | Syntax            |
|-----------------------|--|--|-------------------|
| <i>data_structure</i> | Structure that was declared as a host variable   | Individual elements of structure must be compatible with the data types of the returned values | Language specific |
| <i>data_var</i>       | Variable to receive the value that a user-defined function returns                                 | See <a href="#">Data Variables on page 552</a> .   | Language specific |
| <i>indicator_var</i>  | Program variable to store a return code if the corresponding <i>data_var</i> receives a NULL value | Use an indicator variable if the value of the corresponding <i>data_var</i> might be NULL      | Language specific |

274. ESQL/C only

275. Informix® extension

You must include an INTO clause with EXECUTE FUNCTION to specify the variables that receive the values that a user-defined function returns. If the function returns more than one value, the values are returned into the list of variables in the order in which you specify them.

If the EXECUTE FUNCTION statement stands alone (that is, it is not part of a DECLARE statement and does not use the INTO clause), it must execute a noncursor function. A noncursor function returns only one row of values. The following example shows a SELECT statement in Informix® ESQL/C:

```
EXEC SQL EXECUTE FUNCTION
  cust_num(fname, lname, company_name) INTO :c_num;
```

## Data Variables

If you issue EXECUTE FUNCTION within an ESQ/C program, *data\_var* must be a host variable. Within an SPL routine, *data\_var* must be an SPL variable.

If you issue EXECUTE FUNCTION within a CREATE TRIGGER statement, *data\_var* must be a column name in the triggering table or in another table.

## INTO Clause with Indicator Variables (ESQL/C)

You should use an indicator variable if the possibility exists that data returned from the user-defined function is NULL. For more information about indicator variables, see the *Informix® ESQL/C Programmer's Manual*.

## INTO Clause with Cursors

If EXECUTE FUNCTION calls a UDF that returns more than one row of values, it must execute a cursor function. A cursor function can return one or more rows of values and must be associated with a Function cursor to execute.

If the SPL function returns more than one row or a collection data type, you must access the rows or collection elements with a cursor.

To return more than one row of values, an external function (one written in the C or Java™ language) must be defined as an iterator function. For more information on iterator functions, see the *Informix® DataBlade® API Programmer's Guide*.

In an SPL routine, if a SELECT returns more than one row, you must use the FOREACH statement to access the rows individually. The INTO clause of the SELECT statement can store the fetched values. For more information, see [FOREACH on page 1107](#).

To return more than one row of values, an SPL function must include the WITH RESUME keywords in its RETURN statement. For more information on how to write SPL functions, see the *Informix® Guide to SQL: Tutorial*.

In Informix® ESQ/C programs, the DECLARE statement can declare a Function cursor and the FETCH statement can return rows individually from the cursor. You can put the INTO clause in the EXECUTE FUNCTION or in the FETCH statement, but you cannot put it in both. The following Informix® ESQ/C code examples show different ways you can use the INTO clause:

- Using the INTO clause in the EXECUTE FUNCTION statement:

```
EXEC SQL declare f_curs cursor for
  execute function get_orders(customer_num)
```

```

    into :ord_num, :ord_date;
EXEC SQL open f_curs;
while (SQLCODE == 0)
    EXEC SQL fetch f_curs;
EXEC SQL close f_curs;

```

- Using the INTO clause in the FETCH statement:

```

EXEC SQL declare f_curs cursor for
    execute function get_orders(customer_num);
EXEC SQL open f_curs;
while (SQLCODE == 0)
    EXEC SQL fetch f_curs into :ord_num, :ord_date;
EXEC SQL close f_curs;

```

## Alternatives to PREPARE ... EXECUTE FUNCTION ... INTO

### About this task

In ESQL/C, you cannot prepare an EXECUTE FUNCTION statement that includes the INTO clause. For similar functionality, however, follow these steps:

1. Prepare the EXECUTE FUNCTION statement with no INTO clause.
2. Declare a Function cursor for the prepared statement.
3. Open the cursor.
4. Execute the FETCH statement with an INTO clause to fetch the returned values into program variables.

Alternatively, you can do the following:

1. Declare a cursor for the EXECUTE FUNCTION statement without first preparing the statement, and include the INTO clause in the EXECUTE FUNCTION when you declare the cursor.
2. Open the cursor.
3. Fetch the returned values from the cursor without using the INTO clause of the FETCH statement.

## Dynamic Routine-Name Specification of SPL Functions

*Dynamic routine-name specification* simplifies the writing of an SPL function that calls another SPL routine whose name is not known until runtime. To specify the name of an SPL routine in the EXECUTE FUNCTION statement, instead of listing the explicit name of an SPL routine, you can use an SPL variable to hold the routine name. For more information about how to execute SPL functions dynamically, see the *Informix® Guide to SQL: Tutorial*.

## EXECUTE IMMEDIATE statement

Use the EXECUTE IMMEDIATE statement to perform tasks equivalent to what the PREPARE, EXECUTE, and FREE statements accomplish, but as a single operation.

Use this Dynamic SQL statement with Informix® ESQL/C and SPL.

## Syntax

### EXECUTE IMMEDIATE

' *statement*

<sup>276</sup> ;

; *statement*

;

;

*statement\_var*

<sup>277</sup> *char\_expr*

| Element              | Description  | Restrictions   | Syntax                                  |
|----------------------|--|--|---|
| <i>char_expr</i>     | Expression that evaluates to a character data type   | Must evaluate to a CHAR, LVARCHAR, NCHAR, NVARCHAR, or VARCHAR data type   | <a href="#">Expression on page 1193</a> |
| <i>statement</i>     | Text of a valid SQL statement  | See the same sections that are listed below for <i>statement_var</i>   | See this chapter.                       |
| <i>statement_var</i> | Variable containing <i>statement</i> or (in ESQL/C) a semicolon-separated list of statements | Must be a previously declared variable of type CHAR, NCHAR, NVARCHAR, or VARCHAR (or in SPL, LVARCHAR). See <a href="#">EXECUTE IMMEDIATE and Restricted Statements on page 555</a> and <a href="#">Restrictions on Valid Statements on page 556</a> . | Language specific                       |

## Usage

The EXECUTE IMMEDIATE statement dynamically executes a single SQL statement (or in ESQL/C routines, a semicolon-separated list of SQL statements) that is constructed during program execution. For example, you can obtain the name of a database from program input, construct the DATABASE statement as a program variable, and then use EXECUTE IMMEDIATE to execute the statement, which opens the specified database.

Within ESQL/C routines, the statement text specified by the variable or quoted string can include more than one SQL statement, if consecutive statements are separated by a semicolon (;) delimiter. In SPL routines, however, only one statement can be included. The *statement* cannot be an SPL statement, but can be any SQL statement that is not listed in the sections [EXECUTE IMMEDIATE and Restricted Statements on page 555](#) or [Restrictions on Valid Statements on page 556](#).

The specification that follows the IMMEDIATE keyword, if valid, is parsed and executed; then all data structures and memory resources are released immediately. Unless you use EXECUTE IMMEDIATE, these operations would otherwise require separate PREPARE, EXECUTE, and FREE statements.

276. ESQL/C only

277. SPL only

The session environment values (such as the EXTDIRECTIVES, OPTCOMPIND, or USELASTCOMMITTED settings of the ESQL/C or SPL routine that issues the EXECUTE IMMEDIATE statement) override the corresponding ONCONFIG parameter values, if these are different.

In ANSI/ISO-compliant databases that support implicit transactions, the EXECUTE IMMEDIATE statement does not, by default, begin a new transaction. Execution of the specified SQL statement text, however, can begin a new transaction.

---

**Related reference**

[EXECUTE statement on page 541](#)

[FREE statement on page 574](#)

[PREPARE statement on page 687](#)

## EXECUTE IMMEDIATE and Restricted Statements

The EXECUTE IMMEDIATE statement cannot execute the following SQL statements.

- CLOSE
- CONNECT
- DECLARE
- DISCONNECT
- EXECUTE
- EXECUTE FUNCTION
- EXECUTE PROCEDURE
- FETCH
- FLUSH
- FREE
- GET DESCRIPTOR
- GET DIAGNOSTICS
- OPEN
- OUTPUT
- PREPARE
- PUT
- SELECT
- SET AUTOFREE
- SET CONNECTION
- SET DEFERRED\_PREPARE
- SET DESCRIPTOR
- WHENEVER

For EXECUTE PROCEDURE, this restriction applies only to calls that return one or more values.

The only form of the SELECT statement that EXECUTE IMMEDIATE supports as statement text is `SELECT ... INTO TEMP table`. For the syntax of the INTO TEMP *table* clause in SELECT statements, see [INTO table clauses on page 854](#).

In addition, ESQL/C cannot use the EXECUTE IMMEDIATE statement to execute the following statements in text that contains multiple SQL statements that are separated by semicolons:

- CLOSE DATABASE
- CREATE DATABASE
- DATABASE
- DROP DATABASE
- SELECT (except SELECT INTO TEMP)

The EXECUTE IMMEDIATE statement cannot process SQL statement text that includes question mark ( ? ) symbols as placeholders. Use the PREPARE statement and either a cursor or the EXECUTE statement to execute a dynamically constructed SELECT statement.

(In SPL routines, the EXECUTE IMMEDIATE statement can execute only a single SQL statement. If the specification that immediately follows the IMMEDIATE keyword evaluates to a list of multiple SQL statements, or by a NULL value, or text that is not a valid SQL statement, the database server issues a runtime error.)

## Restrictions on Valid Statements

The following restrictions apply to the statements contained in the character expression, quoted string, or statement variable that immediately follows the EXECUTE IMMEDIATE keywords:

- The SQL statement cannot contain a host-language comment.
- Names of host-language variables are not recognized as such in prepared text.

The only identifiers that you can use are names registered in the system catalog of the current database, such as table names and column names.

- The statement cannot reference a host-variable list or a descriptor; it must not contain any question-mark ( ? ) placeholders, which are allowed with a PREPARE statement.
- The text must not include any embedded SQL statement prefix, such as the dollar sign ( \$ ) or the keywords EXEC SQL.

Although it is not required, the SQL statement terminator ( ; ) can be included in the statement text.

- A SELECT or INSERT statement specified within the EXECUTE IMMEDIATE statement cannot contain a Collection-Derived Table clause.

EXECUTE IMMEDIATE cannot process input host variables, which are required for a collection variable. Use the EXECUTE statement or a cursor to process prepared accesses to collection variables.

## Handling Exceptions from EXECUTE IMMEDIATE Statements

If the Informix® ESQL/C parser detects a syntax error when the EXECUTE IMMEDIATE statement is compiled, it issues a compilation error, and no executable UDR is produced until the syntax is corrected and recompiled. If the parser accepts the EXECUTE IMMEDIATE syntax and the UDR compiles successfully, but an exception occurs during a call to the UDR when the

EXECUTE IMMEDIATE statement is executing, the database server issues an error at runtime. Runtime errors can be trapped by the WHENEVER statement, or by some other exception-handling mechanism in the program logic of the UDR.

For routines written in the SPL language, SQL expressions are evaluated at runtime, not when the routine is compiled or optimized. If an expression that follows the IMMEDIATE keyword specifies invalid SQL statement text, Informix® issues a runtime exception, rather than a compilation error. After any runtime error condition in an SPL routine, program control passes to the ON EXCEPTION statement block (if this is defined); otherwise, execution of the UDR terminates abnormally, and an error is returned to the calling context. For information on how to handle runtime errors in SPL routines, see the descriptions of the SPL statement [ON EXCEPTION on page 1124](#). (See also the built-in SQL function **SQLCODE**.)

## Examples of the EXECUTE IMMEDIATE Statement

The following ESQL/C examples show EXECUTE IMMEDIATE statements in Informix® ESQL/C. Both examples use host variables that contain a CREATE DATABASE statement.

```

sprintf(cdb_text1, "create database %s", usr_db_id);
EXEC SQL execute immediate :cdb_text1;

sprintf(cdb_text2, "create database %s", usr_db_id2);
EXEC SQL execute immediate :cdb_text2;

```

The next example shows an SPL program fragment that declares local SPL variables and assigns to them portions of the text of two DDL statements. It then issues an EXECUTE IMMEDIATE statement to drop a table called **DYN\_TAB**, specifying the DROP TABLE statement text in an SPL variable. The second EXECUTE IMMEDIATE statement in this example creates a table of the same name, in this case specifying the CREATE TABLE statement text in a character expression that concatenates the contents of two SPL variables.

```

CREATE PROCEDURE myproc()
DEFINE COLS   VARCHAR(22);
DEFINE CRTOPER VARCHAR(16);
DEFINE DRPOPER VARCHAR(16);
DEFINE TABNAME VARCHAR(16);
DEFINE QRYSTR  VARCHAR(100);
...
LET CRTOPER = "CREATE TABLE ";
LET DRPOPER = "DROP TABLE ";
LET TABNAME = "DYN_TAB";
LET COLS = "(ID INT, NAME CHAR(20))";
LET QRYSTR = DRPOPER || TABNAME;
EXECUTE IMMEDIATE QRYSTR;

EXECUTE IMMEDIATE CRTOPER || TABNAME || COLS;

END PROCEDURE;

```

## EXECUTE PROCEDURE statement

Use the EXECUTE PROCEDURE statement to invoke a user-defined procedure or a built-in routine. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****EXECUTE PROCEDURE***procedure*<sup>278</sup>*SPL\_var**function*

(

, *Argument*<sup>280</sup>

)

<sup>278</sup> **INTO**, *output\_var*<sup>279</sup> **WITH TRIGGER REFERENCES**

| Element           | Description   | Restrictions  | Syntax  |
|-------------------|---|---|---|
| <i>function</i>   | SPL routine to execute  | Must exist  | <a href="#">Database Object Name on page 1450</a> |
| <i>output_var</i> | Host variable or program variable that receives the returned value from UDR | In the context of a CREATE TRIGGER statement, must contain column names in the triggering table or in another table | Language specific                                 |
| <i>procedure</i>  | User-defined procedure to execute   | Must exist  | <a href="#">Database Object Name on page 1450</a> |
| <i>SPL_var</i>    | Variable that contains the name of the SPL routine to execute               | Must be a character data type that contains the non-NULL name of an SPL routine.                                    | <a href="#">Identifier on page 1456</a>           |

**Usage**

The EXECUTE PROCEDURE statement invokes a user-defined procedure and specifies its arguments.

For compatibility with earlier Informix® versions, you can use the EXECUTE PROCEDURE statement to execute an SPL function that the CREATE PROCEDURE statement defined.

If the EXECUTE PROCEDURE statement returns more than one row, the result set must be processed within a FOREACH loop of an SPL routine, or else accessed through a cursor of an ESQL/C routine.

In ANSI/ISO-compliant databases that support implicit transactions, the EXECUTE PROCEDURE statement does not, by default, begin a new transaction. SQL statements within the invoked procedure, however, can begin a new transaction.

## Causes of Errors

EXECUTE PROCEDURE returns an error under the following conditions.

- It has more arguments than the called procedure expects.
- One or more arguments that do not have default values are missing.
- The fully-qualified procedure name or the routine signature is not unique.
- No procedure with the specified name or signature is found.
- In a distributed transaction, a UDR that is running on a subordinate participating server calls a remote procedure on another server instance

For example, the following statement fails with an error:

```
EXECUTE PROCEDURE ifx_unload_module
('C:\usr\apps\opaque_types\circle.dll');
```

This built-in procedure requires a second argument, as explained in the topic IFX\_UNLOAD\_MODULE Function.

If the *procedure* name is not unique within the database, you must specify enough *parameter\_type* information to disambiguate the name. See [Arguments on page 1433](#) for additional information about how to specify parameters when invoking a procedure. (The *specific name* of an external UDR is valid in DDL statements, but is not valid in contexts where you invoke the procedure.)

## Using the INTO Clause

Use the INTO clause to specify where to store the values that the SPL function returns.

If an SPL function returns more than one value, the values are returned into the list of variables in the order in which you specify them. If an SPL function returns more than one row or a collection data type, you must access the rows or collection elements with a cursor.

You cannot prepare an EXECUTE PROCEDURE statement that has an INTO clause. For more information, see [Alternatives to PREPARE ... EXECUTE FUNCTION ... INTO on page 553](#).

## The WITH TRIGGER REFERENCES Keywords

You must include the WITH TRIGGER REFERENCES keywords when you use the EXECUTE PROCEDURE statement to invoke a trigger procedure.

A trigger procedure is an SPL routine that EXECUTE PROCEDURE can invoke only from the FOR EACH ROW section of the Action clause of a trigger definition. Such procedures must include the REFERENCING clause and the FOR clause in the CREATE PROCEDURE statement that defined the procedure. This REFERENCING clause declares names for correlated variables that the procedure can use to reference the *old* column value in the row when the trigger event occurred, or the *new* value of the column after the row was modified by the trigger. The FOR clause specifies the table or view on which the trigger is defined.

## Example of Invoking a Trigger Procedure

The following example defines three tables and a trigger procedure that references one of these tables in its FOR clause:

```
CREATE TABLE tab1 (col1 INT,col2 INT);
CREATE TABLE tab2 (col1 INT);
CREATE TABLE temptab1
  (old_col1 INTt, new_col1 INT, old_col2 INT, new_col2 INT);

/* The following procedure is invoked from an INSERT trigger in this example.
*/
CREATE PROCEDURE proc1()
REFERENCING OLD AS o NEW AS n FOR tab1;

IF (INSERTING) THEN -- INSERTING Boolean operator
  LET n.col1 = n.col1 + 1; -- You can modify new values.
  INSERT INTO temptab1 VALUES(0,n.col1,1,n.col2);
END IF

IF (UPDATING) THEN -- UPDATING Boolean operator
  -- you can access relevant old and new values.
  INSERT INTO temptab1 values(o.col1,n.col1,o.col2,n.col2);
END IF

if (SELECTING) THEN -- SELECTING Boolean operator
  -- you can access relevant old values.
  INSERT INTO temptab1 VALUES(o.col1,0,o.col2,0);
END IF

if (DELETING) THEN -- DELETING Boolean operator
  DELETE FROM temptab1 WHERE temptab1.col1 = o.col1;
END IF

END PROCEDURE;
```

This example illustrates that the triggered action can be a different DML operation from the triggering event. Although this procedure inserts a row when an Insert trigger calls it, and deletes a row when a Delete trigger calls it, it also performs INSERT operations if it is called by a Select trigger or by an Update trigger.

The **proc1()** trigger procedure in this example uses Boolean conditional operators that are valid only in trigger routines. The **INSERTING** operator returns true only if the procedure is called from the **FOR EACH ROW** action of an **INSERT** trigger. This procedure can also be called from other triggers whose trigger event is an **UPDATE**, **SELECT**, or **DELETE** statement, because the **UPDATING**, **SELECTING** and **DELETING** operators return true ( **T** ) if the procedure is invoked in the triggered action of the corresponding type of triggering event.

The following statement defines an Insert trigger on **tab1** that calls **proc1()** from the **FOR EACH ROW** section as its triggered action, and perform an **INSERT** operation that activates this trigger:

```
CREATE TRIGGER ins_trig_tab1 INSERT ON tab1 REFERENCING NEW AS post
FOR EACH ROW(EXECUTE PROCEDURE proc1() WITH TRIGGER REFERENCES);
```

Note that the **REFERENCING** clause of the trigger declares a correlation name for the **NEW** value that is different from the correlation name that the trigger procedure declared. These names do not need to match, because the correlation name that was declared in the trigger procedure has that procedure as its scope of reference. The following statement activates the **ins\_trig\_tab1** trigger, which executes the **proc1()** procedure.

```
INSERT INTO tab1 VALUES (111,222);
```

Because the trigger procedure increments the new value of **col1** by 1, the value inserted is (112, 222), rather than the value that the triggering event specified.

## Dynamic Routine-Name Specification of SPL Procedures

*Dynamic routine-name specification* simplifies the writing of an SPL routine that calls another SPL routine whose name is not known until runtime.

To specify the name of an SPL routine in the **EXECUTE PROCEDURE** statement, instead of listing the explicit name of an SPL routine, you can use an SPL variable to hold the routine name.

If the SPL variable names an SPL routine that returns a value (an SPL function), include the **INTO** clause of **EXECUTE PROCEDURE** to specify a *receiving variable* (or variables) to hold the value (or values) that the SPL function returns. For more information on how to execute SPL procedures dynamically, see the *Informix® Guide to SQL: Tutorial*.

## FETCH statement

Use the **FETCH** statement to move a cursor to a new row in the active set and to retrieve the row values from memory.

Use this statement with Informix® ESQL/C and with SPL.

## Usage

Except as noted, sections that follow describe how to use the FETCH statement in Informix® ESQ/C routines. For information about the more restricted syntax and semantics of the FETCH statement in SPL routines, see [Fetching from Dynamic Cursors in SPL Routines on page 571](#).

How the database server creates, stores, and fetches members of the active set of rows depends on whether the cursor was declared as a sequential cursor or as a scroll cursor. All cursors that the FETCH statement can reference in SPL routines are sequential cursors.

In X/Open mode, if a cursor-direction value (such as `NEXT` or `RELATIVE`) is specified, a warning message is issued, indicating that the statement does not conform to X/Open standards.

## FETCH with a Sequential Cursor

A sequential cursor can fetch only the next row in sequence from the active set. The only option available is the default option, NEXT. A sequential cursor can read through a table only once each time the table is opened. The following Informix® ESQL/C example illustrates the FETCH statement with a sequential cursor:

```
EXEC SQL FETCH seq_curs INTO :fname, :lname;
EXEC SQL FETCH NEXT seq_curs INTO :fname, :lname;
```

When the program opens a sequential cursor, the database server processes the query to the point of locating or constructing the first row of data. The goal of the database server is to tie up as few resources as possible.

Because the sequential cursor can retrieve only the next row, the database server can frequently create the active set one row at a time.

On each FETCH operation, the database server returns the contents of the current row and locates the next row. This one-row-at-a-time strategy is not possible if the database server must create the entire active set to determine which row is the first row (as would be the case if the SELECT statement included an ORDER BY clause).

## FETCH with a Scroll Cursor

These Informix® ESQL/C examples illustrate the FETCH statement with a scroll cursor:

```
EXEC SQL fetch previous q_curs into :orders;
EXEC SQL fetch last q_curs into :orders;
EXEC SQL fetch relative -10 q_curs into :orders;
printf("Which row? ");
scanf("
EXEC SQL fetch absolute :row_num q_curs into :orders;
```

A scroll cursor can fetch any row in the active set, either by specifying an absolute row position or a relative offset. Use the following cursor-position options to specify a particular row that you want to retrieve.

### **Keyword**

#### **Effect**

#### **NEXT**

Retrieves next row in active set

#### **PREVIOUS**

Retrieves previous row in active set

#### **PRIOR**

Retrieves previous row in active set (Synonymous with PREVIOUS.)

**FIRST**

Retrieves the first row in active set

**LAST**

Retrieves the last row in active set

**CURRENT**

Retrieves the current row in active set (the same row as returned by the previous FETCH statement from the scroll cursor)

**RELATIVE**

Retrieves *n*th row, relative to the current cursor position in the active set, where *position\_num* (or *position\_num\_var*) supplies *n*. A negative value indicates the *n*th row prior to the current cursor position. If *position\_num* = 0, the current row is fetched.

**ABSOLUTE**

Retrieves *n*th row in active set, where *row\_position\_var* (or *row\_position*) = *n*. Absolute row positions are numbered from 1.

**Tip:** Do not confuse row-position values with **rowid** values. A **rowid** value is based on the position of a row in its table and remains valid until the table is rebuilt. A row-position value (a value that the ABSOLUTE keyword retrieves) is the relative position of the row in the current active set of the cursor; the next time the cursor is opened, different rows might be selected.

## How the Database Server Implements Scroll Cursors

Because it cannot anticipate which row the program will ask for next, the database server must retain all the rows in the active set until the scroll cursor closes. When a scroll cursor opens, the database server implements the active set as a temporary table, although it might not populate this table immediately.

The first time a row is fetched, the database server copies it into the temporary table as well as returning it to the program.

When a row is fetched for the second time, it can be taken from the temporary table. This scheme uses the fewest resources, in case the program abandons the query before it fetches all the rows. Rows that are never fetched are usually not copied from the database, or are saved in a temporary table.

## Specifying Where Values Go in Memory

Each value from the select list of the query or the output of the executed user-defined function must be returned into a memory location. You can specify these destinations in one of the following ways:

- Use the INTO clause of a SELECT statement.
- Use the INTO clause of an EXECUTE Function (or EXECUTE PROCEDURE) statement.
- Use the INTO clause of a FETCH statement.

- Use a system-descriptor area.
- Use an **sqllda** structure.

## Using the INTO Clause

If you associate a SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement with a Function cursor, the statement can contain an INTO clause to specify variables to receive the returned values. You can use this method only when you write the SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE statement as part of the cursor declaration; see [DECLARE statement on page 467](#). In this case, the FETCH statement cannot contain an INTO clause.

The following example uses the INTO clause of the SELECT statement to specify program variables in Informix® ESQL/C:

```
EXEC SQL declare ord_date cursor for
  select order_num, order_date, po_num
     into :o_num, :o_date, :o_po;
EXEC SQL open ord_date;
EXEC SQL fetch next ord_date;
```

If you prepare a SELECT statement, the SELECT *cannot* include the INTO clause so you must use the INTO clause of the FETCH statement.

When you create a SELECT statement dynamically, you cannot use an INTO clause because you cannot name host variables in a prepared statement.

If you are certain of the number and data type of values in the projection list, you can use an INTO clause in the FETCH statement. If user input generated the query, however, you might not be certain of the number and data type of values that are being selected. In this case, you must use either a system descriptor or else a pointer to an **sqllda** structure.

## Using Indicator Variables

Use an indicator variable if the returned data might be null.

The *indicator\_var* parameter is optional, but use an indicator variable if the possibility exists that the value of *output\_var* is NULL.

If you specify the indicator variable without the INDICATOR keyword, you cannot put a blank space between *output\_var* and *indicator\_var*.

For information about rules for placing a prefix before the *indicator\_var*, see the *Informix® ESQL/C Programmer's Manual*.

The host variable cannot be a DATETIME or INTERVAL data type.

## When the INTO Clause of FETCH is Required

When SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) omits the INTO clause, you must specify a data destination when a row is fetched.

For example, to dynamically execute a SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement, the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) cannot include its INTO clause in the PREPARE statement. Therefore, the FETCH statement must include an INTO clause to retrieve data into a set of variables. This method lets you store different rows in different memory locations.

You can fetch into a program-array element only by using an INTO clause in the FETCH statement. If you use a program array, you must list both the array name and a specific element of the array in *data\_structure*. When you are declaring a cursor, do not refer to an array element within the SQL statement.

**Tip:** If you are certain of the number and data type of values in the select list of the Projection clause, you can use an INTO clause in the FETCH statement.

In the following Informix® ESQL/C example, a series of complete rows is fetched into a program array. The INTO clause of each FETCH statement specifies an array element as well as the array name:

```
EXEC SQL BEGIN DECLARE SECTION;
char wanted_state[2];
short int row_count = 0;
struct customer_t{
{
int    c_no;
char   fname[15];
char   lname[15];
} cust_rec[100];
EXEC SQL END DECLARE SECTION;

main()
{
EXEC SQL connect to 'stores_demo';
printf("Enter 2-letter state code: ");
scanf ("%s", wanted_state);
EXEC SQL declare cust cursor for
select * from customer where state = :wanted_state;
EXEC SQL open cust;
EXEC SQL fetch cust into :cust_rec[row_count];
while (SQLCODE == 0)
{
printf("\n%s %s", cust_rec[row_count].fname,
cust_rec[row_count].lname);
row_count++;
EXEC SQL fetch cust into :cust_rec[row_count];
}
printf ("\n");
EXEC SQL close cust;
EXEC SQL free cust;
}
```

## Using a System-Descriptor Area (X/Open)

You can use a system-descriptor area to store output values when you do not know the number of return values or their data types that a SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement returns at runtime. A system-descriptor area describes the data type and memory location of one or more return values, and conforms to the X/Open standards.

The keywords USING SQL DESCRIPTOR introduce the name of the system-descriptor area into which you fetch the contents of a row or the return values of a user-defined function. You can then use the GET DESCRIPTOR statement to transfer the values that the FETCH statement returns from the system-descriptor area into host variables.

The following example shows a valid FETCH...USING SQL DESCRIPTOR statement:

```
EXEC SQL allocate descriptor 'desc';
...
EXEC SQL declare selcurs cursor for
  select * from customer where state = 'CA';
EXEC SQL describe selcurs using sql descriptor 'desc';
EXEC SQL open selcurs;
while (1)
  {
    EXEC SQL fetch selcurs using sql descriptor 'desc';
```

You can also use an **sqlda** structure to supply parameters dynamically.

## Using sqlda Structures

You can use a pointer to an **sqlda** structure to store output values when you do not know the number of values or their data types that a SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement returns.

This structure contains data descriptors that specify the data type and memory location for one selected value. The keywords USING DESCRIPTOR introduce the name of the pointer to the **sqlda** structure.

**Tip:** If you know the number and data types of all values in the select list, you can use an INTO clause in the FETCH statement. For more information, see [When the INTO Clause of FETCH is Required on page 566](#).

To specify an **sqlda** structure as the location of parameters:

1. Declare an **sqlda** pointer variable.
2. Use the DESCRIBE statement to fill in the **sqlda** structure.
3. Allocate memory to hold the data values.
4. Use the USING DESCRIPTOR clause of FETCH to specify the **sqlda** structure as the location into which you fetch the returned values.

The following example shows a FETCH USING DESCRIPTOR statement:

```
struct sqlda *sqlda_ptr;
...
EXEC SQL declare selcurs2 cursor for
  select * from customer where state = 'CA';
EXEC SQL describe selcurs2 into sqlda_ptr;
...
EXEC SQL open selcurs2;
while (1)
  {
    EXEC SQL fetch selcurs2 using descriptor sqlda_ptr;
    ...
```

The **sqlda** value specifies the number of output values that are described in occurrences of the **sqlvar** structures of the **sqlda** structure. This number must correspond to the number of values returned from the prepared statement.

## Fetching a Row for Update

The `FETCH` statement does not ordinarily lock a row that is fetched. Thus, another process can modify (update or delete) the fetched row immediately after your program receives it. A fetched row is locked in the following cases:

- When you set the isolation level to Repeatable Read, each row that you fetch is locked with a read lock until the cursor closes or until the current transaction ends. Other programs can also read the locked rows.
- When you set the isolation level to Cursor Stability, the current row is locked.
- In an ANSI-compliant database, an isolation level of Repeatable Read is the default; you can set it to something else.
- When you are fetching through an update cursor (one that is declared `FOR UPDATE`), each row you fetch is locked with a promotable lock. Other programs can read the locked row, but no other program can place a promotable or write lock; therefore, the row is unchanged if another user tries to modify it using the `WHERE CURRENT OF` clause of an `UPDATE` or `DELETE` statement.

When you modify a row, the lock is upgraded to a write lock and remains until the cursor is closed or the transaction ends. If you do not modify the row, the behavior of the database server depends on the isolation level you have set. The database server releases the lock on an unchanged row as soon as another row is fetched, unless you are using Repeatable Read isolation. (See [SET ISOLATION statement on page 974](#).)

**Important:** You can hold locks on additional rows even when Repeatable Read isolation is not in use or is unavailable. Update the row with unchanged data to hold it locked while your program is reading other rows. You must evaluate the effect of this technique on performance in the context of your application, and you must be aware of the increased potential for deadlock.

When you use explicit transactions, be sure that a row is both fetched and modified within a single transaction; that is, both the `FETCH` statement and the subsequent `UPDATE` or `DELETE` statement must fall between a `BEGIN WORK` statement and the next `COMMIT WORK` statement.

## Fetching from a Collection Cursor

A Collection cursor allows you to access the individual elements of Informix® ESQL/C collection variables. To declare a Collection cursor, use the `DECLARE` statement and include the Collection-Derived Table segment in the `SELECT` statement that you associate with the cursor. After you open the collection cursor with the `OPEN` statement, the cursor allows you to access the elements of the collection variable.

To fetch elements, one at a time, from a Collection cursor, use the `FETCH` statement and the `INTO` clause. The `FETCH` statement identifies the Collection cursor that is associated with the collection variable. The `INTO` clause identifies the host variable that holds the element value that is fetched from the Collection cursor. The data type of the host variable in the `INTO` clause must match the element type of the collection.

Suppose you have a table called **children** with the following structure:

```
CREATE TABLE children
(
  age          SMALLINT,
```

```

name          VARCHAR(30),
fav_colors    SET(VARCHAR(20) NOT NULL),
)

```

The following Informix® ESQL/C code fragment shows how to fetch elements from the **child\_colors** collection variable:

```

EXEC SQL BEGIN DECLARE SECTION;
  client collection child_colors;
  varchar one_favorite[21];
  char child_name[31] = "marybeth";
EXEC SQL END DECLARE SECTION;
EXEC SQL allocate collection :child_colors;
/* Get structure of fav_colors column for untyped
 * child_colors collection variable */
EXEC SQL select fav_colors into :child_colors
  from children
  where name = :child_name;
/* Declare select cursor for child_colors collection
 * variable */
EXEC SQL declare colors_curs cursor for
  select * from table(:child_colors);
EXEC SQL open colors_curs;
do
{
  EXEC SQL fetch colors_curs into :one_favorite;
  ...
} while (SQLCODE == 0)
EXEC SQL close colors_curs;
EXEC SQL free colors_curs;
EXEC SQL deallocate collection :child_colors;

```

After you fetch a collection element, you can modify the element with the UPDATE or DELETE statements. For more information, see the UPDATE and DELETE statements in this document. You can also insert new elements into the collection variable with an INSERT statement. For more information, see the INSERT statement.

## Checking the Result of FETCH

You can use the **SQLSTATE** variable to check the result of each FETCH statement. The database server sets the **SQLSTATE** variable after each SQL statement. If a row is returned successfully, the **SQLSTATE** variable contains the value `00000`. If no row is found, the database server sets the **SQLSTATE** code to `02000`, which indicates `no data found`, and the current row is unchanged. The following conditions set the **SQLSTATE** code to `02000`, indicating `no data found`:

- The active set contains no rows.
- You issue a FETCH NEXT statement when the cursor points to the last row in the active set or points past it.
- You issue a FETCH PRIOR or FETCH PREVIOUS statement when the cursor points to the first row in the active set.
- You issue a FETCH RELATIVE *n* statement when no *n*th row exists in the active set.
- You issue a FETCH ABSOLUTE *n* statement when no *n*th row exists in the active set.

The database server copies the **SQLSTATE** code from the **RETURNED\_SQLSTATE** field of the system-diagnostics area. Client-server communication protocols of Informix®, such as SQLI and DRDA®, support **SQLSTATE** code values. For a list of these codes, and for information about how to get the message text, see [Using the SQLSTATE Error Status Code on](#)

[page 582](#). You can use the GET DIAGNOSTICS statement to examine the **RETURNED\_SQLSTATE** field directly. The system-diagnostics area can also contain additional error information.

You can also use **SQLCODE** variable of the SQL Communications Area (**sqlca**) to determine the same results.

## Fetching from Dynamic Cursors in SPL Routines

Use the FETCH statement in an SPL routine to retrieve the next row of the active set of a specified dynamic cursor into an ordered list of SPL variables that were declared in the same SPL routine.

### Syntax

The syntax of the FETCH statement in SPL routines is a subset of the syntax that FETCH supports in Informix® ESQL/C routines.

#### FETCH *cursor\_id* INTO

, *output\_var*

| Element           | Description   | Restrictions  | Syntax                                  |
|-------------------|---|---|---|
| <i>cursor_id</i>  | Name of a dynamic cursor                              | Must be open and must have been declared in the same SPL routine  | <a href="#">Identifier on page 1456</a> |
| <i>output_var</i> | An SPL variable to store a fetched value from the row | Must have been declared locally or globally in the calling context, and must be of a data type compatible with the fetched column value | <a href="#">Identifier on page 1456</a> |

Just as in ESQL/C routines, the list of output variables must correspond in number, order, and data type with column values that the SQL statement associated with the rows returned by the specified cursor.

All SPL cursors are sequential cursors. Your UDR must include logic to detect the end of the active set of the cursor, because the NOTFOUND condition does not automatically raise an exception in SPL.

The built-in **SQLCODE** function, which can only be called from SPL routines, can return the status code of a FETCH operation.

All other restrictions of ESQL/C on FETCH statements that reference sequential Select or Function cursors also apply to FETCH operations in SPL.

The FETCH statement in SPL routines does not support the following ESQL/C features:

- cursor names specified as host variables
- positional specifications or positional keywords (which require scroll cursors)
- the USING clause with descriptors or with **sqlda** pointers.

In the SPL language, indicator variables are not needed. If the FETCH operation retrieves a NULL value, the SPL variable that receives that fetched value is set to NULL.

The FETCH statement can reference only dynamic cursors that the DECLARE statement defined. The *cursor\_id* cannot specify the name of a direct cursor that the FOREACH statement of SPL declared.

## FLUSH statement

Use the FLUSH statement to force rows that a PUT statement buffered to be written to the database.

### Syntax

#### FLUSH

*cursor\_id cursor\_id\_var*

| Element              | Description   | Restrictions                  | Syntax                                  |
|----------------------|---|-------------------------------|---|
| <i>cursor_id</i>     | Name of a cursor  | Must have been declared       | <a href="#">Identifier on page 1456</a> |
| <i>cursor_id_var</i> | Host variable that holds the value of<br><i>cursor_id</i> | Must be a character data type | Language specific                       |

### Usage

Use this statement, which is an extension to the ANSI/ISO standard for SQL, with Informix® ESQL/C.

The PUT statement adds a row to a buffer, whose content is written to the database when the buffer is full. Use the FLUSH statement to force the insertion when the buffer is not full.

If the program terminates without closing the cursor, the buffer is left unflushed. Rows placed into the buffer since the last flush are lost. Do not expect the end of the program to close the cursor and flush the buffer automatically. The following example shows a FLUSH statement that operates on a cursor called **icurs**:

```
FLUSH icurs
```

### Example

The following example assumes that a function named *next\_cust* returns either information about a new customer or null data to signal the end of input:

```
EXEC SQL BEGIN WORK;
EXEC SQL OPEN new_custs;

while(SQLCODE == 0)
{
  next_cust();
  if(the_company == NULL)
    break;

  EXEC SQL PUT new_custs;
}

if(SQLCODE == 0) /* if no problem with PUT */
{
  EXEC SQL FLUSH new_custs;
  /* write any rows left */

  if(SQLCODE == 0) /* if no problem with FLUSH */
    EXEC SQL COMMIT WORK; /* commit changes */
```

```

}
else
EXEC SQL ROLLBACK WORK; /* else undo changes */

```

The code in this example calls `next_cust` repeatedly. When it returns non-null data, the **PUT** statement sends the returned data to the row buffer. When the buffer fills, the rows it contains are automatically sent to the database server. The loop normally ends when `next_cust` has no more data to return.

---

[CLOSE statement on page 179](#)

[DECLARE statement on page 467](#)

[OPEN statement on page 677](#)

[PREPARE statement on page 687](#)

[INSERT statement on page 638](#)

## Error Checking FLUSH Statements

The SQL Communications Area (**sqlca**) structure contains information on the success of each FLUSH statement and the number of rows that are inserted successfully. The result of each FLUSH statement is described in the fields of the **sqlca**: **sqlca.sqlcode**, **SQLCODE**, and **sqlca.sqlerrd[2]**.

When you use data buffering with an Insert cursor, you do not discover errors until the buffer is flushed. For example, an input value that is incompatible with the data type of the column for which it is intended is discovered only when the buffer is flushed. When an error is discovered, any rows in the buffer that are located after the error are *not* inserted; they are lost from memory.

The **SQLCODE** field is set either to an error code or to zero (0) if no error occurs. The third element of the **SQLERRD** array is set to the number of rows that are successfully inserted into the database:

- If a block of rows is successfully inserted into the database, **SQLCODE** is set to zero (0) and **SQLERRD** to the count of rows.
- If an error occurs while the FLUSH statement is inserting a block of rows, **SQLCODE** shows which error, and **SQLERRD** contains the number of rows that were successfully inserted. (Uninserted rows are discarded from the buffer.)

**Tip:** When you encounter an **SQLCODE** error, a corresponding **SQLSTATE** error value also exists. Client-server communication protocols of Informix®, such as SQLI and DRDA®, support **SQLSTATE** code values. For a list of these codes, and for information about how to get the message text, see [Using the SQLSTATE Error Status Code on page 582](#).

**To count the number of rows actually inserted into the database as well as the number not yet inserted**

1. Prepare two integer variables, for example, **total** and **pending**.
2. When the cursor opens, set both variables to 0.
3. Each time a PUT statement executes, increment both **total** and **pending**.
4. Whenever a FLUSH statement executes or the cursor is closed, subtract the third field of the **SQLERRD** array from **pending**.

## FREE statement

Use the FREE statement to release resources that are allocated to a prepared statement or to a cursor.

### Syntax

#### FREE

*cursor\_id statement\_id*

<sup>283</sup> *cursor\_id\_var statement\_id\_var*

| Element                 | Description   | Restrictions                                    | Syntax  |
|-------------------------|---|---|---|
| <i>cursor_id</i>        | Name of a cursor  | Must have been declared                         | <a href="#">Identifier on page 1456</a>       |
| <i>cursor_id_var</i>    | Host variable that holds the value of <i>cursor_id</i>  | Must be a character data type                   | Language specific                             |
| <i>statement_id</i>     | Identifier of a prepared SQL statement                  | Must be defined in a previous PREPARE statement | <a href="#">PREPARE statement on page 687</a> |
| <i>statement_id_var</i> | Host variable that stores the name of a prepared object | Must be declared as a character data type.      | <a href="#">PREPARE statement on page 687</a> |

### Usage

Use this statement, which is an extension to the ANSI/ISO standard for SQL, with Informix® ESQL/C or with SPL.

FREE releases the resources that the database server and (for ESQL/C) the application-development tool allocated for a prepared statement or for a cursor.

If you declared a cursor for a prepared statement, FREE *statement\_id* (or *statement\_id\_var*) releases only the resources in the application development tool; the cursor can still be used. The resources in the database server are released only when you free the cursor.

If you prepared a statement (but did not declare a cursor for it), FREE *statement\_id* (or FREE *statement\_id\_var*) releases the resources in both the application development tool and the database server.

After you free a statement, you cannot execute it or declare a cursor for it until you prepare it again.

The following Informix® ESQL/C example shows the sequence of statements that is used to free an implicitly prepared statement:

283. ESQL/C only

```
EXEC SQL prepare sel_stmt from 'select * from orders';
...
EXEC SQL free sel_stmt;
```

The following Informix® ESQL/C example shows the sequence of statements that are used to release the resources of an explicitly prepared statement. The first FREE statement in this example frees the cursor. The second FREE statement in this example frees the prepared statement.

```
sprintf(demoselect, "%s %s",
  "select * from customer ",
  "where customer_num between 100 and 200");
EXEC SQL prepare sel_stmt from :demoselect;
EXEC SQL declare sel_curs cursor for sel_stmt;
EXEC SQL open sel_curs;
...
EXEC SQL close sel_curs;
EXEC SQL free sel_curs;
EXEC SQL free sel_stmt;
```

If you declared a cursor for a prepared statement, freeing the cursor releases only the resources in the database server. To release the resources for the statement in the application-development tool, use `FREE statement_id` (or `FREE statement_id_var`). If a cursor is not declared for a prepared statement, freeing it releases the resources in both the application-development tool and the database server. For an ESQL/C example of a FREE statement that frees a cursor, see the previous example.

After a cursor is freed, it cannot be opened until it is declared again. The cursor should be explicitly closed before it is freed.

When an SPL routine completes execution, the database server automatically releases any resources that had been allocated to the cursor or to prepared statements by PREPARE or DECLARE statements in the routine, if these have not already been released by the FREE statement.

The FREE statement in SPL routines cannot reference the *cursor\_id* of a direct cursor that the FOREACH statement of SPL can declare.

| Element                | Description  | Restrictions  | Syntax                                      |
|------------------------|--|---|---|
| <i>descriptor</i>      | Quoted string that identifies a system-descriptor area (SDA)   | System-descriptor area must already have been allocated         | <a href="#">Quoted String on page 1424</a>  |
| <i>descriptor_var</i>  | Variable that stores <i>descriptor</i> value                   | Same restrictions as <i>descriptor</i>                          | Language specific                           |
| <i>field_var</i>       | Host variable to receive the contents of a field from an SDA   | Must be of type that can receive value of a specified SDA field | Language specific                           |
| <i>item_num</i>        | Unsigned ordinal number of an item described in the SDA        | 0 <i>item_num</i> (number of item descriptors in the SDA)       | <a href="#">Literal Number on page 1419</a> |
| <i>item_num_var</i>    | Host variable storing <i>item_num</i>                          | Must be an integer data type                                    | Language specific                           |
| <i>total_items_var</i> | Host variable storing the number of items described in the SDA | Must be an integer data type                                    | Language specific                           |

**Usage**

Use this statement with Informix® ESQL/C.

Use the GET DESCRIPTOR statement to accomplish any of the following tasks:

- Determine how many items are described in a system-descriptor area.
- Determine the characteristics of each column or expression that is described in the system-descriptor area.
- Copy a value from the system-descriptor area into a host variable after a FETCH statement.

You can use GET DESCRIPTOR after you describe EXECUTE FUNCTION, INSERT, SELECT, or UPDATE statements with the DESCRIBE . . . USING SQL DESCRIPTOR statement.

The host variables that you reference in the GET DESCRIPTOR statement must be declared in the BEGIN DECLARE SECTION of a program.

284. Informix® extension

If an error occurs during the assignment of a value to any specified host variable, the contents of the host variable are undefined.

## Examples

The following ESQL/C example shows how to use a GET DESCRIPTOR statement with a host variable to determine how many items are described in the system-descriptor area called desc1: GET DESCRIPTOR

```
main()
{
  EXEC SQL BEGIN DECLARE SECTION;
  int h_count;
  EXEC SQL END DECLARE SECTION;

  EXEC SQL allocate descriptor 'desc1' with max 20;

  /* This section of program would prepare a SELECT or INSERT
  * statement into the s_id statement id.
  */

  EXEC SQL describe s_id using sql descriptor 'desc1';
  EXEC SQL get descriptor 'desc1' :h_count = count;
```

The following ESQL/C example uses GET DESCRIPTOR to obtain data type information from the demodesc system-descriptor area:

```
EXEC SQL get descriptor 'demodesc' value
:index :type = TYPE,
:len = LENGTH,
:name = NAME;
printf("Column %d: type = %d, len = %d, name = %s\n",
index, type, len, name);
```

The following ESQL/C example shows how you can copy data from the DATA field into a host variable (result) after a fetch. For this example, it is predetermined that all returned values are the same data type:

```
EXEC SQL get descriptor 'demodesc' :desc_count = count;
. . .
EXEC SQL fetch democursor using sql descriptor 'demodesc';
for (i = 1; i <= desc_count; i++)
{
  if (sqlca.sqlcode != 0) break;
  EXEC SQL get descriptor 'demodesc' value :i :result = DATA;
  printf("%s ", result);
}
printf("\n");
```

---

## Using the COUNT Keyword

Use the COUNT keyword to determine how many items are described in the system-descriptor area.

The following Informix® ESQL/C example shows how to use a GET DESCRIPTOR statement with a host variable to determine how many items are described in the system-descriptor area called **desc1**:

```
main()
{
EXEC SQL BEGIN DECLARE SECTION;
int h_count;
EXEC SQL END DECLARE SECTION;

EXEC SQL allocate descriptor 'desc1' with max 20;

/* This section of program would prepare a SELECT or INSERT
 * statement into the s_id statement id.
 */
EXEC SQL describe s_id using sql descriptor 'desc1';

EXEC SQL get descriptor 'desc1' :h_count = count;
...
}
```

## Using the VALUE Clause

Use the VALUE clause to obtain information about a described column or expression or to retrieve values that the database server returns in a system descriptor area.

The *item\_num* must be greater than zero (0) but not greater than the number of item descriptors that were specified when the system-descriptor area was allocated with the ALLOCATE DESCRIPTOR statement.

## Using the VALUE Clause After a DESCRIBE

After you describe a SELECT, EXECUTE FUNCTION (or EXECUTE PROCEDURE), INSERT, or UPDATE statement, the characteristics of each column or expression in the select list of the SELECT statement, the characteristics of the values returned by the EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement, or the characteristics of each column in an

INSERT or UPDATE statement are returned to the system-descriptor area. Each value in the system-descriptor area describes the characteristics of one returned column or expression.

The following Informix® ESQL/C example uses GET DESCRIPTOR to obtain data type information from the **demodesc** system-descriptor area:

```
EXEC SQL get descriptor 'demodesc' value :index
        :type = TYPE,
        :len = LENGTH,
        :name = NAME;
printf("Column %d: type = %d, len = %d, name = %s\n",
        index, type, len, name);
```

The value that the database server returns into the TYPE field is a defined integer. To evaluate the data type that is returned, test for a specific integer value. For additional information about integer data type values, see [Setting the TYPE or ITYPE Field on page 892](#).

In X/Open mode, the X/Open code is returned to the TYPE field. You cannot mix the two modes because errors can result. For example, if a particular data type is not defined under X/Open mode but is defined for Informix® products, executing a GET DESCRIPTOR statement can result in an error.

In X/Open mode, a warning message appears if ILENGTH, IDATA, or ITYPE is used. It indicates that these fields are not standard X/Open fields for a system-descriptor area.

If the TYPE of a fetched value is DECIMAL or MONEY, the database server returns the precision and scale information for a column into the PRECISION and SCALE fields after a DESCRIBE statement is executed. If the TYPE is *not* DECIMAL or MONEY, the SCALE and PRECISION fields are undefined.

## Using the VALUE Clause After a FETCH

Each time your program fetches a row, it must copy the fetched value into host variables so that the data can be used. To accomplish this task, use a GET DESCRIPTOR statement after each fetch of each value in the select list. If three values exist in the select list, you need to use three GET DESCRIPTOR statements after each fetch (assuming you want to read all three values). The item numbers for each of the three GET DESCRIPTOR statements are 1, 2, and 3.

The following Informix® ESQL/C example shows how you can copy data from the DATA field into a host variable (**result**) after a fetch. For this example, it is predetermined that all returned values are the same data type:

```
EXEC SQL get descriptor 'demodesc' :desc_count = count;
. . .
EXEC SQL fetch democursor using sql descriptor 'demodesc';
for (i = 1; i <= desc_count; i++)
{
    if (sqlca.sqlcode != 0) break;
    EXEC SQL get descriptor 'demodesc' value :i :result = DATA;
    printf("%s ", result);
}
printf("\n");
```

## Fetching a NULL Value

When you use GET DESCRIPTOR after a fetch, and the fetched value is NULL, the INDICATOR field is set to `-1` to indicate the NULL value. The value of DATA is undefined if INDICATOR indicates a NULL value. The host variable into which DATA is copied has an unpredictable value.

## Using LENGTH or ILENGTH

If your DATA or IDATA field contains a character string, you must specify a value for LENGTH. If you specify `LENGTH=0`, LENGTH is automatically set to the maximum length of the string. The DATA or IDATA field might contain a literal character string or a character string that is derived from a character variable of CHAR or VARCHAR data type. This provides a method to determine the length of a string in the DATA or IDATA field dynamically.

If a DESCRIBE statement precedes a GET DESCRIPTOR statement, LENGTH is automatically set to the maximum length of the character field that is specified in your table.

This information is identical for ILENGTH. Use ILENGTH when you create a dynamic program that does not comply with the X/Open standard.

## Describing an Opaque-Type Column

The DESCRIBE statement sets the following item-descriptor fields when the column to fetch has an opaque type as its data type:

- The EXTTYPEID field stores the extended ID for the opaque type. This integer is the value in the corresponding **extended\_id** column of the **sysxdtypes** system catalog table.
- The EXTYPENAME field stores the name of the opaque type. This character value is the value in the **name** column of the row with the matching **extended\_id** value in the **sysxdtypes** system catalog table.
- The EXTYPELENGTH field stores the length of the opaque-type name. This integer is the length of the data type name (in bytes).
- The EXTTYPEOWNERNAME field stores the name of the opaque-type owner. This character value is the value in the **owner** column of the row with the matching **extended\_id** value in the **sysxdtypes** system catalog table.
- The EXTTYPEOWNERLENGTH field stores the length of the value in the EXTTYPEOWNERNAME field. This integer is the length, in bytes, of the name of the owner of the opaque type.

Use these field names with the GET DESCRIPTOR statement to obtain information about an opaque column.

## Describing a Distinct-Type Column

The DESCRIBE statement sets the following item-descriptor fields when the column to fetch has a distinct type as its data type:

- The SOURCEID field stores the extended identifier for the source data type.

This integer has the value of the **source** column for the row of the **sysxdtypes** system catalog table whose **extended\_id** value matches that of the distinct data type. This field is set only if the source data type is an opaque data type.

- The SOURCETYPE field stores the data type constant for the source data type.

This value is the data type constant (from the **sqltypes.h** file) for the data type of the source type for the DISTINCT data type. The codes for the SOURCETYPE field are listed in the description of the TYPE field in the SET DESCRIPTOR statement. (For more information, see [Setting the TYPE or ITYPE Field on page 892](#).) This integer value must correspond to the value in the **type** column for the row of the **sysxdtypes** system catalog table whose **extended\_id** value matches that of the DISTINCT data type.

Use these field names with the GET DESCRIPTOR statement to obtain information about a distinct-type column.

## GET DIAGNOSTICS statement

Use the GET DIAGNOSTICS statement to return diagnostic information about the most recently executed SQL statement.

### Syntax

#### GET DIAGNOSTICS

Statement Clause<sup>285</sup>

EXCEPTION Clause<sup>286</sup>

### Usage

Use this statement with Informix® ESQL/C.

The GET DIAGNOSTICS statement retrieves specified status information that the database server records in a structure called the *diagnostics area*. Using GET DIAGNOSTICS does not change the contents of the diagnostics area.

The GET DIAGNOSTICS statement uses one of the following two clauses:

- The Statement clause returns count and overflow information about errors and warnings that the most recent SQL statement generates.
- The EXCEPTION clause provides specific information about errors and warnings that the most recent SQL statement generates.

## Using the SQLSTATE Error Status Code

When an SQL statement executes, an error status code is automatically generated. This code represents `success`, `failure`, `warning`, or `no data found`. This error status code is stored in a built-in variable called **SQLSTATE**.

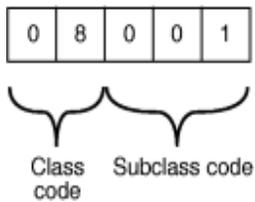

### Class and Subclass Codes

The **SQLSTATE** status code is a five-character string that can contain only digits and uppercase letters.

The first two characters of the **SQLSTATE** status code indicate a class. The last three characters of the **SQLSTATE** code indicate a subclass. [Figure 5: Structure of the SQLSTATE Code on page 582](#) shows the structure of the **SQLSTATE** code.

This example uses the value `08001`, where `08` is the class code and `001` is the subclass code. The value `08001` represents the error `unable to connect with database environment`.

Figure 5. Structure of the SQLSTATE Code

The following table is a quick reference for interpreting class code values.

#### SQLSTATE Class Code Value

##### Outcome

**00**

Success

**01**

Success with warning

**02**

No data found

**> 02**

Error or warning

## SQLSTATE Support for the ANSI/ISO Standard for SQL

All status codes returned to the **SQLSTATE** variable are ANSI-compliant except in the following cases:

- **SQLSTATE** codes with a class code of 01 and a subclass code that begins with an I are Informix®-specific warning messages.
- **SQLSTATE** codes with a class code of IX and any subclass code are Informix®-specific error messages.
- **SQLSTATE** codes whose class code begins with a digit in the range 5 to 9 or with an uppercase letter in the range I to Z indicate conditions that are currently undefined by the ANSI/ISO standard for SQL. The only exception is that **SQLSTATE** codes whose class code is IX are Informix®-specific error messages.

Client-server communication protocols of Informix®, such as SQLI and DRDA®, support these **SQLSTATE** code values.

## List of SQLSTATE Codes

This table describes the class codes, subclass codes, and the meaning of all valid warning and error codes associated with the **SQLSTATE** variable.

| Class | Subclass | Meaning  |
|-------|----------|--|
| 00    | 000      | Success.   |
| 01    | 000      | Success with warning.  |
| 01    | 002      | Disconnect error. Transaction rolled back.                               |
| 01    | 003      | NULL value eliminated in set function.                                   |
| 01    | 004      | String data, right truncation.   |
| 01    | 005      | Insufficient item descriptor areas.                                      |
| 01    | 006      | Privilege not revoked.   |
| 01    | 007      | Privilege not granted.   |
| 01    | I01      | Database has transactions.   |
| 01    | I03      | ANSI-compliant database selected.  |
| 01    | I04      | HCL Informix® database server selected.                                  |
| 01    | I05      | Float to decimal conversion was used.                                    |
| 01    | I06      | Informix® extension to ANSI-compliant syntax.                            |
| 01    | I07      | UPDATE or DELETE statement does not have a WHERE clause.                 |
| 01    | I08      | An ANSI keyword was used as a cursor name.                               |
| 01    | I09      | Cardinalities of the projection list and of the INTO list are not equal. |
| 01    | I10      | Database server running in secondary mode.                               |
| 01    | I11      | Dataskip is turned on.   |

| <b>Class</b> | <b>Subclass</b> | <b>Meaning</b>                                      |
|--------------|-----------------|---|
| 02           | 000             | No data found.                                      |
| 07           | 000             | Dynamic SQL error.                                  |
| 07           | 001             | USING clause does not match dynamic parameters.     |
| 07           | 002             | USING clause does not match target specifications.  |
| 07           | 003             | Cursor specification cannot be executed.            |
| 07           | 004             | USING clause is required for dynamic parameters.    |
| 07           | 005             | Prepared statement is not a cursor specification.   |
| 07           | 006             | Restricted data type attribute violation.           |
| 07           | 008             | Invalid descriptor count.                           |
| 07           | 009             | Invalid descriptor index.                           |
| 08           | 000             | Connection exception.                               |
| 08           | 001             | Database server rejected the connection.            |
| 08           | 002             | Connection name in use.                             |
| 08           | 003             | Connection does not exist.                          |
| 08           | 004             | Client unable to establish connection.              |
| 08           | 006             | Transaction rolled back.                            |
| 08           | 007             | Transaction state unknown.                          |
| 08           | S01             | Communication failure.                              |
| 0A           | 000             | Feature not supported.                              |
| 0A           | 001             | Multiple server transactions.                       |
| 21           | 000             | Cardinality violation.                              |
| 21           | S01             | Insert value list does not match column list.       |
| 21           | S02             | Degree of derived table does not match column list. |
| 22           | 000             | Data exception.                                     |
| 22           | 001             | String data, right truncation.                      |
| 22           | 002             | NULL value, no indicator parameter.                 |
| 22           | 003             | Numeric value out of range.                         |
| 22           | 005             | Error in assignment.                                |

| <b>Class</b> | <b>Subclass</b> | <b>Meaning</b>  |
|--------------|-----------------|---|
| 22           | 027             | Data exception trim error.  |
| 22           | 012             | Division by zero (0).   |
| 22           | 019             | Invalid escape character.   |
| 22           | 024             | Unterminated string.  |
| 22           | 025             | Invalid escape sequence.  |
| 23           | 000             | Integrity constraint violation.                                   |
| 24           | 000             | Invalid cursor state.   |
| 25           | 000             | Invalid transaction state.  |
| 2B           | 000             | Dependent privilege descriptors still exist.                      |
| 2D           | 000             | Invalid transaction termination.                                  |
| 26           | 000             | Invalid SQL statement identifier.                                 |
| 2E           | 000             | Invalid connection name.  |
| 28           | 000             | Invalid user-authorization specification.                         |
| 33           | 000             | Invalid SQL descriptor name.                                      |
| 34           | 000             | Invalid cursor name.  |
| 35           | 000             | Invalid exception number.   |
| 37           | 000             | Syntax error or access violation in PREPARE or EXECUTE IMMEDIATE. |
| 3C           | 000             | Duplicate cursor name.  |
| 40           | 000             | Transaction rollback.   |
| 40           | 003             | Statement completion unknown.                                     |
| 42           | 000             | Syntax error or access violation.                                 |
| S0           | 000             | Invalid name.   |
| S0           | 001             | Base table or view table already exists.                          |
| S0           | 002             | Base table not found.   |
| S0           | 011             | Index already exists.   |
| S0           | 021             | Column already exists.  |
| S1           | 001             | Memory allocation failure.  |
| IX           | 000             | Informix® reserved error message.                                 |

## Using SQLSTATE in Applications

You can use a built-in variable, called **SQLSTATE**, which you do not need to declare in your program. **SQLSTATE** contains the status code, essential for error handling, which is generated every time your program executes an SQL statement. **SQLSTATE** is created automatically. You can examine the **SQLSTATE** variable to determine whether an SQL statement was successful. If the **SQLSTATE** variable indicates that the statement failed, you can execute a GET DIAGNOSTICS statement to obtain additional error information.

For an example of how to use an **SQLSTATE** variable in a program, see [Using GET DIAGNOSTICS for Error Checking on page 591](#).

## Statement Clause

Statement Clause

, *status\_var* =

**ROW\_COUNT NUMBER MORE**

| Element           | Description   | Restrictions                      | Syntax            |
|-------------------|---|-----------------------------------|-------------------|
| <i>status_var</i> | Host variable to receive status information about the most recent SQL statement for the specified status field name | Must match data type of the field | Language specific |

When retrieving count and overflow information, GET DIAGNOSTICS can deposit the values of the three statement fields into a corresponding host variable. The host-variable data type must be the same as that of the requested field. The following keywords represent these three fields.

| Field Name Keyword | Field Data Type | Field Contents   | ESQL/C Host Variable Data Type |
|--------------------|-----------------|------------------|--------------------------------|
| MORE               | Character       | Y or N           | char[2]                        |
| NUMBER             | Integer         | 1 to 35,000      | int                            |
| ROW_COUNT          | Integer         | 0 to 999,999,999 | int                            |

## Using the MORE Keyword

Use the MORE keyword to determine if the most recently executed SQL statement resulted in the following actions by the database server:

- Stored all the exceptions that it detected in the diagnostics area  
If so, GET DIAGNOSTICS returns a value of **N**.
- Detected more exceptions than it stored in the diagnostics area  
If so, GET DIAGNOSTICS returns a value of **Y**. (The value of MORE is always **N**.)

## Using the ROW\_COUNT Keyword

The ROW\_COUNT keyword returns the number of rows the most recently executed DML statement processed. ROW\_COUNT counts these rows:

- Inserted into a table
- Updated in a table
- Deleted from a table

## Using the NUMBER Keyword

The NUMBER keyword returns the number of exceptions that the most recently executed SQL statement raised. The NUMBER field can hold a value from 1 to 35,000, depending on how many exceptions are counted.

## EXCEPTION Clause

Exception Clause

### EXCEPTION

*exception\_num exception\_var*

*, information =*

**CLASS\_ORIGIN CONNECTION\_NAME INFORMIX\_SQLCODE MESSAGE\_LENGTH MESSAGE\_TEXT RETURNED\_SQLSTATE  
SERVER\_NAME SUBCLASS\_ORIGIN**

| Element              | Description   | Restrictions                                     | Syntax                                      |
|----------------------|---|--|---|
| <i>exception_num</i> | Number of exceptions  | Integer in range 1 to 35,000                     | <a href="#">Literal Number on page 1419</a> |
| <i>exception_var</i> | Variable storing <i>exception_num</i>                             | Must be SMALLINT or INT                          | Language specific                           |
| <i>information</i>   | Host variable to receive the value of a specified exception field | Data type must match that of the specified field | Language specific                           |

The *exception\_num* literal indicates one of the exception values from the number of exceptions that the NUMBER field in the Statement clause returns.

When retrieving exception information, GET DIAGNOSTICS writes the values of each of the seven fields into corresponding host variables. These fields are located in the diagnostics area and are derived from an exception raised by the most recent SQL statement.

The host-variable data type must be the same as that of the requested field. The following table describes the seven exception information fields.

| Field Name Keyword | Field Data Type | Field Contents                 | ESQL/C Host Variable Data Type |
|--------------------|-----------------|--------------------------------|--------------------------------|
| RETURNED_SQLSTATE  | Character       | <b>SQLSTATE</b> value          | char[6]                        |
| INFORMIX_SQLCODE   | Integer         | Informix®-specific status code | int4                           |
| CLASS_ORIGIN       | Character       | String                         | char[255]                      |
| SUBCLASS_ORIGIN    | Character       | String                         | char[255]                      |
| MESSAGE_TEXT       | Character       | String                         | char[255]                      |
| MESSAGE_LENGTH     | Integer         | Numeric value                  | int                            |
| SERVER_NAME        | Character       | String                         | char[255]                      |
| CONNECTION_NAME    | Character       | String                         | char[255]                      |

The application specifies the exception by number, using either an unsigned integer or an integer host variable (an exact numeric with a scale of 0). An exception with a value of 1 corresponds to the **SQLSTATE** value set by the most recent SQL statement other than GET DIAGNOSTICS. The association between other exception numbers and other exceptions raised by that SQL statement is undefined. Thus, no set order exists in which the diagnostic area can be filled with exception values. You always get at least one exception, even if the **SQLSTATE** value indicates success.

If an error occurs within the GET DIAGNOSTICS statement (that is, if an invalid exception number is requested), the Informix® internal **SQLCODE** and **SQLSTATE** variables are set to the value of that exception. In addition, the GET DIAGNOSTICS fields are undefined.

## Using the RETURNED\_SQLSTATE Keyword

The RETURNED\_SQLSTATE keyword returns the **SQLSTATE** value that describes the exception.

## Using the INFORMIX\_SQLCODE Keyword

The INFORMIX\_SQLCODE keyword returns the Informix®-specific status code. The same value is also available in the global **SQLCODE** variable. For more information, see the discussion of the **SQLCODE** variable in the *Informix® ESQL/C Programmer's Manual*.

## Using the CLASS\_ORIGIN Keyword

Use the CLASS\_ORIGIN keyword to retrieve the class portion of the RETURNED\_SQLSTATE value. If the ISO standard for SQL defines the class, the value of CLASS\_ORIGIN is equal to ISO 9075. Otherwise, the value returned by CLASS\_ORIGIN is defined by Informix® and cannot be ISO 9075. The terms ANSI SQL and ISO SQL are synonymous.

## Using the SUBCLASS\_ORIGIN Keyword

The SUBCLASS\_ORIGIN keyword returns data on the RETURNED\_SQLSTATE subclass. (This value is `ISO 9075` if the ISO standard defines the subclass.)

## Using the MESSAGE\_TEXT Keyword

The MESSAGE\_TEXT keyword returns the message text of the exception (for example, an error message).

## Using the MESSAGE\_LENGTH Keyword

The MESSAGE\_LENGTH keyword returns the length in bytes of the current message text string.

## Using the SERVER\_NAME Keyword

The SERVER\_NAME keyword returns the name of the database server associated with a CONNECT or DATABASE statement. GET DIAGNOSTICS updates the SERVER\_NAME field when any of the following events occur:

- A CONNECT statement successfully executes.
- A SET CONNECTION statement successfully executes.
- A DISCONNECT statement successfully terminates the current connection.
- A DISCONNECT ALL statement fails.

The SERVER\_NAME field is not updated, however, after these events:

- A CONNECT statement fails.
- A DISCONNECT statement fails (but this does not include the DISCONNECT ALL statement).
- A SET CONNECTION statement fails.

The SERVER\_NAME field retains the value set in the previous SQL statement. If any of the preceding conditions occur on the first SQL statement that executes, the SERVER\_NAME field is blank.

## The Contents of the SERVER\_NAME Field

The SERVER\_NAME field contains different information after you execute the following statements.

### Executed Statement

#### SERVER\_NAME Field Contents

#### CONNECT

Contains the name of the database server to which you connect or fail to connect. Field is blank if you do not have a current connection or if you make a default connection.

#### DATABASE

Contains the name of the database server on which the specified database resides.

### **DISCONNECT**

Contains the name of the database server from which you disconnect or fail to disconnect. If you disconnect and then you execute a DISCONNECT statement for a connection that is not current, the SERVER\_NAME field remains unchanged.

### **DISCONNECT ALL**

Sets the field to blank if the statement executes successfully. If the statement fails, SERVER\_NAME contains the names of all the database servers from which you did not disconnect. (This information does not mean that the connection still exists.)

### **SET CONNECTION**

Contains the name of the database server to which you switch or fail to switch

If CONNECT succeeds, SERVER\_NAME is set to one of the following values:

- The **INFORMIXSERVER** value (if the connection is to a default database server, because CONNECT specified no database server)
- The name of the database server (if the connection is to a specific database server)

## Using the CONNECTION\_NAME Keyword

Use the CONNECTION\_NAME keyword to return the name of the connection specified in your CONNECT or SET CONNECTION statement.

## When the CONNECTION\_NAME Keyword Is Updated

GET DIAGNOSTICS updates the CONNECTION\_NAME field when the following situations occur:

- A CONNECT statement successfully executes.
- A SET CONNECTION statement successfully executes.
- A DISCONNECT statement successfully executes at the current connection.

GET DIAGNOSTICS fills the CONNECTION\_NAME field with blanks because no current connection exists.

- A DISCONNECT ALL statement fails.

## When the CONNECTION\_NAME Is Not Updated

The CONNECTION\_NAME field is not updated in the following cases:

- A CONNECT statement fails.
- A DISCONNECT statement fails (but this does not include the DISCONNECT ALL statement).
- A SET CONNECTION statement fails.

The CONNECTION\_NAME field retains the value set in the previous SQL statement. If any of the preceding conditions occurs on the first SQL statement that executes, the CONNECTION\_NAME field is blank.

An implicit connection has no name. After a DATABASE statement successfully creates an implicit connection, the CONNECTION\_NAME field is blank.

## The contents of the CONNECTION\_NAME field

The CONNECTION\_NAME field contains connection information that depends on the previously executed CONNECT, SET CONNECTION, DISCONNECT, or DISCONNECT ALL statement.

The CONNECTION\_NAME field contains different information after you execute the following statements.

### Executed Statement

#### CONNECTION\_NAME Field Contents

#### CONNECT

Contains the name, as specified in the CONNECT statement, of the connection to which you connect or fail to connect. The field is blank for no current connection or a default connection.

#### SET CONNECTION

Contains the name, as specified in the SET CONNECTION statement, of the connection to which you switch or fail to switch.

#### DISCONNECT

Contains the name, as specified in the DISCONNECT statement, of the connection from which you disconnect or fail to disconnect. If you disconnect successfully, and then execute a DISCONNECT statement for a connection that is not current, the CONNECTION\_NAME field remains unchanged.

#### DISCONNECT ALL

Contains no information if the DISCONNECT ALL statement executes successfully. If the statement does not execute successfully, the CONNECTION\_NAME field contains the names of all the connections specified in your CONNECT statements from which you did not disconnect. This information does not mean, however, that the connection still exists.

If CONNECT is successful, CONNECTION\_NAME takes one of these values:

- The name of the database environment as specified in the CONNECT statement if the CONNECT statement does not include the AS clause
- The name of the connection (the identifier that was declared after the AS keyword) if the CONNECT statement includes the AS clause

## Using GET DIAGNOSTICS for Error Checking

GET DIAGNOSTICS returns values from various fields in the diagnostics area. For each field in the diagnostics area that you wish to access, you must supply a host variable of a compatible data type.

The following example illustrates how to use the GET DIAGNOSTICS statement to display error information. The example shows the Informix® ESQL/C error display routine called **disp\_sqlstate\_err()**:

```

void disp_sqlstate_err()
{
int j;
EXEC SQL BEGIN DECLARE SECTION;
    int exception_count;
    char overflow[2];
    int exception_num=1;
    char class_id[255];
    char subclass_id[255];
    char message[255];
    int messlen;
    char sqlstate_code[6];
    int i;
EXEC SQL END DECLARE SECTION;
printf("-----");
printf("-----\n");
printf("SQLSTATE:
printf("SQLCODE: %d\n", SQLCODE);
printf("\n");
EXEC SQL get diagnostics :exception_count = NUMBER,
    :overflow = MORE;
printf("EXCEPTIONS: Number=%d\t", exception_count);
printf("More? %s\n", overflow);
for (i = 1; i <= exception_count; i++)
{
    EXEC SQL get diagnostics exception :i
        :sqlstate_code = RETURNED_SQLSTATE,
        :class_id = CLASS_ORIGIN, :subclass_id = SUBCLASS_ORIGIN,
        :message = MESSAGE_TEXT, :messlen = MESSAGE_LENGTH;
printf(" - - - - - \n");
printf("EXCEPTION %d: SQLSTATE=%s\n", i, sqlstate_code);
message[messlen-1] = '\0';
printf("MESSAGE TEXT: %s\n", message);
j = stleng(class_id);
while((class_id[j] == '\0') ||
    (class_id[j] == ' '))
    j--;
class_id[j+1] = '\0';
printf("CLASS ORIGIN:
j = stleng(subclass_id);
while((subclass_id[j] == '\0') ||
    (subclass_id[j] == ' '))
    j--;
subclass_id[j+1] = '\0';
printf("SUBCLASS ORIGIN:
}
printf("-----");
printf("-----\n");
}

```

## GRANT statement

Use the GRANT statement to assign access privileges and roles to users and to other roles. Users who hold the DBSECADM role can use this statement to assign user security labels and exemptions from label-based access control (LBAC) security rules.

**Syntax****GRANT**

| Element     | Description  | Restrictions   | Syntax                                  |
|-------------|--|--|---|
|             |  | On Windows™, the <i>user</i> name cannot exceed 20 bytes. On other platforms, the limit is 32 bytes. |   |
| <i>role</i> | Name of an existing role to which you grant one or more access privileges, or to which you assign another role   | Must exist in the database   | <a href="#">Owner name on page 1488</a> |
| <i>user</i> | Authorization identifier of a user to whom you grant one or more access privileges, or to whom you assign a role | Same as for <i>grantor</i>   | <a href="#">Owner name on page 1488</a> |

## Usage

The GRANT statement extends to other users specific discretionary access privileges or LBAC labels and exceptions that would normally accrue only to the DBA or to the creator of an object. Subsequent GRANT statements do not affect privileges that have already been granted to a user.

You can use the GRANT statement for operations like the following:

- Authorize others to use or administer a database that you create
- Allow others to view, alter, or drop a table, synonym, view or a sequence object that you create
- Allow others to use a data type or the SPL language, or to execute a user-defined routine (UDR) that you create
- Assign a role and its privileges to users, or to PUBLIC, or to another role
- Assign a default role to one or more users or to PUBLIC
- If you hold the DBSECADM role, assign LBAC security labels or exemptions from rules of LBAC security policies to users,

You can grant privileges to a previously created role or to a built-in role. You can grant a role to PUBLIC, to individual users, or to another role.

If you enclose *grantor*, *role*, or *user* in quotation marks, the name is case sensitive and is stored exactly as you typed it. In an ANSI-compliant database, if you do not use quotation marks as delimiters, the name is stored in uppercase letters.

On Windows™ only, the database server does not support *user* name that consists of more than 20 characters.

Privileges that you grant remain in effect until you cancel them with a REVOKE statement. Only the grantor of a privilege can revoke that privilege. The grantor is the person who issues the GRANT statement, unless the AS *grantor* clause transfers the right to revoke those privileges to another user.

Only the owner of an object or a user to whom privileges were explicitly granted with the WITH GRANT OPTION keywords can grant privileges on an object. Having DBA privileges is not sufficient. As DBA, however, you can grant a privilege on behalf of another user by using the AS *grantor* clause. For privileges on database objects whose owner is not a user recognized by the operating system (for example, user **informix**), the AS *grantor* clause is useful.

The keyword PUBLIC extends the specified privilege or role to the PUBLIC group of all users who connect to the database. If you intend to restrict privileges that PUBLIC already holds to only a subset of users, you must first revoke those privileges from PUBLIC.

To grant privileges on one or more fragments of a table that has been fragmented by expression, see [GRANT FRAGMENT statement on page 631](#).

## Database-Level Privileges

Database-level access privileges affect access to a database. Only individual users, rather than roles, can hold database privileges.

### Database-Level Privileges

#### CONNECT RESOURCE DBA

When you create a database with the CREATE DATABASE statement, you are the owner and automatically receive all database-level privileges.

The database remains inaccessible to any other users until you, as DBA, grant database privileges to them.

As database owner, you also receive table-level privileges on all tables in the database automatically. For more information about table-level privileges, see [Table-Level Privileges on page 597](#).

**Recommendation:** Only user **informix** can modify system catalog tables directly. Except as noted specifically in your database server documentation, however, do not use DML statements to insert, delete, or update rows of system catalog tables directly, because modifying data in these tables can destroy the integrity of the database.

When database-level privileges conflict with table-level privileges, the more restrictive privileges take precedence.

Database access levels are, from lowest to highest, Connect, Resource, and DBA. Use the corresponding keyword to grant a level of access privilege.

| Privilege | Effect   |
|-----------|--|
| CONNECT   | <p>Lets you query and modify data</p> <p>You can modify the database schema if you own the database object that you intend to modify. Any user with the Connect privilege can perform the following operations:</p> <ul style="list-style-type: none"> <li>• Connect to the database with the CONNECT statement or another connection statement</li> <li>• Execute SELECT, INSERT, UPDATE, and DELETE statements, provided the user has the necessary table-level privileges</li> <li>• Create views, provided the user has the Select privilege on the underlying tables</li> <li>• Create synonyms</li> <li>• Create temporary tables and create indexes on the temporary tables</li> <li>• Alter or drop a table or an index, provided the user owns the table or index (or has Alter, Index, or References privileges on the table)</li> <li>• Grant privileges on a table or view, provided the user owns the table (or was given privileges on the table with the WITH GRANT OPTION keywords)</li> </ul> |
| RESOURCE  | <p>Lets you extend the structure of the database In addition to the capabilities of the Connect privilege, the holder of the Resource privilege can perform the following functions:</p> <ul style="list-style-type: none"> <li>• Create new tables</li> <li>• Create new indexes</li> </ul>   |

| Privilege | Effect   |
|-----------|--|
|           | <ul style="list-style-type: none"> <li>• Create new UDRs</li> <li>• Create new data types</li> </ul>   |
| DBA       | <p>Has all the capabilities of the Resource privilege and can perform the following additional operations:</p> <ul style="list-style-type: none"> <li>• Grant any database-level privilege, including the DBA privilege, to another user</li> <li>• Grant any table-level privilege to another user or to a role</li> <li>• Grant a role to a user or to another role</li> <li>• Revoke a privilege whose grantor you specify as the <i>revoker</i> in the AS clause of the REVOKE statement</li> <li>• Restrict the Execute privilege to DBAs when registering a UDR</li> <li>• Execute the SET SESSION AUTHORIZATION statement</li> <li>• Create any database object</li> <li>• Create tables, views, and indexes, designating another user as owner of these objects</li> <li>• Alter, drop, or rename database objects, regardless of who owns them</li> <li>• Execute the DROP DISTRIBUTIONS option of the UPDATE STATISTICS statement</li> <li>• Execute DROP DATABASE and RENAME DATABASE statements</li> </ul> |

User **informix** has the privilege required to alter the tables of the system catalog, including the **sysables** table.

The following example uses the PUBLIC keyword to grant the Connect privilege on the currently active database to all users:

```
GRANT CONNECT TO PUBLIC;
```

You cannot grant database-level privileges to a role. Only individual users or PUBLIC can hold database-level privileges.

## Table-Level Privileges

When you create a table with the CREATE TABLE statement, you are the table owner and automatically receive all table-level privileges. You cannot transfer ownership to another user, but you can grant table-level privileges to another user or to a role. (See, however, [RENAME TABLE statement on page 717](#), which can change both the name and the ownership of a table.)

A user with the database-level DBA privilege automatically receives all table-level privileges on every table in that database.

## Table-Level Privileges

**ALL****PRIVILEGES**

,

**INSERT****DELETE****UPDATE**<sup>297</sup> **SELECT REFERENCES**

(

, *column*

)

<sup>297</sup><sup>297</sup> **ALTER INDEX****UNDER****ON***owner* .*table view synonym*

| Element  | Description  | Restrictions   | Syntax                                  |
|--|--|--|---|
| <i>column</i>                                  | Column on which the References, Select, or Update privilege is granted. Default scope is all columns of <i>table</i> , <i>view</i> , or <i>synonym</i> . | Must be a column of the <i>table</i> , <i>view</i> , or <i>synonym</i> | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>                                   | Name of the user who owns the <i>table</i> , <i>view</i> , or <i>synonym</i>   | Must be a valid authorization identifier                               | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> ,<br><i>table</i> , <i>view</i> | Synonym, table, or view on which privileges are granted.   | Must exist in the current database                                     | <a href="#">Identifier on page 1456</a> |

The GRANT statement can list one or more of the following keywords to specify the table privileges that you grant to the same users or roles.

| Privilege | Effect  |
|-----------|---|
| INSERT    | Lets you insert rows  |
| DELETE    | Lets you delete rows  |
| SELECT    | Lets you access any column in SELECT statements. You can restrict the Select privilege to one or more columns by listing the columns. |
| UPDATE    | Lets you access any column in UPDATE statements. You can restrict the Update privilege to one or more columns by listing the columns. |

297. Informix® extension

| Privilege  | Effect   |
|------------|--|
| REFERENCES | Lets you define referential constraints on columns. You must have the Resource privilege to take advantage of the References privilege. (You can add, however, a referential constraint during an ALTER TABLE statement without holding the Resource privilege on the database.) You need only the References privilege to indicate cascading deletes. You do not need the Delete privilege to place cascading deletes on a table. You can restrict the References privilege to one or more columns by listing the columns.                                  |
| INDEX      | Lets you create permanent indexes. You must have the Resource privilege to use the Index privilege. (Any user with the Connect privilege can create an index on temporary tables.)   |
| ALTER      | Lets you add or delete columns, modify column data types, add or delete constraints, change the locking mode of the table from PAGE to ROW, or add or drop a corresponding ROW data type for your table. It also lets you enable or disable indexes, constraints and triggers, as described in <a href="#">SET Database Object Mode statement on page 871</a> .<br><br>You must have the Resource privilege to use the Alter privilege. In addition, you also need the Usage privilege for any user-defined data type affected by the ALTER TABLE statement. |
| UNDER      | Lets you create sub-tables under a typed table.  |
| ALL        | Provides all privileges listed above. The PRIVILEGES keyword is optional.  |

You can narrow the scope of a Select, Update, or References privilege by specifying the columns to which the privilege applies.

Specify the keyword PUBLIC as *user* if you intend the GRANT statement to apply to all users.

Some simple examples that follow illustrate how to give table-level privileges with the GRANT statement.

The following statement grants the privilege to delete and select values in any column in the table **customer** to users **mary** and **john**. It also grants the Update privilege, but only for columns **customer\_num**, **fname**, and **lname**:

```
GRANT DELETE, SELECT, UPDATE (customer_num, fname, lname)
ON customer TO mary, john;
```

To grant the same privileges as those above to all authorized users, use the keyword PUBLIC as the following example shows:

```
GRANT DELETE, SELECT, UPDATE (customer_num, fname, lname)
ON customer TO PUBLIC;
```

For example, suppose a user named **mary** has created a typed table named **tab1**. By default, only user **mary** can create subtables under the **tab1** table. If **mary** wants to grant the ability to create subtables under the **tab1** table to a user named **john**, **mary** must enter the following GRANT statement:

```
GRANT UNDER ON tab1 TO john;
```

After receiving the Under privilege on table **tab1**, user **john** can create one or more subtables under **tab1**.

## Effect of the ALL Keyword

The ALL keyword grants all possible table-level privileges to the specified user. If any or all of the table-level privileges do not exist for the grantor, the GRANT statement with the ALL keyword succeeds (in the sense of **SQLCODE** being set to zero, even if the possible privileges are an empty set for the grantor on the table). In this case, however, the following **SQLSTATE** warning is returned:

```
01007 - Privilege not granted.
```

For example, assume that user **ted** has the Select and Insert privileges on the **customer** table with the authority to grant those privileges to other users.

User **ted** wants to grant all table-level privileges to user **tania**. So user **ted** issues the following GRANT statement:

```
GRANT ALL ON customer TO tania;
```

This statement executes successfully but returns **SQLSTATE** code **01007** for the following reasons:

- The statement succeeds in granting the Select and Insert privileges to user **tania** because user **ted** has those privileges and the right to grant those privileges to other users.
- The other privileges implied by the ALL keyword were not grantable by user **ted** and, therefore, were not granted to user **tania**.

If you grant all table-level privileges with the ALL keyword, the privileges includes the Under privilege only if the table is a typed table. The grant of ALL privileges does not include the Under privilege if the table is not based on a ROW type.

If the table owner grants ALL privileges on a traditional relational table and later changes that table to a typed table, the table owner must explicitly grant the Under privilege to allow other users to create subtables under it.

## Table Reference

You grant table-level privileges directly by specifying the name or an existing synonym of a table or of a view, which you can qualify with the *owner* name.

Table Reference

*owner* .

*view table synonym*

| Element                     | Description  | Restrictions  | Syntax                                  |
|-----------------------------|--|---|---|
| <i>owner</i>                | Name of the user who owns the <i>table</i> , <i>view</i> , or <i>synonym</i> | Must be a valid authorization identifier                                      | <a href="#">Owner name on page 1488</a> |
| <i>synonym, table, view</i> | Synonym, table, or view on which privileges are granted                      | The <i>table</i> , <i>view</i> , or <i>synonym</i> must exist in the database | <a href="#">Identifier on page 1456</a> |

The object on which you grant privileges must reside in the current database.

For table objects that the CREATE EXTERNAL TABLE statement has registered in the current database, the Select privilege and the Insert privilege are supported, but no other table or column access privileges can be granted or revoked.

In an ANSI-compliant database, if *owner* is not enclosed between quotation marks, the database stores the owner name in lowercase letters.

## Privileges on Tables and Synonyms

In an ANSI-compliant database, if you create a table, only you, its owner, have any table-level privileges until you explicitly grant them to others.

When you create a table in a database that is *not* ANSI compliant, however, PUBLIC receives Select, Insert, Delete, Under, and Update privileges for that table and its synonyms. (The **NODEFDAC** environment variable, when set to `yes`, prevents PUBLIC from automatically receiving these table-level privileges.)

To allow access only to some users, or only on some columns in a database that is not ANSI compliant, you must explicitly revoke the privileges that PUBLIC receives by default, and then grant only the privileges that you intend. For example, this series of statements grants privileges on the entire **customer** table to users **john** and **mary**, but restricts PUBLIC access to the Select privilege on only four of the columns in that table:

```
REVOKE ALL ON customer FROM PUBLIC;
GRANT ALL ON customer TO john, mary;
GRANT SELECT (fname, lname, company, city) ON customer TO PUBLIC;
```

## Privileges on a View

You must have at least the Select privilege on a table or columns to create a view on that table. For views that reference only tables in the current database, if the owner of a view loses the Select privilege on any base table underlying the view, the view is dropped.

You have the same privileges for the view that you have for the table or tables contributing data to the view. For example, if you create a view from a table to which you have only Select privileges, you can select data from your view but you cannot delete or update data. For information on how to create a view, see [CREATE VIEW statement on page 452](#).

When you create a view, PUBLIC does not automatically receive any privileges for a view that you create. Only you have access to table data through that view. Even users who have privileges on the base table of the view do not automatically receive privileges for the view.

You can grant (or revoke) privileges on a view only if you are the owner of the underlying base tables, or if you received these privileges on the base table with the right to grant them (specified by the WITH GRANT OPTION keywords). You must explicitly grant those privileges within your authority, because PUBLIC does not automatically receive any privileges on a view when it is created.

The creator of a view can explicitly grant Select, Insert, Delete, and Update privileges for the view to other users or to a role. You cannot grant Index, Alter, Under, or References privileges on a view (nor can you specify the ALL keyword for views, because ALL confers Index, References, and Alter privileges).

When a GRANT or REVOKE statement changes the discretionary access privileges on any table referenced in the definition of an existing view, the database server does not automatically apply those privilege modifications to the view. To apply the

new table access privileges to a view that depends on that table, you can use the DROP VIEW and CREATE VIEW statements to drop and recreate the view.

In this case, if the definitions of other views reference the view that you drop, or if INSTEAD OF triggers are defined on that view, you can also use CREATE VIEW and CREATE TRIGGER statements to recreate, respectively, the dependent views and the INSTEAD OF triggers that the DROP VIEW statement destroyed.

## Type-Level Privileges

You can specify two privileges on data types that are not built-in data types:

- The Usage privilege on a user-defined data type
- The Under privilege on a named ROW type

Type-Level Privileges

**USAGE ON TYPE***type\_name*

**UNDER ON TYPE***row\_type\_name*

| Element              | Description   | Restrictions                       | Syntax   |
|----------------------|---|------------------------------------|--|
| <i>row_type_name</i> | Named ROW type on which the Under privilege is granted    | Named ROW data type must exist     | <a href="#">Identifier on page 1456</a> ; <a href="#">Data Type on page 1163</a> |
| <i>type_name</i>     | User-defined type on which the Usage privilege is granted | User-defined data type must exist. | <a href="#">Identifier on page 1456</a> ; <a href="#">Data Type on page 1163</a> |

To see what privileges exist on user-defined data types, check the **sysxdtypes** system catalog table for the owner of each UDT, and the **sysxdtypeauth** system catalog table for any other users or roles that hold privileges on UDTs. See the *Informix® Guide to SQL: Reference* for information on the system catalog tables.

For all the *built-in data types*, however, these access privileges are automatically available to PUBLIC and cannot be revoked.

## USAGE Privilege

You own any user-defined data type (UDT) that you create. As owner, you automatically receive the Usage privilege on that data type and can grant the Usage privilege to others so that they can reference the type name or data of that type in SQL statements. DBAs can also grant the Usage privilege for UDTs.

The following example grants user **mark** access privileges to use the **widget** user-defined type:

```
GRANT USAGE ON TYPE widget TO mark;
```

If you grant Usage privilege to a user (or to a role) that has Alter privileges, that grantee can add a column to a table that contains values of your UDT.

Without privileges from the GRANT statement, any user can issue SQL statements that reference built-in data types. In contrast, a user must receive an explicit Usage privilege from a GRANT statement to use a distinct data type, even if the distinct type is based on a built-in type.

For more information about user-defined types, see [CREATE OPAQUE TYPE statement on page 281](#), [CREATE DISTINCT TYPE statement on page 210](#), the discussion of data types in the *Informix® Guide to SQL: Reference* and the *Informix® Database Design and Implementation Guide*.

## UNDER Privilege

You own any named ROW type that you create. If you want other users to be able to create subtypes under this named ROW type, you must grant to these users the Under privilege on your named ROW type.

For example, suppose that you create a ROW type named **rtype1**:

```
CREATE ROW TYPE rtype1 (cola INT, colb INT);
```

If you want another user named **kathy** to be able to create a subtype under this named ROW type, you must grant the Under privilege on this named ROW type to user **kathy**:

```
GRANT UNDER ON ROW TYPE rtype1 TO kathy;
```

Now user **kathy** can create another ROW type under the **rtype1** ROW type, even though **kathy** is not the owner of the **rtype1** ROW type:

```
CREATE ROW TYPE rtype2 (colc INT, cold INT) UNDER rtype1;
```

For more about named ROW types, see [CREATE ROW TYPE statement on page 307](#), and the discussion of data types in the *Informix® Guide to SQL: Reference* and the *Informix® Database Design and Implementation Guide*.

## Routine-Level Privileges

When you create a user-defined routine (UDR), you become owner of the UDR and you automatically receive the Execute privilege on that UDR.

The Execute privilege allows you to invoke the UDR with an EXECUTE FUNCTION or EXECUTE PROCEDURE statement, whichever is appropriate, or with a CALL statement in an SPL routine. The Execute privilege also allows you to use a user-defined function in an expression, as in this example:

```
SELECT * FROM table WHERE in_stock(partnum) < 20;
```

For users, roles, or members of the PUBLIC group who need the Execute privilege on a given UDR, the GRANT statement supports the following syntax:

## Routine-Level Privileges

**EXECUTE ON***SPL\_routine***PROCEDURE FUNCTION ROUTINE***routine*(Routine Parameter List <sup>298</sup>

)

**SPECIFIC****ROUTINE FUNCTION PROCEDURE**Specific Name <sup>299</sup>

| Element            | Description            | Restrictions                   | Syntax                                  |
|--------------------|------------------------|--------------------------------|---|
| <i>routine</i>     | A user-defined routine | Must exist                     | <a href="#">Identifier on page 1456</a> |
| <i>SPL_routine</i> | An SPL routine         | Must be unique in the database | <a href="#">Identifier on page 1456</a> |

The following statement grants Execute privilege on the **delete\_order** routine to user **finn**:

```
GRANT EXECUTE ON ROUTINE delete_order TO finn;
```

Whether you must grant the Execute privilege explicitly depends on the following conditions:

- If you have DBA-level privileges, you can use the DBA keyword of CREATE FUNCTION or CREATE PROCEDURE to restrict the default Execute privilege to users with the DBA privilege. You must explicitly grant the Execute privilege on that UDR to users who do not have the DBA privilege.
- If you have the Resource database-level privilege but not the DBA privilege, you cannot use the DBA keyword when you create a UDR:
  - When you create a UDR in a database that is *not* ANSI compliant, PUBLIC can execute that UDR. You do not need to issue a GRANT statement for other users to receive the Execute privilege.
  - Setting the **NODEFDAC** environment variable to `yes` prevents PUBLIC from executing the UDR until you explicitly grant the Execute privilege.
- In an ANSI-compliant database, the creator of a UDR must explicitly grant the Execute privilege on the UDR for other users to be able to execute it.

In Informix®, if two or more UDRs have the same name, use a keyword from this list to specify which of those UDRs a user list can execute.

**Keyword****UDR that the User Can Execute****SPECIFIC**

The UDR identified by *specific name*

298. See [Routine Parameter List on page 1514](#)

299. See [Specific Name on page 1521](#)

**FUNCTION**

Any function with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

**PROCEDURE**

Any procedure with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

**ROUTINE**

Functions or procedures with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

If both a user-defined function and a user-defined procedure of Informix® have the same name and the same list of parameter data types, you can grant the Execute privilege to both with the keyword ROUTINE.

To limit the Execute privilege to one routine among several that have the same identifier, use the FUNCTION, PROCEDURE, or SPECIFIC keyword.

To limit the Execute privilege to a UDR that accepts certain data types as arguments, include the routine parameter list or use the SPECIFIC keyword to introduce the specific name of a UDR.

If an external function has a negator function, you must grant the Execute privilege on both the external function and on its negator function before other users can execute the external function.

A user must hold the Usage privilege on the language in which the user-defined routine is written to register a UDR with the CREATE FUNCTION, CREATE FUNCTION FROM, CREATE PROCEDURE, CREATE PROCEDURE FROM, or CREATE ROUTINE FROM statement. For more information on the requirements to register a UDR, see [Privileges necessary for using CREATE FUNCTION on page 243](#).

## Granting the Execute privilege to PUBLIC

The GRANT statement supports syntax for granting access to the PUBLIC group, which includes all users who hold the Connect privilege on the database.

Figure 6. GRANT EXECUTE TO PUBLIC

**GRANT****Routine level privileges****TOPUBLIC**

AS'grantor '

| Element        | Description      | Restrictions     | Syntax                                  |
|----------------|------------------|------------------|---|
| <i>grantor</i> | Owner of the UDR | Cannot be a role | <a href="#">Owner name on page 1488</a> |

This statement enables everyone in the PUBLIC group to execute the specified routine. It overrides the NODEFDAC environment variable, if that is set to prevent the PUBLIC group from receiving Execute privilege on the routine by default. This statement also enables users who do not hold the DBA privilege to execute the specified routine, whether that routine was created with the DBA keyword.

Only users who hold the DBA privilege can specify the *AS grantor* clause. The specified grantor must be the owner of the specified routine, as listed in the **owner** column of the **sysprocedures** system catalog table. The grantor cannot be the name of a role or the PUBLIC keyword.

In an ANSI-compliant database, the *AS grantor* clause is required, rather than optional, if the DBA who issues the GRANT EXECUTE statement is not the owner of the specified routine.

Only the user specified in the optional *AS grantor* clause can use the REVOKE statement of SQL to revoke the Execute privilege from the PUBLIC group

The user specified in the optional *AS grantor* clause can use the REVOKE statement to revoke the Execute privilege from the PUBLIC group.

## Revoking the Execute privilege from PUBLIC

The REVOKE statement supports the following syntax for revoking access to the specified routine from the PUBLIC group, which includes all users who hold the Connect privilege on the database.

Figure 7. REVOKE EXECUTE TO PUBLIC

### GRANT

#### Routine level privileges

### FROMPUBLIC

### AS'revoker'

| Element        | Description      | Restrictions     | Syntax                                  |
|----------------|------------------|------------------|---|
| <i>revoker</i> | Owner of the UDR | Cannot be a role | <a href="#">Owner name on page 1488</a> |

This statement prevents the PUBLIC group from receiving Execute privileges on the specified routine by default. (Individual users who hold the DBA privilege, however, or who own the routine, or who were granted Execute privilege on the routine individually or through a role, are not affected by this statement.)

Only users who hold the DBA privilege can specify the *AS revoker* clause. The specified revoker must be the owner of the specified routine, as listed in the **owner** column of the **sysprocedures** system catalog table. The name cannot be the name of a role or the PUBLIC keyword.

In an ANSI-compliant database, the *AS revoker* clause is required, rather than optional, if the DBA who issues the REVOKE EXECUTE statement is not the owner of the specified routine.

In databases where the PUBLIC group holds Execute privilege on owner-privileged routines by default, the REVOKE EXECUTE ON PUBLIC statement must be successfully executed before the discretionary access privilege to execute the specified

routine can be granted to a subset of users or to one or more roles. Otherwise, only users with the DBA privilege or the owner of the routine can start it.

## Language-Level Privileges

Informix® also supports *language-level privileges*, which specify the programming languages of UDRs that users who have been granted Usage privileges for a given language can register in the database.

This is the syntax of the USAGE ON LANGUAGE clause for granting Usage privileges on a programming language:

Language-Level Privileges

**USAGE ON LANGUAGE**

**SPL C JAVA**

The SPL, C, and JAVA keywords can specify a programming language in the USAGE ON LANGUAGE clause. Each GRANT USAGE ON LANGUAGE statement can specify no more than one programming language. By default, Usage privilege on SPL is granted to PUBLIC.

When a user executes the CREATE FUNCTION or CREATE PROCEDURE statement to register a UDR that is written in the SPL, C, or Java™ language, the database server verifies that the user has the Usage privilege on the language in which the UDR is written. If the IFX\_EXTEND\_ROLE configuration parameter has enabled the built-in EXTEND role, only users who also hold that role can register or drop UDRs written in the C language or in the Java™ language, even if the users hold USAGE ON LANGUAGE privileges for those languages.

The GRANT USAGE ON LANGUAGE statement can grant Usage privilege on a programming language to a restricted group of users. The following example grants Usage privileges on the C language to a user-defined role named **developers**:

```
GRANT USAGE ON LANGUAGE C TO developers;
```

If the preceding example executes successfully, users who hold the **developers** role as their current role can create or drop C routines (if they also hold the EXTEND role, or if the IFX\_EXTEND\_ROLE parameter is set to 0 or to OFF).

For information on other access privileges that these statements require, see [CREATE FUNCTION statement on page 240](#) and [CREATE PROCEDURE statement on page 290](#).

## Usage Privilege in Stored Procedure Language

The Usage privilege on SPL is granted to PUBLIC by default. Only user **informix**, the DBA, or a user who was granted the Usage privilege WITH GRANT OPTION can grant the Usage privilege on SPL to another user.

In the following example, assume that the default Usage privilege on SPL was revoked from PUBLIC and the DBA wants to grant the Usage privilege on SPL to the role named **developers**:

```
GRANT USAGE ON LANGUAGE SPL TO developers;
```

## Sequence-Level Privileges

Although Informix® implements sequence objects as tables, only a subset of table-level privileges (page [Table-Level Privileges on page 597](#)) can be granted on a sequence. You can grant the Select or Alter privilege (or both) on a sequence:

```
Sequence-Level Privileges
ALL
,
SELECT300
ALTER
ON
owner.
300sequence
synonym
```

| Element         | Description                                     | Restrictions      | Syntax                                  |
|-----------------|---|-------------------|---|
| <i>owner</i>    | Owner of sequence (or owner of <i>synonym</i> ) | Must be the owner | <a href="#">Owner name on page 1488</a> |
| <i>sequence</i> | Sequence on which to grant privileges           | Must exist        | <a href="#">Identifier on page 1456</a> |
| <i>synonym</i>  | Synonym for a sequence object                   | Must exist        | <a href="#">Identifier on page 1456</a> |

The sequence object must exist in the current database. You can qualify the *sequence* or *synonym* identifier with a valid *owner* name, but the name of a remote *database* (or *database@server*) is not valid as a qualifier. You can include the WITH GRANT OPTION keywords when you grant ALTER, SELECT, or ALL to a user or to PUBLIC (but not to a role) as privileges on a sequence object.

## Alter Privilege

You can grant the Alter privilege on a sequence to another user or to a role. The Alter privilege enables a specified user or role to modify the definition of a sequence with the ALTER SEQUENCE statement or to rename the sequence with the RENAME SEQUENCE statement.

The following statement grants the Alter privilege to user **mark** on the **cust\_seq** sequence object:

```
GRANT ALTER ON cust_seq TO mark;
```

## Select Privilege

You can grant the Select privilege on a sequence to another user or to a role. The Select privilege enables a specified user or role to use *sequence.CURRVAL* and *sequence.NEXTVAL* expressions in SQL statements to read and to increment (respectively) the value of a sequence.

300. Informix® extension

The following statement grants the Select privilege to user **mark** on the **cust\_seq** sequence object:

```
GRANT SELECT ON cust_seq TO mark;
```

## ALL Keyword

You can specify the ALL keyword to grant both Alter and Select privileges on a sequence object to another user or to a role, or to a list of users or roles.

## The User List

You can grant privileges to an individual user or to a list of users. You can also specify the PUBLIC keyword to grant privileges to all users.

User List

**PUBLIC**

, user 'user'

| Element     | Description  | Restrictions                             | Syntax                                  |
|-------------|--|--|---|
| <i>user</i> | Login name of a user to whom you are granting privilege or granting a role | Must be a valid authorization identifier | <a href="#">Owner name on page 1488</a> |

The following example grants the Insert table-level privilege on **table1** to the user **mary** in a database that is not ANSI-compliant:

```
GRANT INSERT ON table1 TO mary;
```

In an ANSI-compliant database, if you do not include quotation marks as delimiters around *user*, the name of the user is stored in uppercase letters.

## Role Name

You can use the GRANT statement to associate a list of one or more users (or all users, using the PUBLIC keyword) with a *role* name that can describe what they do. After you declare and grant a role, access privileges that you grant to that role are thereby granted to all users who are currently associated with that role.

Role Name

*role*'role'

| Element     | Description  | Restrictions  | Syntax                                  |
|-------------|--|---|---|
| <i>role</i> | Role that is granted, or to which a privilege or another role is granted | Must exist. If enclosed between quotation marks, <i>role</i> is case sensitive. | <a href="#">Owner name on page 1488</a> |

You can also grant an existing role to another role. This action gives whatever privileges the granted role possesses to all users who have the receiving role.

## Granting a Role to a User or to Another Role

You must register a role in the database before the role can be used in a GRANT statement. For more information, see [CREATE ROLE statement on page 303](#).

A DBA has the authority to grant a new role to another user. If a user receives a role WITH GRANT OPTION, that user can grant the role to other users or to another role. Users keep a role that was granted to them until the REVOKE statement breaks the association between their login names and the role name.

**Important:** The CREATE ROLE and GRANT statements do not activate the role. A non-default role has no effect until SET ROLE enables it. The grantor or the grantee of a role can issue the SET ROLE statement.

The following example shows the actions required to grant and activate the role **payables** to a group of employees who perform account payable functions. First the DBA creates role **payables**, then grants it to **maryf**.

```
CREATE ROLE payables;
GRANT payables TO maryf WITH GRANT OPTION;
```

The DBA or **maryf** can activate the role with the following statement:

```
SET ROLE payables;
```

User **maryf** has the WITH GRANT OPTION authorization to grant **payables** to other employees who pay accounts.

```
GRANT payables TO charly, gene, marvin, raoul;
```

If you grant privileges for one role to another role, the recipient role has the combined set of privileges that have been granted to both roles. The following example grants the role **petty\_cash** to the role **payables**:

```
CREATE ROLE petty_cash;
SET ROLE petty_cash;
GRANT petty_cash TO payables;
```

After all of these statements execute successfully, if user **raoul** uses the SET ROLE statement to make **payables** their current role, then (aside from the effects of any REVOKE operations) they (raoul) hold the following combined set of access privileges:

- The privileges granted to the **payables** role
- The privileges granted to the **petty\_cash** role
- The privileges granted individually to **raoul**
- The privileges granted to PUBLIC

If you attempt to grant a role to yourself, either directly or indirectly, the database server generates an error. (For an important exception to this rule, however, see the description of the [DBSECADM Clause on page 615](#).)

The database server also generates an error if you include the WITH GRANT OPTION keywords in a GRANT statement that assigns a role to another role.

## Granting privileges to a role

You can grant table-level and routine-level access privileges to a role if you have the authority to grant these same privileges to login names or to PUBLIC. You can also grant type-level privileges to a role. A role cannot hold database-level privileges.

 **Important:** The scope of a user-defined role (and of discretionary access privileges that the GRANT statement assigns to the role) is the current database. When the GRANT DEFAULT ROLE or SET ROLE statement activates a role, the role and its privileges take effect in the current database only. As a security precaution, discretionary access privileges that a user receives only from a role cannot provide access to tables outside the current database through a view or through the action of a trigger.

The syntax is more restricted for granting privileges to a role than to a user:

- You can specify the AS *grantor* clause.

In this way, whoever has the role can revoke these same privileges. For more information, see [AS grantor clause on page 614](#).

- You cannot include the WITH GRANT OPTION clause.

A role cannot, in turn, grant the same access privileges to another user.

This example grants Insert privilege on the **supplier** table to the role **payables**:

```
GRANT INSERT ON supplier TO payables;
```

Anyone who has been granted the **payables** role, and who successfully activates it by issuing the SET ROLE statement, can now insert rows into **supplier**.

## Granting a Default Role

The DBA or the owner of the database (by default, user **informix**) can define a *default role* for one or more users or for PUBLIC with the GRANT DEFAULT ROLE statement. A default role is activated when the user connects to the database. The SET ROLE statement is not required to activate a default role.

Default roles are useful if users access databases through client applications that cannot modify access privileges nor set roles.

A default role can specify a set of access privileges to all the users who are assigned that role, as in the following example:

```
CREATE ROLE accounting;
GRANT ALTER, INSERT, SELECT ON stock TO accounting;
GRANT DEFAULT ROLE accounting TO mary, asok, vlad;
```

The last statement provides users **mary**, **asok**, and **vlad** with **accounting** as their default role. If any of these users connects to a database, that user activates whatever privileges the **accounting** role holds, in addition to any privileges that the user already possesses as an individual or as PUBLIC.

The role must already exist and the user must have the access privileges to set the role. If the role has not previously been granted to a user, it is granted as part of setting the default role.

If no default role is defined for a user nor for PUBLIC, then no role is set, and the existing privileges of the user are in effect.

The following example shows how the default role can be assigned to all users:

```
DATABASE hrdb;
CREATE ROLE emprole;
GRANT CONNECT TO PUBLIC;
GRANT SELECT ON emptab TO emprole;
GRANT emprole TO PUBLIC;
GRANT DEFAULT ROLE emprole TO PUBLIC;
```

**Note:** Using GRANT DEFAULT ROLE is an alternative to issuing the SET ROLE statement in the `sysdbopen()` procedure. Default roles defined using the `sysdbopen()` procedure, however, have precedence over any other role when a user establishes a connection.

Changing the default role for a user or for PUBLIC only affects new database connections. Existing connections continue to run under currently assigned roles. If one default role was granted to *user*, and another default role was granted to PUBLIC, the default role granted to *user* takes precedence at connection time.

A default role cannot be assigned to another role. Because roles are not defined across databases, the default role must be assigned for each database. No options besides the *user-list* are valid after the TO keyword in the GRANT DEFAULT ROLE statement. The database server issues an error if you attempt to include the AS *grantor* clause or the WITH GRANT OPTION clause.

## Granting the EXTEND Role

If the IFX\_EXTEND\_ROLE configuration parameter is set to `ON` or to `1`, only users who hold the EXTEND role (and who also hold the Resource privilege on the database and the Usage privilege on the programming language in which the UDR is written) can create or drop UDRs that are written in the C or Java™ external languages that can support shared libraries.

The Database Server Administrator (DBSA), by default user **informix**, can grant the EXTEND role to one or more users or to PUBLIC with the GRANT EXTEND TO *user-list* statement.

Because EXTEND is a built-in role, the SET ROLE statement is not required for the EXTEND role to have this effect. It is sufficient for a user to hold the EXTEND role without using SET ROLE to enable it.

For example, suppose that user **max** holds Resource privileges on the database, and has also been granted Usage privilege on the C language by the GRANT USAGE ON LANGUAGE C statement. The following statement grants the EXTEND role to user **max**:

```
GRANT EXTEND TO 'max';
```

This statement enables user **max** to create or drop UDRs that are written in the C language, without requiring **max** to issue the SET ROLE EXTEND statement. (Here the quotation marks preserve the lowercase letters in the authorization identifier **max**.) Before user **max** can create or drop UDRs written in the Java™ language, however, the TO clause of a valid GRANT USAGE ON LANGUAGE JAVA statement must specify either `'max'`, or `PUBLIC`, or the name of a user-defined role that **max** holds (and that **max** has used the SET ROLE statement to specify as their current role).

In databases for which this security feature is not needed, the DBSA can disable this restriction on who can create or drop external UDRs by setting the `IFX_EXTEND_ROLE` configuration parameter to `OFF` or to `0` in the `ONCONFIG` file. When `IFX_EXTEND_ROLE` is set to `OFF` or to `0`, any user who holds the Resource privilege (and also holds the Usage privilege on the programming language in which the UDR is written) can create or drop external UDRs.

Resource privileges on the database and Usage privilege on the external language are required for any user to create or drop an external UDR, regardless of the `IFX_EXTEND_ROLE` configuration parameter setting, or whether the user holds the `EXTEND` role. User **informix**, the DBA, or any user who has received Usage privileges `WITH GRANT OPTION` can grant Usage privileges on the SPL, C, and Java™ languages to `PUBLIC`. See [Database-Level Privileges on page 595](#) for information about granting the Resource privilege. See [Language-Level Privileges on page 607](#) for information about granting Usage privileges on programming languages.

## WITH GRANT OPTION keywords

The `WITH GRANT OPTION` keywords convey the privilege or role to a *user* with the right to grant the same privileges or role to other users.

You create a chain of privileges that begins with you and extends to *user* as well as to whomever *user* subsequently conveys the right to grant privileges. If you include `WITH GRANT OPTION`, you can no longer control the dissemination of privileges.

The following example grants the Alter and Select privileges to user **mark** on the **cust\_seq** sequence object, with the ability to grant those privileges to others:

```
GRANT ALL ON cust_seq TO mark WITH GRANT OPTION;
```

If you revoke from *user* the privilege that you granted using the `WITH GRANT OPTION` keyword, you sever the chain of privileges. That is, when you revoke privileges from *user*, you automatically revoke the privileges of all users who received privileges from *user* or from the chain that *user* created (unless *user*, or the users who received privileges from *user*, were granted the same set of privileges by someone else).

The following examples illustrate this situation. You, as the owner of the table **items**, issue the following statements to grant access to user **mary**:

```
REVOKE ALL ON items FROM PUBLIC;
GRANT SELECT, UPDATE ON items TO mary WITH GRANT OPTION;
```

User **mary** uses their privilege to grant users **cathy** and **paul** access to the table:

```
GRANT SELECT, UPDATE ON items TO cathy;
GRANT SELECT ON items TO paul;
```

Later you revoke the access privileges for user **mary** on the **items** table:

```
REVOKE SELECT, UPDATE ON items FROM mary;
```

This single statement effectively revokes all privileges on the **items** table from users **mary**, **cathy**, and **paul**. If you want to create a chain of privileges with another user as the source of the privilege, use the `AS grantor` clause.

In Informix®, the WITH GRANT OPTION keywords are valid only for users. They are not valid when a role is the grantee of a privilege or of another role. You cannot specify WITH GRANT OPTION in a statement that grants a privilege to the PUBLIC group.

The Database Server Administrator cannot include the WITH GRANT OPTION keywords in the GRANT EXTEND or GRANT DBSECADM statements. The DBSA cannot delegate to another user the authorization to grant the built-in EXTEND or DBSECADM roles. If more than one user needs either of these authorizations, they should be included in the **DBSA** group when the database server is installed.

In addition to the GRANT DBSECADM statement, none of the other security administration options of the GRANT statement support the WITH GRANT OPTION keywords. For more information about these statements and their syntax, see [Security Administration Options on page 615](#).

---

[DBA keyword and Execute privilege on the created function on page 243](#)

## AS grantor clause

When you grant discretionary access privileges to other users, roles, or to PUBLIC, by default you are the one who can revoke those privileges. The AS *grantor* clause lets you establish another user as the source of the privileges that you are granting.

When you use the AS *grantor* clause, the login provided in the AS *grantor* clause replaces your login in the appropriate system catalog table. You can use this clause only if you have the DBA privilege on the database.

After you use this clause, only the specified *grantor* can revoke the effects of the current GRANT operation. Even a DBA cannot revoke a privilege unless that DBA is listed in the system catalog table as the user who granted the privilege.

The following example illustrates this situation. You are the DBA and you grant all privileges on the **items** table to user **tom** with the right to grant all privileges:

```
REVOKE ALL ON items FROM PUBLIC;  
GRANT ALL ON items TO tom WITH GRANT OPTION;
```

The next example illustrates a different situation. You also grant Select and Update privileges to user **jim**, but you specify that the privileges are granted as user **tom**. (The records of the database server in the **sysstabauth** system catalog table show that user **tom** is the grantor of those privileges, rather than you.)

```
GRANT SELECT, UPDATE ON items TO jim AS tom;
```

Later, you decide to revoke privileges on the **items** table from user **tom**, so you issue the following statement:

```
REVOKE ALL ON items FROM tom;
```

If instead, however, you try to revoke privileges from user **jim** with a similar statement, the database server returns an error, as the next example shows:

```
REVOKE SELECT, UPDATE ON items FROM jim;
580: Cannot revoke permission.
```

You receive an error because the database server record shows the original grantor as user **tom**, and you cannot revoke the privilege. Although you are the DBA, you cannot revoke a privilege that another user granted.

The AS *grantor* clause is not valid in the GRANT DEFAULT ROLE statement.

For contexts where the AS *grantor* clause is required, rather than optional, see [Granting the Execute privilege to PUBLIC on page 605](#).

## Security Administration Options

In conjunction with the REVOKE statement, the GRANT statement supports the discretionary access control (DAC) data security feature of Informix® by specifying which users or roles hold privileges that are required to access the database or objects within the database.

The Security Administration Options of the GRANT statement, like their counterparts for the REVOKE statement, support an additional set of data security features, called label-based access control (LBAC). These features enable Informix® to allow or withhold access to protected data on the basis of a comparing a row security label or column security label that is contained in the data object to the user security label and other credentials that have been granted to the user who is seeking access.

Security Administration Options

DBSECADM Clause<sup>302</sup>

EXEMPTION Clause<sup>303</sup>

SECURITY LABEL Clause<sup>304</sup>

SETSESSIONAUTH Clause<sup>305</sup>

Use of these GRANT statement security administration options is restricted:

- Only the Database Server Administrator (DBSA), by default user **informix**, or (on UNIX™) a member of the **DBSA** group, or (on Windows™) a member of the **Informix-Admin** group, can use the GRANT DBSECADM statement to grant the DBSECADM role.
- Only a user who holds the DBSECADM role can issue the GRANT EXEMPTION, GRANT SECURITY LABEL, or GRANT SETSESSIONAUTH statements, or the corresponding REVOKE statements.

301. Informix® extension

302. See [DBSECADM Clause on page 615](#)

303. See [EXEMPTION Clause on page 617](#)

304. See [SECURITY LABEL Clause on page 620](#)

305. See [SETSESSIONAUTH Clause on page 624](#)

## DBSECADM Clause

The GRANT DBSECADM statement enables the user to whom the DBSECADM role is granted to issue DDL statements that can create, alter, rename, or drop security objects, including security policies, security labels, and security components.

DBSECADM Clause

### DBSECADM TO

```
,
USER
user
```

| Element     | Description                            | Restrictions                                   | Syntax                                  |
|-------------|--|--|---|
| <i>user</i> | User to whom the role is to be granted | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

The DBSECADM role is a built-in role that only the DBSA can grant. Unlike user-defined roles, whose scope is the database in which the role is created, the scope of the DBSECADM role is all of the databases of the Informix® instance. It is not necessary for DBSA to reissue the GRANT DBSECADM statement in other databases of the same server. Like all built-in roles of Informix®, the DBSECADM role is enabled when it is granted, without requiring activation by the SET ROLE statement, and it remains in effect until it is revoked.

Only a user who holds the DBSECADM role can issue the following SQL statements that create or modify security objects:

- ALTER SECURITY LABEL COMPONENT
- CREATE SECURITY LABEL
- CREATE SECURITY LABEL COMPONENT
- CREATE SECURITY POLICY
- DROP SECURITY LABEL
- DROP SECURITY LABEL COMPONENT
- DROP SECURITY POLICY
- RENAME SECURITY LABEL
- RENAME SECURITY LABEL COMPONENT
- RENAME SECURITY POLICY

Only a user who holds the DBSECADM role can use the following SQL statements to reference tables that are protected by a security policy:

- ALTER TABLE ... ADD SECURITY POLICY
- ALTER TABLE ... ADD ... IDSSECURITYLABEL [DEFAULT *label*]
- ALTER TABLE ... ADD ... [COLUMN] SECURED WITH
- ALTER TABLE ... DROP SECURITY POLICY
- ALTER TABLE ... MODIFY ... [COLUMN] SECURED WITH
- ALTER TABLE ... MODIFY ... DROP COLUMN SECURITY

- CREATE TABLE ... COLUMN SECURED WITH
- CREATE TABLE ... IDSSECURITYLABEL [DEFAULT *label*]
- CREATE TABLE ... SECURITY POLICY

The following GRANT and REVOKE statements also cannot be issued by a user who does not hold the DBSECADM role:

- GRANT EXEMPTION
- GRANT SECURITY LABEL
- GRANT SETSESSIONAUTH
- REVOKE EXEMPTION
- REVOKE SECURITY LABEL
- REVOKE SETSESSIONAUTH

The USER keyword that can follow the TO keyword is optional, and has no effect, but any authorization identifier that the DBSA specifies in the GRANT DBSECADM statement must be the identifier of an individual user, rather than the identifier of a role, or the PUBLIC group.

The *user* can be the DBSA who issues this GRANT DBSECADM statement. This is an important exception to the general restriction that the TO clause of the GRANT statement (like the FROM clause in the REVOKE statements) cannot explicitly reference the authorization identifier of the user who issues the statement. Unlike other roles, access privileges, user security labels, and exemptions on rules that the GRANT statement can specify, you can grant the DBSECADM role to yourself, if you are user **informix**, or a member of the DBSA group, or (on Windows™ if you are a member of the **Informix-Admin** group.

In the following example, the DBSA grants the DBSECADM role to user **niccolo**:

```
GRANT DBSECADM TO niccolo;
```

If this statement executes successfully, user **niccolo** can perform the LBAC operations listed above, provided that **niccolo** also holds sufficient discretionary access privileges on the database and on the database objects that those SQL statements reference.

After a user is granted the DBSECADM role, only the DBSA can revoke it.

For a discussion of LBAC security objects, see your Informix® Security Guide.

## EXEMPTION Clause

The GRANT EXEMPTION statement modifies the security credentials of the specified user (or list of users) by disabling one or all of the rules of a specified security policy.

EXEMPTION Clause

**EXEMPTION ON RULE****IDSLBACREADARRAY IDSLBACREADTREE IDSLBACREADSET****IDSLBACWRITEARRAY****WRITEDOWN WRITEUP****IDSLBACWRITESET IDSLBACWRITETREE ALL****FOR***policy***TO****USER***user*

| Element       | Description   | Restrictions                                   | Syntax                                  |
|---------------|---|--|---|
| <i>policy</i> | The security policy from which the exemption is granted | Must exist in the database                     | <a href="#">Identifier on page 1456</a> |
| <i>user</i>   | User to whom the exemption is to be granted             | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can issue the GRANT EXEMPTION statement.

**Related reference**[RENAME SECURITY statement on page 714](#)[DROP SECURITY statement on page 526](#)[CREATE SECURITY LABEL statement on page 316](#)[CREATE SECURITY LABEL COMPONENT statement on page 318](#)[ALTER SECURITY LABEL COMPONENT statement on page 91](#)[CREATE SECURITY POLICY statement on page 322](#)

## Rules on Which Exemptions Are Granted

The keyword that follows the ON keyword specifies the predefined LBAC access rule of the security policy (whose identifier follows the FOR keyword) for which an exemption is granted. The access rule for which exemption is granted does not apply when a table that is protected by the specified security policy is accessed by a user to whom the exemption is granted. For descriptions of the predefined rules for read access and for write access that are associated with a security policy, see the section [Rules Associated with a Security Policy on page 325](#).

The following keywords of the GRANT EXEMPTION statement identify specific **IDSLBACRULES** rules from which this statement can exempt users:

- **IDSLBACREADARRAY** exempts the user from the **IDSLBACREADARRAY** rule for the specified security policy. That rule requires that each array component of the user security label must be greater than or equal to the corresponding array component of the data row security label.
- **IDSLBACREADSET** exempts the user from the **IDSLBACREADSET** rule for the specified security policy. That rule requires that each set component of the user security label must include the set component of the data row security label
- **IDSLBACREADTREE** exempts the user from the **IDSLBACREADTREE** rule for the specified security policy. That rule requires that each tree component of the user security label must include at least one of the elements in the tree component of the data row security label, or else the ancestor of one such element.
- **IDSLBACWRITEARRAY WRITEDOWN** exempts the user from one aspect of the **IDSLBACWRITEARRAY** rule for the specified security policy. That rule requires that each array component of the user security label must be equal to the array component of the data row security label. The user who holds this exemption can write to a row whose array component level is below the level in the label of the user. The user cannot, however, write to a row in whose label the array component level is above the level in the label of the user.
- **IDSLBACWRITEARRAY WRITEUP** exempts the user from one aspect of the **IDSLBACWRITEARRAY** rule for the specified security policy. The user who holds this exemption can write to a row whose array component level is above the level in the label of the user. The user cannot, however, write to a row in whose label the array component level is below the level in the label of the user.
- **IDSLBACWRITEARRAY** (with no **WRITEDOWN** or **WRITEUP** keyword) exempts the user from the **IDSLBACWRITEARRAY** rule for the specified security policy. The user who holds this exemption can write to a row without regard to the corresponding array component level of the row label.
- **IDSLBACWRITESET** exempts the user from the **IDSLBACWRITESET** rule for the specified security policy. That rule requires that each set component of the user security label must include the set component of the data row security label
- **IDSLBACWRITETREE** exempts the user from the **IDSLBACWRITETREE** rule for the specified security policy. That rule requires that each tree component of the user security label must include at least one of the elements in the tree component of the data row security label, or an ancestor of one such element.
- **ALL** exempts the user from all **IDSLBACRULES** rules for the specified security policy. This form of exemption is required to load data into a protected table.

In the following example, **DBSECADM** grants an exemption from all of the rules of the **MegaCorp** security policy to users **manoj** and **sam**:

```
GRANT EXEMPTION ON RULE ALL FOR MegaCorp TO manoj, sam;
```

## Security Policies and Grantees of Exemptions

An exemption applies only to the rules of the security policy whose name follows the **FOR** keyword. A protected table can have multiple security labels, but no more than one security policy.

The **GRANT EXEMPTION** statement fails with an error if the specified policy does not exist in the database.

The **USER** keyword that can follow the **TO** keyword is optional, and has no effect, but any authorization identifier specified in the **GRANT EXEMPTION** statement must be the identifier of an individual user, rather than the identifier of a role. This *user* cannot be the **DBSECADM** who issues the same **GRANT EXEMPTION** statement.

In the following example, DBSECADM grants an exemption to user **lynette** from rule **IDSLBACREADARRAY** of the **MegaCorp** security policy:

```
GRANT EXEMPTION ON RULE IDSLBACREADARRAY FOR MegaCorp TO lynette;
```

This exemption bypasses the read access rules for all array components of security labels of the specified policy.

When the GRANT EXEMPTION statement successfully grants an exemption to a user, the database server updates the **syssecpolicyexemptions** table of the system catalog to register the new exemption (or multiple exemptions, if several users are listed after the TO keyword).

For a discussion of LBAC security objects, see your Informix®.

## SECURITY LABEL Clause

The GRANT SECURITY LABEL statement grants a security label to a user or to a list of users.

SECURITY LABEL Clause

**SECURITY LABEL***policy.label*

**TO**

,

**USER**

*user*

**FOR ALL ACCESS**

**FOR READ ACCESS**

**FOR WRITE ACCESS**

| Element       | Description                              | Restrictions   | Syntax                                  |
|---------------|--|--|---|
| <i>label</i>  | Name of an existing security label       | Must exist as a label for the specified security <i>policy</i> | <a href="#">Identifier on page 1456</a> |
| <i>policy</i> | The security policy of this <i>label</i> | Must already exist in the database                             | <a href="#">Identifier on page 1456</a> |
| <i>user</i>   | User to whom the label is to be granted  | Must be the authorization identifier of a user                 | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can issue the GRANT SECURITY LABEL statement.

A security label is a database object that is always associated with a security policy. That policy defines the set of valid security components that make up the security label. The label stores a set of one or more values for each component of the security policy.

The DBSECADM can associate a security label with the following entities:

- A column of a database table, which a *column security label* can protect
- A row of a database table, which a *row security label* can protect
- A user, whose *user security label* (and any exemptions from rules of the security policy that have been granted to the user) are called the *security credentials* of the user.

When a user who holds a security label for a specific security policy attempts to access a row that is protected by a row security label of the same security policy, the database server compares the sets of values in the user security label and in the row security label to determine whether the user should be allowed access to the data. Similarly, LBAC takes into account the user security label and the column security label in determining whether the credentials of the user should allow access to the protected column.

The GRANT SECURITY LABEL statement is the mechanism by which DBSECADM associates a user with a security label. (Data values in a protected table are associated with a row security label or with a column security label by options to the CREATE TABLE or ALTER TABLE statements that only DBSECADM can execute, rather than by the GRANT SECURITY LABEL statement.)

The USER keyword that can follow the TO keyword is optional, and has no effect, but any authorization identifier specified in the GRANT SECURITY LABEL statement must be the identifier of an individual user, rather than of a role.

[CREATE SECURITY POLICY statement on page 322](#)

## Access Specifications

The list of users to whom the security label is granted can optionally be followed by keywords that specify the type of access to data that the security policy of the label protects

- FOR WRITE ACCESS

These keywords restrict the label to the write access rules of **IDSLBACRULES**, namely **IDLSBACWRITEARRAY**, **IDLSBACWRITESET**, and **IDLSBACWRITETREE**. These rules affect INSERT, DELETE, and UPDATE operations on protected data.

- FOR READ ACCESS

These keywords restrict the label to the read access rules of **IDSLBACRULES**, namely **IDLSBACWREADARRAY**, **IDLSBACREADSET**, and **IDLSBACREADTREE**. These rules affect SELECT, DELETE, and UPDATE operations on protected data.

- FOR ALL ACCESS

These keywords apply the label to all of the read and write access rules that are listed above. If the GRANT SECURITY LABEL statement includes no FOR ... ACCESS specification, this option takes effect as the default.

For more information about these **IDSLBACRULES** rules for label-based read and write access, see [Rules Associated with a Security Policy on page 325](#). For information about exemptions to these rules that can be granted for a specific security policy, see [Rules on Which Exemptions Are Granted on page 618](#).

If a user is granted a different security label for read access than for write access, then the values given for the security label components must follow these rules:

- For security label components of type ARRAY, the value must be the same in both security labels.
- For security label components of type SET, the values given in the security label used for WRITE access must be a subset of the values given in the security label used for READ access. If all of the values are the same, this is interpreted as being a subset, and is allowed.
- For security label components of type TREE, every element in the tree component of the security label for write access must be either an element or a descendent of an element in the tree component of the security label for read access.

In summary, when DBSECADM attempts to grant a security label for read access to a user who already holds a security label for write access, or vice versa, the read label cannot be more restrictive than the write label. Otherwise, the GRANT SECURITY LABEL statement fails with an error.

A user can be granted no more than two labels for the same security policy. If two labels are granted for the same policy, one label must be for read access and the other for write access. If DBSECADM attempts to grant a security label for read access to a user who already holds a security label for read access that is based on the same security policy, the GRANT SECURITY LABEL statement fails with an error. A similar failure result if both labels are for write access and are on the same security policy.

In both of these cases, the first security label must be revoked explicitly by the REVOKE SECURITY LABEL statement before a second label can be granted for the same access mode and the same security policy. The only exception to this rule is if both labels specify the same values for component elements, because in this case both security labels are functionally identical, and no error is issued.

## Rules for User Security Labels

The following rules affect security labels that are granted to users by the GRANT SECURITY LABEL statement:

- The *user* cannot be the DBSECADM who issues this GRANT SECURITY LABEL statement.
- A user without a security label has a NULL or zero label. A user with no security label cannot access data in a protected table, unless the user holds the necessary exemptions on the policy.
- By default, the IDSSecurityLabel column of a protected table cannot have NULL values. A user with no security label cannot insert data into a table with row protection, even if the user has been granted the necessary exemptions on the security policy, unless the row label is explicitly specified in the INSERT statement. For details of how to specify a security label explicitly in the INSERT statement, see [Security Label Support Functions on page 1294](#).

- User security labels have no effect on the following types of database tables, because these tables cannot be protected by a security policy:
  - Virtual Table Interface tables,
  - tables with Virtual Index Interface indexes,
  - tables in a typed-table hierarchy,
  - temporary tables.

## Examples of Granting User Security Labels

The following three statements create three security label components called **level**, **compartments**, and **groups** respectively:

```
CREATE SECURITY LABEL COMPONENT
  level ARRAY ['TS','S','C','U'];

CREATE SECURITY LABEL COMPONENT
  compartments SET {'A','B','C','D'};

CREATE SECURITY LABEL COMPONENT
  groups TREE ('G1' ROOT,
              'G2' UNDER ROOT,
              'G3' UNDER ROOT);
```

The following statement creates a security policy called **secPolicy** based on the three components above:

```
CREATE SECURITY POLICY secPolicy COMPONENTS
  level, compartments, groups;
```

The following statement creates a security label called **secLabel1**:

```
CREATE SECURITY LABEL secPolicy.secLabel1
  COMPONENT level 'S',
  COMPONENT compartments 'A', 'B',
  COMPONENT groups 'G2';
```

The following statement creates a security label called **secLabel2**:

```
CREATE SECURITY LABEL secPolicy.secLabel2
  COMPONENT level 'S',
  COMPONENT compartments 'B',
  COMPONENT groups 'G2';
```

The following statement creates a security label called **secLabel3**:

```
CREATE SECURITY LABEL secPolicy.secLabel3
  COMPONENT level 'S',
  COMPONENT compartments 'A',
  COMPONENT groups 'G3';
```

The following statement creates a security label called **secLabel4**:

```
CREATE SECURITY LABEL secPolicy.secLabel4
  COMPONENT level 'TS';
```

```
COMPONENT compartments 'A',  
COMPONENT groups 'G1';
```

The following statement grants a security label for read access to user **sam**:

```
GRANT SECURITY LABEL secPolicy.secLabel1  
TO sam FOR READ ACCESS;
```

The following statement grants a security label for write access to user **sam**. This statement succeeds because it satisfies the rules given above.

```
GRANT SECURITY LABEL secPolicy.secLabel2  
TO sam FOR WRITE ACCESS;
```

The following statement grants a security label for read access to user **lynette**:

```
GRANT SECURITY LABEL secPolicy.secLabel1  
TO lynette FOR READ ACCESS;
```

The following statement attempts to grant a security label for write access to user **sam**. This statement fails because it violates the rule with respect to the tree component.

```
GRANT SECURITY LABEL secPolicy.secLabel3  
TO sam FOR WRITE ACCESS;
```

The following statement attempts to grant a security label for write access to user **sam**. This statement fails because it violates the rule with respect to the array component.

```
GRANT SECURITY LABEL secPolicy.secLabel4  
TO sam FOR WRITE ACCESS;
```

When the GRANT SECURITY LABEL statement successfully grants a security label to a user, the database server updates the **sysseclabelauth** table of the system catalog to register the new holder of the security label.

For a discussion of LBAC security objects, see your Informix® Security Guide

---

## SETSESSIONAUTH Clause

The GRANT SETSESSIONAUTH statement grants the SETSESSIONAUTH privilege to one or more users or roles. This privilege allows the holder to use the SET SESSION AUTHORIZATION statement to set the session authorization to PUBLIC or to any one of a list of specified users.

SETSESSIONAUTH Clause

**SETSESSIONAUTH ON  
PUBLIC**

,  
**USER**

*user*

**TO**

,  
**USER**

*user*

**ROLE**

*role*

| Element     | Description  | Restrictions                                   | Syntax                                  |
|-------------|--|--|---|
| <i>role</i> | Role to which the privilege is to be granted   | Must be the authorization identifier of a role | <a href="#">Owner name on page 1488</a> |
| <i>user</i> | After the TO keyword, a user to whom the privilege is to be granted. After the ON keyword, a user whose identity the grantee can specify in the SET AUTHORIZATION statement. | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can grant the SETSESSIONAUTH privilege. Both the SETSESSIONAUTH privilege and the DBA privilege are required to execute the SET AUTHORIZATION statement.

The user or PUBLIC specification that follows the ON keyword specifies whose identity the grantee of the SETSESSIONAUTH privilege can take while using SET SESSION AUTHORIZATION statement. This can be a user or PUBLIC but not a role. If PUBLIC is specified, then the grantee of the privilege can assume the identity of any database user.

The USER and ROLE keywords that can follow the TO keyword are optional. Neither the *user* nor the *role* can be the holder of the DBSECADM role who issues the GRANT SETSESSIONAUTH statement. The TO clause cannot specify PUBLIC as the grantee.

The following example grants to user **sam** the ability to set the session authorization to users **lynette** and **manoj**:

```
GRANT SETSESSIONAUTH ON lynette, manoj TO sam;
```

The next example grants to user **lynette** the ability to set the session authorization to PUBLIC:

```
GRANT SETSESSIONAUTH ON PUBLIC TO lynette;
```

Only a user who holds the DBSECADM role can revoke the SETSESSIONAUTH privilege. For a discussion of LBAC security objects, see your Informix® Security Guide

## Surrogate user properties (UNIX™, Linux™)

Use the ACCESS TO PROPERTIES clause of the GRANT statement to map users to surrogate user properties required for access to Informix® resources.

### Note:

Only a DBSA can map externally authenticated users to valid surrogate user properties. If the USERMAPPING configuration parameter is set to enable support for mapped users, a DBSA issues the GRANT ACCESS TO PROPERTIES statement to map users to properties that correspond to the appropriate level of authorization.

Mapped users can connect to Informix® with the surrogate user properties if they authenticate with a pluggable authentication module (PAM) or single sign-on (SSO).

### Usage

The best practice is to map *user* to a specific OS user name that is reserved as a surrogate user identity only. You can add groups associated with the surrogate user identity with the GROUP keyword, and change the home directory with the HOME keyword. If the operating system administrator has specified acceptable surrogates in the `/etc/informix/allowed.surrogates` file, you can only map users to those specified OS users or groups.

If you map *user* to a user ID number, then remember to not create a user account on the Informix® host computer with the same number.

The USERMAPPING configuration parameter must be set to ADMIN in order to assign *user* a server administrative privilege with the ADMINISTRATOR keyword.

**Note:**

Use of this AUTHORIZATION clause (and of the AUTHORIZATION clause of the ALTER USER, CREATE USER, or CREATE DEFAULT USER statements) is not recommended. Different syntax will support role separation in a future release.

The PUBLIC and AUTHORIZATION keywords cannot be used together in the same statement, because the PUBLIC group cannot be granted server administrator privileges.

Specifying a directory for the user files with the HOME keyword is optional, but in some cases it is highly recommended. When an externally authenticated user is mapped to a surrogate user name but no HOME directory is specified in the GRANT ACCESS TO statement, then the mapped user has the same home directory as the user account on the Informix® host computer. When a user is mapped to a surrogate user identity with no set home directory, then Informix® creates a directory for user files in `$INFORMIXDIR/users`. In the latter case, the directory name in `$INFORMIXDIR/users` takes the form `uid.ID_number` (for example, `uid.101`).

## Examples

The syntax and explanations in this section are examples for the following environment, where the acronym GID abbreviates *group ID number*, and the acronym UID abbreviates *user ID number*:

- There is a user **fred** with an OS account on the Informix® host computer. User **fred** has database server access with UID 3000, GID 3000 (**users**), auxiliary group 200 (**staff**), and home directory `/home/fred`.
- On the same computer, there exists an OS account for user **dbuser**. This account is locked so that **dbuser** cannot log in. The **dbuser** account exists only for the purpose of surrogate user mapping. It has UID 3050, GID 4000 (**ifx\_user**), and home directory `/home/dbuser`.
- The group **ifx\_user** has GID 4000, with users **bill** and **eileen**.
- The administrator setting up mapped users knows that there is no entry for UID 101 in `/etc/passwd` (or its equivalent) and no entry for GID 10011 or 10101 in `/etc/group` (or its equivalent) .
- User **bob** does not have OS account on the Informix® host computer but can authenticate through PAM or LDAP. The database server is configured to accept authentication through the PAM or LDAP module.
- The USERMAPPING parameter in the `onconfig` file is set to ADMIN.

Mapping an externally authenticated user to a surrogate user name:

The administrator maps **bob** to the database server access privileges that already exist for user **fred** by issuing the following GRANT statement:

```
GRANT ACCESS TO bob PROPERTIES USER fred;
```

Granting Informix® access to all externally authenticated users:

In this environment, the purpose of the user **dbuser** account on the Informix® host computer is to grant database server access to mapped users. In a situation where there are many mapped users and they do not need to know about the user files created in the home directory, the administrator might find it efficient and sufficiently secure to map PUBLIC to the **dbuser** surrogate user identity. The administrator can map all authenticated users (PUBLIC) to the privileges established for **dbuser** with the following GRANT ACCESS statement:

```
GRANT ACCESS TO PUBLIC PROPERTIES USER dbuser;
```

**Note:** The mapping of PUBLIC to a surrogate user identity is designed for mapped users who do not create or are not concerned with user files on the home directory, such as a consumer who is accessing Informix® databases on a retail Web site. If you want to map users concerned with the functioning of the database server to a surrogate user identity like **dbuser**, it is recommended to map these users individually with a designated home directory, as in the following example:

```
GRANT ACCESS TO bob PROPERTIES USER dbuser HOME "/home/dbuser/bob";
```

Mapping an externally authenticated user to a UID-GID pair:

The administrator maps **bob** to a surrogate user identity that consists of a UID-GID pair that enables database server access by running the following statement:

```
GRANT ACCESS TO bob PROPERTIES UID 101, GROUP (10011);
```

Because no specific directory was specified, a directory under `$INFORMIXDIR/users` will be created with the name `uid.101` and this path will be used as the home directory. The UID 101 and GROUP (10011) are anonymous because they do not have entries in the respective `/etc` directories that designate UIDs and GIDs that can access Informix®.

Alternatively, the administrator can map **bob** to a surrogate user identity that is a combination of an anonymous UID and to an explicit group, such as in the following example:

```
GRANT ACCESS TO bob PROPERTIES 101, GROUP (ifx_user);
```

Because the **ifx\_user** group has members **bill** and **eileen**, the group is not anonymous.

Mapping an externally authenticated user to a surrogate user identity that has server administrative privileges:

In the following example, the administrator grants DBSA privileges to **bob**:

```
GRANT ACCESS TO bob PROPERTIES USER fred, GROUP (ifx_user), AUTHORIZATION (dbsa);
```

User **bob** is assigned UID 3000 (**fred**) and GIDs 3000 (**users**), 200 (**staff**), and the extra group 1000 (**ifx\_user**). The administrative role granted to **bob** could be different by replacing `dbsa` with a different privilege (DBSSO, AAO, or BARGROUP). If the USERMAPPING parameter were set to BASIC in the `onconfig` file, then **bob** would not be granted DBSA privileges by this statement. If USERMAPPING were set to OFF, then **bob** would not be able to connect to the database server at all.

## Examples

The following GRANT statements are examples of valid ACCESS TO PROPERTIES clauses, using hypothetical values. These examples do not represent the entire syntax and possible semantics of the ACCESS TO PROPERTIES clause.

- `GRANT ACCESS TO bob PROPERTIES USER fred;`
- `GRANT ACCESS TO PUBLIC PROPERTIES USER dbuser;`
- `GRANT ACCESS TO bob PROPERTIES USER dbuser HOME "/home/dbuser/bob";`
- `GRANT ACCESS TO bob PROPERTIES UID 101, GROUP (10011);`
- `GRANT ACCESS TO bob PROPERTIES 101, GROUP (ifx_user);`
- `GRANT ACCESS TO bob PROPERTIES USER fred, GROUP (ifx_user), AUTHORIZATION (DBSA);`

307. See [Fragment-Level Privileges on page 632](#)

## Usage

This statement is an extension to the ANSI/ISO standard for SQL.

Use the GRANT FRAGMENT statement to grant to users (or roles) any of the Insert, Update, and Delete access privileges on individual fragments of a table. The GRANT FRAGMENT statement is valid only for tables that are fragmented according to an expression-based distribution scheme. For an explanation of this type of fragmentation strategy, see [Expression Distribution Scheme on page 35](#).

---

[REVOKE statement on page 727](#)

## Fragment-Level Privileges

The keyword or keywords that follow the FRAGMENT keyword specify *fragment-level privileges*, which are a logical subset of table-level privileges:

Fragment-Level Privileges

**ALL**

**, INSERT DELETE UPDATE**

These keywords correspond to the following fragment-level privileges:

### Keyword

#### Effect on Grantee

**ALL**

Receives Insert, Delete, and Update privileges on the fragment

**INSERT**

Can insert rows into the fragment

**DELETE**

Can delete rows from the fragment

**UPDATE**

Can update rows in the fragment and in any columns.

## Definition of Fragment-Level Authorization

In an ANSI-compliant database, the owner implicitly receives all table-level privileges on a newly created table, but no other users receive privileges.

A user who has table privileges on a fragmented table has the privileges implicitly on all fragments of the table. These privileges are not recorded in the **sysfragauth** system catalog table.

When a fragmented table is created in a database that is not ANSI compliant, the table owner implicitly receives all table-level privileges on the table, and other users (that is, PUBLIC) receive all fragment-level privileges by default. The privileges granted to PUBLIC are explicitly recorded in the **systabauth** system catalog table.

If you use the REVOKE statement to withdraw existing table-level privileges, however, you can then use the GRANT FRAGMENT statement to restore specified table-level privileges to users, roles, or PUBLIC on some subset of the fragments.

Whether or not the database is ANSI compliant, you can use the GRANT FRAGMENT statement to grant explicit Insert, Update, and Delete privileges on one or more fragments of a table that is fragmented by expression. The privileges that the GRANT FRAGMENT statement grants are explicitly recorded in the **sysfragauth** system catalog table.

The Insert, Update, and Delete privileges that are conferred on table fragments by the GRANT FRAGMENT statement are collectively known as *fragment-level privileges* or *fragment-level authority*.

## Effect of Fragment-Level Authorization in Statement Validation

Fragment-level privilege enables users to execute INSERT, DELETE, and UPDATE data manipulation language (DML) statements on table fragments, even if the grantees lack Insert, Update, and Delete privileges on the table as a whole. Users who lack the table privileges can insert, delete, and update rows in authorized fragments because of the algorithm by which the database server validates DML statements. This algorithm consists of the following checks:

1. When a user executes an INSERT, DELETE, or UPDATE statement, the database server first checks whether the user has the table privileges necessary for the operation attempted. If the table privileges exist, the statement continues processing.
2. If the table privileges do not exist, the database server checks whether the table is fragmented by expression. If the table is not fragmented by expression, the database server returns an error to the user. This error indicates that the user does not have the privilege to execute the statement.
3. If the table is fragmented by expression, the database server checks whether the user holds the fragment privileges necessary for the attempted operation. If the user holds the required fragment privileges, the database server continues to process the statement. If the fragment privileges do not exist, the database server returns an error to the user. This error indicates that the user does not have the privilege to execute the statement.

## Duration of Fragment-Level Privileges

The duration of fragment-level privileges is tied to the duration of the fragmentation strategy for the table as a whole.

If you drop a fragmentation strategy by means of a DROP TABLE statement or by the INIT, DROP, or DETACH clauses of an ALTER FRAGMENT statement, you also drop any privileges that exist for the affected fragments. Similarly, if you drop a fragment of a table, you also drop any privileges that exist for the fragment.

Tables that are created as a result of a DETACH or INIT clause of an ALTER FRAGMENT statement do not keep the privileges that the former fragment or fragments had when they were part of the fragmented table. Instead, such tables assume the default table privileges.

If a table on which fragment privileges are defined is changed to a table with a round-robin strategy or some other expression strategy, the fragment privileges are also dropped, and the table assumes the default table privileges.

## Specifying Fragments

You can specify one fragment or a comma-separated list of fragments, with the name (or list of names) enclosed between parentheses that immediately follow the ON *table* specification. You cannot use quotation marks to delimit fragment names. The database server issues an error if you include no fragment, or if no fragment of the specified table matches a fragment that you list.

Each *fragment* must be referenced by its name. If you did not declare an explicit identifier when you created the fragment, its name defaults to the name of the dbspace in which it resides.

After a dbspace is renamed successfully by the onspaces utility, only the new name is valid. Informix® automatically updates existing fragmentation strategies in the system catalog to substitute the new dbspace name, but you must specify the new name in GRANT FRAGMENT statement to reference a fragment whose default name is the name of a renamed dbspace.

## The TO Clause

The list of one or more users or roles that follows the TO keyword identifies the grantees. You can specify the PUBLIC keyword to grant the specified fragment-level privileges to all users.

You cannot use GRANT FRAGMENT to grant fragment-level privileges to yourself, either directly or through roles.

If you enclose *user* or *role* in quotation marks, the name is case sensitive and is stored exactly as you typed it. In an ANSI-compliant database, if you do not use quotation marks around *user* or around *role*, the name is stored in uppercase letters.

The following statement grants the Insert, Update, and Delete privileges on the fragment of the **customer** table in **part1** to user **larry**:

```
GRANT FRAGMENT ALL ON customer (part1) TO larry;
```

The following statement grants the Insert, Update, and Delete privileges on the fragments of the **customer** table in **part1** and **part2** to user **millie**:

```
GRANT FRAGMENT ALL ON customer (part1, part2) TO millie;
```

To grant privileges on all fragments of a table to the same user or users, you can use the GRANT statement instead of the GRANT FRAGMENT statement. You can also use the GRANT FRAGMENT statement for this purpose.

Assume that the **customer** table is fragmented by expression into three fragments, and these fragments reside in the dbspaces named **part1**, **part2**, and **part3**. You can use either of the following statements to grant the Insert privilege on all fragments of the table to user **helen**:

```
GRANT FRAGMENT INSERT ON customer (part1, part2, part3) TO helen;
GRANT INSERT ON customer TO helen;
```

## Granting Privileges to One User or a List of Users

### About this task

You can grant fragment-level privileges to a single user or to a list of users.

The following statement grants the Insert, Update, and Delete privileges on the fragment of the **customer** table in **part3** to user **oswald**:

```
GRANT FRAGMENT ALL ON customer (part3) TO oswald;
```

The following statement grants the Insert, Update, and Delete privileges on the fragment of the **customer** table in **part3** to users **jerome** and **hilda**:

```
GRANT FRAGMENT ALL ON customer (part3) TO jerome, hilda;
```

## Granting One Privilege or a List of Privileges

### About this task

When you specify fragment-level privileges in a GRANT FRAGMENT statement, you can specify one privilege, a list of privileges, or all privileges.

The following statement grants the Update privilege on the fragment of the **customer** table in **part1** to user **ed**:

```
GRANT FRAGMENT UPDATE ON customer (part1) TO ed;
```

The following statement grants the Update and Insert privileges on the fragment of the **customer** table in **part1** to user **susan**:

```
GRANT FRAGMENT UPDATE, INSERT ON customer (part1) TO susan;
```

The following statement grants the Insert, Update, and Delete privileges on the fragment of the **customer** table in **part1** to user **harry**:

```
GRANT FRAGMENT ALL ON customer (part1) TO harry;
```

## WITH GRANT OPTION Clause

As in other GRANT statements, the WITH GRANT OPTION keywords specify that the grantee can grant the same fragment-level privileges to other users. WITH GRANT OPTION is not valid if the TO clause specifies a *role* as grantee. For additional information, see [WITH GRANT OPTION keywords on page 613](#).

The following statement grants the Update privilege on the fragment of the **customer** table in **part3** to user **george** and also gives george the right to grant the Update privilege on the same fragment to other users:

```
GRANT FRAGMENT UPDATE ON customer (part3) TO george WITH GRANT OPTION;
```

## AS grantor Clause

The *AS grantor* clause of the GRANT FRAGMENT statement can specify the grantor of the privilege. You can use this clause only if you have the DBA privilege on the database. When you include the *AS grantor* clause, the database server lists the user or role who is specified as *grantor* as the grantor of the privilege in the **grantor** column of the **sysfragauth** system catalog table.

In the next example, the DBA grants the Delete privilege on the fragment of the **customer** table in the **part3** fragment to user **martha**, and uses the *AS grantor* clause to specify that user **jack** is listed in **sysfragauth** as the grantor of the privilege:

```
GRANT FRAGMENT DELETE ON customer (part3) TO martha AS jack;
```

One effect of the *AS grantor* clause in the previous example is that user **jack** can execute the REVOKE FRAGMENT statement to cancel the Delete fragment-level privilege that **martha** holds, if this GRANT FRAGMENT statement were the only source of the fragment authority of **martha** on the **customer** rows in **part3**.

## Omitting the AS grantor Clause

When GRANT FRAGMENT does not include the *AS grantor* clause, the user who issues the statement is the default grantor of the specified fragment privileges.

In the next example, the user grants the Update privilege on the fragment of the **customer** table in **part3** to user **fred**. Because this statement does not specify the *AS grantor* clause, the user who issues the statement is listed by default as the grantor of the privilege in the **sysfragauth** system catalog table.

```
GRANT FRAGMENT UPDATE ON customer (part3) TO fred;
```

If you omit the *AS grantor* clause of GRANT FRAGMENT, or if you specify your own login name as the *grantor*, you can later use the REVOKE FRAGMENT statement to revoke the privilege that you granted to the specified user. For example, if you grant the Delete privilege on the fragment of the **customer** table in **part3** to user **martha** but specify user **jack** as the grantor of the privilege, user **jack** can revoke that privilege from user **martha**, but you cannot revoke that privilege from user **martha**.

The DBA, or the owner of the fragment, can use the *AS* clause of the REVOKE FRAGMENT statement to revoke privileges on the fragment.

## INFO statement

Use the INFO statement to list the names of all the user-defined tables in the current database, or to display information about a specific table.

### Syntax

This statement is an extension to the ANSI/ISO standard for SQL. You can use this statement only with DB-Access.

**INFO****TABLES****COLUMNS INDEXES STATUS****PRIVILEGES ACCESS****FRAGMENTS REFERENCES****FOR***table*

| Element      | Description                            | Restrictions | Syntax  |
|--------------|--|--------------|---|
| <i>table</i> | Table about which you seek information | Must exist   | <a href="#">Database Object Name on page 1450</a> |

**Usage**

The INFO TABLES statement lists the names of all the user-defined tables in the current database. Other keywords that can immediately follow the INFO keyword instruct DB-Access to display various attributes of the *table* whose name follows the FOR keyword. To display information from more than one keyword option, issue multiple INFO statements.

The keyword options that the INFO statement supports can display the following information:

- **TABLES Keyword**

Use TABLES (with no FOR clause) to list the identifier of every table in the current database, not including system catalog tables. Each user-defined table is listed in one of the following formats:

- If you are the owner of the **cust\_calls** table, it appears as **cust\_calls**.
- If you are not the owner of the **cust\_calls** table, the authorization identifier of the owner precedes the table name, such as **'june'.cust\_calls**.

- **COLUMNS Keyword**

Use COLUMNS to display the names and data types of the columns in the specified table, showing for each column whether NULL values are allowed.

- **INDEXES Keyword**

Use INDEXES to display the name, owner, and type of each index of the specified table, the clustered status, and listing the indexed columns.

- **FRAGMENTS Keyword**

Use FRAGMENTS to display the fragmentation strategy and the names of the dbspaces storing the fragments of a fragmented table. If the table is fragmented with an expression-based distribution scheme, the INFO statement also shows the expressions.

- **ACCESS or PRIVILEGES Keyword**

Use ACCESS or PRIVILEGES to display the discretionary access privileges currently held by users, roles, and the PUBLIC group for the specified table. (These two keywords are synonyms in this context.)

- **REFERENCES Keyword**

Use REFERENCES to display the References access privilege for users who can define referential constraints on the columns of the specified table. For database-level privileges, use a SELECT statement to query the **sysusers** system catalog table.

- **STATUS Keyword**

Use STATUS to display information about the owner, row length, number of rows and columns, creation date, and the status of audit trails for the specified table.

An alternative to using the INFO statement of SQL is to use the **Info** command of the **SQL** menu or of the **Table** menu of DB-Access to display the same and additional information.

## Examples

Use the following example to list the user tables in a database:

```
INFO TABLES;
```

To display information about a specific table, use the syntax:

```
INFO info_keyword FOR table
```

Here *table* is the table name and *info\_keyword* is one of the seven keyword options, besides TABLES, to the INFO statement. For example, to display the names of the columns of the table **customer**, use this statement:

```
INFO COLUMNS FOR customer;
```

This example produces the following output:

| Column name  | Type     | Nulls |
|--------------|----------|-------|
| customer_num | serial   | no    |
| fname        | char(15) | yes   |
| lname        | char(15) | yes   |
| company      | char(20) | yes   |
| address1     | char(20) | yes   |
| address2     | char(20) | yes   |
| city         | char(15) | yes   |
| state        | char(2)  | yes   |
| zipcode      | char(5)  | yes   |
| phone        | char(18) | yes   |

|-----------------------------|--|---|---|
| <i>position</i>             | Position at which to insert an element of a LIST data type | Literal integer or an INT or SMALLINT type SPL variable.    | <a href="#">Literal Number on page 1419</a>       |
| <i>synonym, table, view</i> | Table, view, or synonym in which to insert data            | Synonym or view and the table to which it points must exist | <a href="#">Database Object Name on page 1450</a> |

## Usage

To insert data into a table, you must either own the table or have the Insert privilege for the table (see [GRANT statement on page 592](#)). To insert data into a view, you must have the required Insert privilege, and the view must meet the requirements explained in [Inserting Rows Through a View on page 641](#).

If the table or view has data integrity constraints, the inserted rows must meet the constraint criteria. If they do not, the database server returns an error. If the checking mode is set to IMMEDIATE, all specified constraints are checked at the end of each INSERT statement. If the checking mode is set to DEFERRED, all specified constraints are *not* checked until the transaction is committed.

## Specifying Columns

If you do not explicitly specify one or more columns, data is inserted into columns using the column order that was established when the table was created or last altered. The column order is listed in the **syscolumns** system catalog table.

In Informix® ESQL/C, you can use the DESCRIBE statement with an INSERT statement to identify the column order and the data type of the columns in a table.

The number of columns specified in the INSERT INTO clause must equal the number of values supplied in the VALUES clause or by the SELECT statement, either implicitly or explicitly. If you specify a column list, the columns receive data in the order in which you list the columns. The first value following the VALUES keyword is inserted into the first column listed, the second value is inserted into the second column listed, and so on.

If you omit a column from the column list, and the column does not have a default value associated with it, the database server places a NULL value in the column when the INSERT statement is executed.

## Using the AT Clause (ESQL/C, SPL)

Use the AT clause to insert LIST elements at a specified position in a collection variable. By default, Informix® adds a new element at the end of a LIST collection.

If you specify a position greater than the number of elements in the list, the database server adds the element to the end of the list. You must specify a position value of at least 1 because the first element in the list is at position 1.

The following SPL example inserts a value at a specific position in a list:

```
CREATE PROCEDURE test3()
  DEFINE a_list LIST(SMALLINT NOT NULL);
  SELECT list_col INTO a_list FROM table1 WHERE id = 201;
  INSERT AT 3 INTO TABLE(a_list) VALUES( 9 );
  UPDATE table1 VALUES list_col = a_list WHERE id = 201;
END PROCEDURE;
```

Suppose that before this INSERT, **a\_list** contained the elements {1, 8, 4, 5, 2}. After this INSERT, **a\_list** contains the elements {1, 8, 9, 4, 5, 2}. The new element 9 was inserted at position 3 in the list. For more information on inserting values into collection variables, see [Collection-Derived Table on page 1436](#).

## Inserting Rows Through a View

You can insert data through a *single-table* view if you have the Insert privilege on the view. To do this, the defining SELECT statement can select from only one table, and it cannot contain any of the following components:

- DISTINCT keyword
- GROUP BY clause
- Derived value (also referred to as a virtual column)
- Aggregate value

Columns in the underlying table that are unspecified in the view receive either a default value or a NULL value if no default is specified. If one of these columns has no default value, and a NULL value is not allowed, the INSERT fails.

You can use data-integrity constraints to prevent users from inserting values into the underlying table that do not fit the view-defining SELECT statement. For further information, see [WITH CHECK OPTION Keywords on page 457](#).

You can insert rows through a *single-table* or a *multiple-table* view if an INSTEAD OF trigger specifies valid INSERT operations in its Action clause. See [INSTEAD OF Triggers on Views on page 439](#) for information on how to create INSTEAD OF triggers that insert through views.

If several users are entering sensitive information into a single table, the built-in USER function can limit their view to only the specific rows that each user inserted. The following example contains a view and an INSERT statement that achieves this effect:

```
CREATE VIEW salary_view AS
  SELECT lname, fname, current_salary FROM salary WHERE entered_by = USER;

INSERT INTO salary VALUES ('Smith', 'Pat', 75000, USER);
```

## Inserting Rows with a Cursor

In Informix® ESQL/C, if you associate a cursor with an INSERT statement, you must use the OPEN, PUT, and CLOSE statements to carry out the INSERT operation. For databases that have transactions but are not ANSI-compliant, you must issue these statements within a transaction.

If you are using a cursor that is associated with an INSERT statement, the rows are buffered before they are written to the disk. The insert buffer is flushed under the following conditions:

- The buffer becomes full.
- A FLUSH statement executes.
- A CLOSE statement closes the cursor.
- In a database that is not ANSI-compliant, an OPEN statement implicitly closes and then reopens the cursor.
- A COMMIT WORK statement ends the transaction.

When the insert buffer is flushed, the client processor performs appropriate data conversion before it sends the rows to the database server. When the database server receives the buffer, it converts any user-defined data types and then begins to insert the rows one at a time into the database. If an error is encountered while the database server inserts the buffered rows into the database, any buffered rows that follow the last successfully inserted rows are discarded.

## Inserting Rows into a Database Without Transactions

If you are inserting rows into a database with no transaction logging, you must take explicit action to restore inserted rows if the operation fails. For example, if INSERT fails after entering some rows, the successfully inserted rows remain in the table. You cannot recover automatically from a failed insert into a database for which no transaction log exists

## Inserting Rows into a Database with Transactions

If you are inserting rows into a database and you are using explicit transactions, use the ROLLBACK WORK statement to undo the INSERT. If you do not execute BEGIN WORK before the INSERT, and the INSERT fails, the database server automatically rolls back any data modifications made since the beginning of the INSERT. If you are using an explicit transaction, and the INSERT fails, the database server automatically undoes the effects of the INSERT.

In an ANSI-compliant database, transactions are implicit, and all database modifications take place within a transaction. In this case, if an INSERT statement fails, use the ROLLBACK WORK statement to undo the insertions.

Tables that you create with the RAW logging type are not logged. Thus, raw tables are not recoverable, even if the database uses logging.

Rows that you insert with a transaction remain locked until the end of the transaction. The end of a transaction is either a COMMIT WORK statement, where all modifications are made to the database, or a ROLLBACK WORK statement, where none of the modifications are made to the database. If many rows are affected by a *single* INSERT statement, you can exceed the maximum number of simultaneous locks permitted. To prevent this situation, either insert fewer rows per transaction, or lock the page (or the entire table) before you execute the INSERT statement.

## VALUES Clause

The VALUES clause can specify values to insert into one or more columns. When you use the VALUES clause, you can insert only one row at a time.

Each value that follows the VALUES keyword is assigned to the corresponding column listed in the INSERT INTO clause (or in column order, if a list of columns is not specified). If you are inserting a quoted string into a column, the maximum length that can be inserted without error is 256 bytes.

VALUES Clause

**VALUES**

```
(
,

315.indicator_var
316$ indicator_var
NULL USER
Quoted String317
Literal Number318
316Constant Expression319
Column Expression320
Literal Collection321
Literal Row322
Expression323
'literal_Boolean' literal_opaque
)
```

| Element                | Description   | Restrictions  | Syntax                                     |
|------------------------|---|---|--|
| <i>indicator_var</i>   | Variable to show if SQL statement returns NULL to <i>input_var</i>      | See the <i>Informix® ESQL/C Programmer's Manual</i> .                           | Language specific                          |
| <i>input_var</i>       | Variable that holds value to insert. This can be a collection variable. | Can contain any value option of VALUES clause                                   | Language specific                          |
| <i>literal_opaque</i>  | Literal representation for an opaque data type                          | Must be recognized by the <b>input</b> support function of the opaque data type | See documentation of the opaque type.      |
| <i>literal_Boolean</i> | Literal representation of a BOOLEAN value as a single character         | Either 'T' (TRUE) or 'F' (FALSE)  | <a href="#">Quoted String on page 1424</a> |

In Informix® ESQL/C, if you use an *input\_var* variable to specify the value, you can insert character strings longer than 256 bytes into a table.

315. ESQL/C only

For the keywords and the types of literal values that are valid in the VALUES clause, refer to [Constant Expressions on page 1235](#).

## Considering Data Types

The value that the INSERT statement puts into a column does not need to be of the same data type as the column that receives it. These two data types, however, must be compatible. Two data types are *compatible* if the database server has some way to cast one data type to another. A *cast* is the mechanism by which the database server converts one data type to another.

The database server makes every effort to perform data conversion. If the data cannot be converted, the INSERT operation fails. Data conversion also fails if the target data type cannot hold the value that is specified. For example, you cannot insert the integer 123456 into a column defined as a SMALLINT data type because this data type cannot hold a number that large.

For a summary of the casting that the database server provides, see the *Informix® Guide to SQL: Reference*. For information on how to create a user-defined cast, see the CREATE CAST statement in this document and *Informix® User-Defined Routines and Data Types Developer's Guide*.

In a database that uses a nondefault locale, if the **GL\_DATETIME** environment variable has a nondefault setting, the **USE\_DTENV** environment variable must be set to 1 before the INSERT statement can correctly insert localized DATETIME values into a database table, or into a view, or into an EXTERNAL table object.

---

## Inserting Values into Serial Columns

You can insert successive numbers, explicit values, or explicit values that reset the value in a SERIAL, BIGSERIAL, or SERIAL8 column:

- To insert a consecutive serial value

Specify a zero (0) for the serial column in the INSERT statement. In this case, the database server assigns the next highest value.

- To insert an explicit value

Specify the nonzero value after first verifying that it does not duplicate one already in the table. If the serial column is uniquely indexed or has a unique constraint, and your value duplicates one already in the table, an error results. If the value is greater than the current maximum value, you will create a gap in the series.

- To create a gap in the series (that is, to reset the serial value)

Specify a positive value that is greater than the current maximum value in the column.

Alternatively, you can use the MODIFY clause of the ALTER TABLE statement to reset the next value of a serial column.

For more information, see [Altering the Next Serial Value on page 146](#).

NULL values are not valid in serial columns.

In Informix®, inserting a serial value into a table that is part of a table hierarchy updates all tables in the hierarchy that contain the serial counter with the value that you insert. You can express this value either as zero (0) for the next highest value, or as a specific positive integer.

## Inserting Values into Opaque-Type Columns

Informix® supports INSERT operations that specify literal values of opaque data types as quoted strings in the VALUES clause. You can use this syntax to insert values of opaque UDTs into columns of tables in the local database, or into columns of tables in other databases of the local instance.

Some opaque data types require special processing when they are inserted. For example, if an opaque data type contains spatial or multirepresentational data, it might provide a choice of how to store the data: inside the internal structure or, for large objects, in a smart large object.

This is accomplished by calling a user-defined support function called **assign()**. When you execute INSERT on a table whose rows contains one of these opaque types, the database server automatically invokes the **assign()** function for the type. The **assign()** function can make the decision of how to store the data. For more information about the **assign()** support function, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Inserting Values into Collection Columns

You can use the VALUES clause to insert values into a collection column. For more information, see [Collection Constructors on page 1248](#).

For example, suppose you define the **tab1** table as follows:

```
CREATE TABLE tab1
(
  int1 INTEGER,
  list1 LIST(ROW(a INTEGER, b CHAR(5)) NOT NULL),
  dec1 DECIMAL(5,2)
);
```

The following INSERT statement inserts a row into **tab1**:

```
INSERT INTO tab1 VALUES
(
  10,
  LIST{ROW(1, 'abcde'),
        ROW(POW(3,3), '=27'),
        ROW(ROUND(ROOT(126)), '=11')},
  100
);
```

The collection column, **list1**, in this example, has three elements. Each element is an unnamed row type with an INTEGER field and a CHAR(5) field. The first element is composed of two literal values, an integer (1) and a quoted string (`'abcde'`). The second and third elements also use a quoted string to indicate the second field, but specify the value for the first field with an expression.

Regardless of what method you use to insert values into a collection column, you cannot insert NULL elements into the column. Thus expressions that you use cannot evaluate to NULL. If the collection that you are attempting to insert contains a NULL element, the database server returns an error.

You can also use a collection variable to insert the values of one or more collection elements into a collection column. For more information, see [Collection-Derived Table on page 1436](#).

## Inserting Values into ROW-Type Columns

Use the VALUES clause to insert values into a named or unnamed ROW type column, as in the following example:

```
CREATE ROW TYPE address_t
(
  street CHAR(20),
  city CHAR(15),
  state CHAR(2),
  zipcode CHAR(9)
);
CREATE TABLE employee
(
  name ROW ( fname CHAR(20), lname CHAR(20)),
  address address_t
);
```

The next example inserts literal values in the **name** and **address** columns:

```
INSERT INTO employee VALUES
(
  ROW('John', 'Williams'),
  ROW('103 Baker St', 'Tracy', 'CA', 94060)::address_t
);
```

INSERT uses ROW constructors to generate values for the **name** column (an unnamed ROW data type) and the **address** column (a named ROW data type). When you specify a value for a named ROW data type, you must use the CAST AS keywords or the double colon (::) operator, with the name of the ROW data type, to cast the value to the named ROW data type.

For the syntax of ROW constructors, see [Constructor Expressions on page 1247](#) in the Expression segment. For information on literal values for named ROW and unnamed ROW data types, see [Literal Row on page 1421](#).

When you use a ROW variable in the VALUES clause, the ROW variable must contain values for each field value. For more information, see [Inserting into a Row Variable \(ESQL/C, SPL\) on page 652](#).

You can use Informix® ESQL/C host variables to insert *nonliteral* values in two ways:

- An entire ROW type into a column. Use a **row** variable in the VALUES clause to insert values for all fields in a ROW column at one time.
- Individual fields of a ROW type. To insert nonliteral values in a ROW-type column, insert the elements into a **row** variable and then specify the **collection** variable in the SET clause of an UPDATE statement.

## Data Types in Distributed INSERT Operations

Distributed INSERT operations across tables in databases of different server instances can return only a subset of the data types that distributed INSERT operations can return from tables that are all in databases of the same Informix® instance.

An INSERT statement (or any other SQL data-manipulation language statement) that accesses a database of another Informix® instance can reference only the following data types:

- Built-in data types that are not opaque or complex
- BOOLEAN
- BSON
- JSON
- LVARCHAR
- DISTINCT of built-in types that are not opaque
- DISTINCT of BOOLEAN
- DISTINCT of BSON
- DISTINCT of JSON
- DISTINCT of LVARCHAR
- DISTINCT of the DISTINCT types in this list.

Cross-server distributed INSERT operations can support these DISTINCT types only if the DISTINCT types are cast explicitly to built-in types, and all of the DISTINCT types, their data type hierarchies, and their casts are defined exactly the same way in each participating database.

Cross-server DML operations cannot reference a column or expression of a complex, large-object, nor user-defined data type (UDT), nor of an unsupported DISTINCT or built-in opaque type. For additional information about the data types that Informix® supports in cross-server DML operations, see [Data Types in Cross-Server Transactions on page 781](#).

Distributed operations that access other databases of the local Informix® instance, however, can access the cross-server data types that are listed above, and also the following data types:

- Most of the *built-in opaque data types*, as listed in [Data Types in Cross-Database Transactions on page 779](#)
- DISTINCT of the built-in types that are referenced in the line above
- DISTINCT of any of the data types that are listed in either of the two lines above
- Opaque user-defined data types (UDTs) that can be cast explicitly to built-in data types.

Cross-database INSERT operations can support these DISTINCT and opaque UDTs only if all the opaque UDTs and DISTINCT types are cast explicitly to built-in types, and all of the opaque UDTs, DISTINCT types, data type hierarchies, and casts are defined exactly the same way in each participating database.

Distributed INSERT transactions cannot access the database of another Informix® instance unless both servers define TCP/IP or IPCSTR connections in their DBSERVERNAME or DBSERVERALIASES configuration parameters and in the **sqlhosts** file or SQLHOSTS registry subkey. The requirement, that both participating servers support the same type of connection (either TCP/IP or else IPCSTR), applies to any communication between Informix® instances, even if both reside on the same computer.

## Using Expressions in the VALUES Clause

With HCL Informix®, you can insert any type of expression except a column expression into a column. For example, you can insert built-in functions that return the current date, date and time, login name of the current user, or database server name where the current database resides.

The TODAY keyword returns the system date. The CURRENT or SYSDATE keyword returns the system date and time. The USER or CURRENT\_USER keyword returns a string that contains the login account name of the current user. The SITENAME or DBSERVERNAME keyword returns the database server name where the current database resides. The following example uses built-in functions to insert data:

```
INSERT INTO cust_calls (customer_num, call_dtime, user_id,
                       call_code, call_descr)
VALUES (212, CURRENT, USER, 'L', '2 days');
```

For more information, see [Expression on page 1193](#).

## Inserting NULL Values

When you execute the INSERT statement, the database server inserts a NULL value into any column for which you provide no value, as well as for all columns that have no default values and that are not listed explicitly. You also can specify the NULL keyword in the VALUES clause to indicate that a column should be assigned a NULL value.

The following example inserts values into three columns of the **orders** table:

```
INSERT INTO orders (orders_num, order_date, customer_num) VALUES (0, NULL, 123);
```

In this example, a NULL value is explicitly entered in the **order\_date** column, and all other columns of the **orders** table that are *not* explicitly listed in the INSERT INTO clause are also filled with NULL values.

## Inserting Values into Protected Tables

In a database that uses label-based access control (LBAC), the INTO clause of the INSERT statement can reference a table that is protected by a security policy if the user holds sufficient credentials for the security policy of the label that protects the table, as well as holding the Insert privilege on the table.

A user who holds no security label, however, cannot insert data into a table that has LBAC row protection, even if the user has been granted the required exemptions from rules of the security policy, unless the row label of the protected table is specified in the VALUES clause of the INSERT statement. Data manipulation language statements can provide the row label of a protected table by calling any of three built-in functions whose first argument specifies the name of the security policy, and whose additional arguments are one of the following:

- name of the security label
- name of the IDSSECURITYLABEL column in the table.
- names of the security policy components in the label and the values of their elements

For example, the following INSERT statement calls the built-in **SECLABEL\_BY\_NAME** function in order to insert a new row into a table called **tab002** that is protected by a row label called **Decca** of the **MegaCorp** security policy:

```
INSERT INTO tab002
VALUES (SECLABEL_BY_NAME('Megacorp', 'Decca'), 45, 'A.C.Deussy');
```

Whether this INSERT operation succeeds depends on whether the security credentials of the user are sufficient, relative to the component values of the **Decca** label, to enable write access to the **tab002** table.

For additional examples of INSERT statements that access protected tables by calling **SECLABEL\_BY\_NAME** or similar built-in functions, see [Security Label Support Functions on page 1294](#). For general information about LBAC security policies, security labels, read and write access rules, and exemptions from those rules, see your Informix® Security Guide.

## Truncated CHAR Values

In a database that is not ANSI-compliant, if you assign a value to a CHAR(*n*) column or variable and the length of that value exceeds *n* characters, the database server truncates the last characters without raising an error. For example, suppose that you define this table:

```
CREATE TABLE tab1 (col_one CHAR(2));
```

The database server truncates the data values in the following INSERT statements to "jo" and "sa" respectively, but does not return a warning:

```
INSERT INTO tab1 VALUES ("john");
INSERT INTO tab1 VALUES ("sally");
```

Thus, in a database that is not ANSI-compliant, the semantic integrity of data for a CHAR(*n*) column or variable is not enforced when the value inserted or updated exceeds the declared length *n*. (But in an ANSI-compliant database, the database server issues error -1279 when truncation of character data occurs.)

## Subset of SELECT Statement

As indicated in the [INSERT statement on page 638](#) syntax diagram, not all clauses and options of the SELECT statement are available for you to use in a query within an INSERT statement. The following SELECT clauses and options are not supported in an INSERT statement:

- FIRST and LIMIT
- INTO TEMP, INTO RAW, and INTO STANDARD result table options
- UNION, UNION ALL, INTERSECT, MINUS, and EXCEPT set operators.

In an ANSI-compliant database, if this statement has a WHERE clause that does not return rows, **sqlca** returns SQLNOTFOUND (100).

If an INSERT statement that is part of a multistatement prepared object inserts no rows, **sqlca** returns SQLNOTFOUND (100) for both ANSI-compliant databases and databases that are not ANSI-compliant. In databases that are not ANSI-compliant, **sqlca** returns zero (0) if no rows satisfy the WHERE clause.

In Informix®, if you are inserting values into a supertable in a table hierarchy, the subquery can reference a subtable. If you are inserting values into a subtable in a table hierarchy, the subquery can reference the supertable if it references only the supertable. That is, the subquery must use the `SELECT...FROM ONLY (supertable)` syntax.

## Execute Routine Clause

You can specify the `EXECUTE FUNCTION` statement (or the `EXECUTE PROCEDURE` statement) to insert values that a user-defined function returns

.

Execute Routine Clause

**EXECUTE**

**PROCEDURE***procedure*

**FUNCTION***function*

(  
 , Argument<sup>324</sup>  
 )

| Element                               | Description   | Restrictions | Syntax  |
|---------------------------------------|---|--------------|---|
| <i>function</i> ,<br><i>procedure</i> | User-defined function or procedure to insert the data | Must exist   | <a href="#">Database Object Name on page 1450</a> |

When you use a user-defined function to insert column values, the return values of the function must have a one-to-one correspondence with the listed columns. That is, each return value

- must be of a data type the same or compatible with the corresponding *column*,
- and its order among return values must match the *column*'s order in the column list.

For backward compatibility, Informix® can use the `EXECUTE PROCEDURE` keywords to execute an SPL function that was created with the `CREATE PROCEDURE` statement.

If the called SPL routine scans or updates the target table of the `INSERT` statement, the database returns an error. That is, the SPL routine cannot select data from the table into which you are inserting rows.

If a called SPL routine contains certain SQL statements, the database server returns an error. For information on which SQL statements cannot be used in an SPL routine that is called within a data manipulation statement, see [Restrictions on SPL Routines in Data-Manipulation Statements on page 1525](#).

324. See [Arguments on page 1433](#)

## Number of Values Returned by SPL, C, and Java™ Functions

An SPL function can return one or more values. Make sure that the number of returned values matches the number of columns in the table or the number of columns in the column list of the INSERT statement. These columns must have data types that are compatible with the values that the SPL function returns.

An external function written in the C or Java™ language can only return *one* value. Make sure that you specify only one column in the column list of the INSERT statement. This column must have a compatible data type with the value that the external function returns. The external function can be an iterator function.

The following example shows how to insert data into a temporary table called **result\_tmp** in order to output to a file the results of a user-defined function (**f\_one**) that returns multiple rows:

```
CREATE TEMP TABLE result_tmp( ... );
INSERT INTO result_tmp EXECUTE FUNCTION f_one();
UNLOAD TO 'file' SELECT * FROM foo_tmp;
```

## Inserting into a Row Variable (ESQL/C, SPL)

The INSERT statement does not support a row variable in the Collection- Derived-Table segment. You can use the UPDATE statement, however, to insert new field values into a row variable. For example, the following Informix® ESQL/C code fragment inserts a new row into the **rectangles** table (which [Inserting Values into ROW-Type Columns on page 647](#) defines):

```
EXEC SQL BEGIN DECLARE SECTION;
    row (x int, y int, length float, width float) myrect;
EXEC SQL END DECLARE SECTION;

...
EXEC SQL update table(:myrect)
    set x=7, y=3, length=6, width=2;
EXEC SQL insert into rectangles values (12, :myrect);
```

For more information, see [Updating a Row Variable \(ESQL/C\) on page 1053](#).

## Using INSERT as a Dynamic Management Statement

In Informix® ESQL/C, you can use the INSERT statement to handle situations where you need to write code that can insert data whose structure is unknown at the time you compile. For more information, refer to the dynamic management section of the *Informix® ESQL/C Programmer's Manual*.

## LOAD statement

Use the LOAD statement to insert data from an operating-system file into an existing table or view.

### Syntax

Only DB-Access supports the LOAD statement.

**LOAD FROM**'filename'

**DELIMITER**'delimiter'

**INSERT INTO**

table view synonym

(  
 , column  
 )

| Element                     | Description   | Restrictions   | Syntax  |
|-----------------------------|---|--|---|
| <i>column</i>               | Column to receive data values from<br><i>filename</i>   | See <a href="#">INSERT INTO Clause on page 658</a> .                         | <a href="#">Identifier on page 1456</a>           |
| <i>delimiter</i>            | Character to separate data values in each line of the load file. Default <i>delimiter</i> is the pipe ( ) symbol. | See <a href="#">DELIMITER Clause on page 658</a> .                           | <a href="#">Quoted String on page 1424</a>        |
| <i>filename</i>             | Path and filename of file to read. Default pathname is current directory  | See <a href="#">LOAD FROM File on page 653</a> .                             | Specific to operating system rules                |
| <i>synonym, table, view</i> | Synonym for the table in which to insert data from <i>filename</i>  | <i>Synonym</i> and <i>table</i> or <i>view</i> to which it points must exist | <a href="#">Database Object Name on page 1450</a> |

## Usage

This statement is an extension to the ANSI/ISO standard for SQL. You can use this statement only with DB-Access.

The LOAD statement appends new rows to the table. It does not overwrite existing data. You cannot add a row that has the same key as an existing row.

To use the LOAD statement, you must have Insert privileges for the table where you want to insert data. For information on database-level and table-level privileges, see the [GRANT statement on page 592](#).

In a database that uses a nondefault locale, if the **GL\_DATETIME** environment variable has a nondefault setting, the **USE\_DTENV** environment variable must be set to 1 before the LOAD statement can correctly insert localized DATETIME values into a database table, or into a view, or into an object that the CREATE EXTERNAL TABLE statement defined. For more information on the **GL\_DATETIME**, **GL\_DATE**, **DBTIME**, and **USE\_DTENV** environment variables, refer to the *Informix® GLS User's Guide*.

---

[INSERT statement on page 638](#)

## LOAD FROM File

The LOAD FROM file contains the data to be loaded into the specified table or view. The default pathname for the load file is the current directory.

You can use the file that the UNLOAD statement creates as the LOAD FROM file. (See [UNLOAD TO File on page 1031](#) for a description of how values of various data types are represented within the UNLOAD TO file.)

If you do not include a list of columns in the INSERT INTO clause, the fields in the file must match the columns that are specified for the table in number, order, and data type.

Each line of the file must have the same number of fields. You must define field lengths that are less than or equal to the length that is specified for the corresponding column. Specify only values that can convert to the data type of the corresponding column. The following table indicates how the database server expects you to represent the data types in the LOAD FROM file (when you use the default locale, U.S. English).

| Type of Data                      | Input Format   |
|-----------------------------------|--|
| blank                             | One or more blank characters between delimiters You can include leading blanks in fields that do not correspond to character columns.  |
| BOOLEAN                           | A <code>T</code> or <code>t</code> indicates a TRUE value, and an <code>F</code> or <code>f</code> indicates a FALSE value.  |
| COLLECTIONS                       | Collection must have its values surrounded by braces ( <code>{ }</code> ) and a field delimiter separating each element. For more information, see <a href="#">Loading Complex Data Types on page 657</a> .  |
| DATE                              | Character string in the following format: <i>mm/dd/year</i> You must state the month as a two-digit number. You can use a two-digit number for the year if the year is in the 20th century. (You can specify another century algorithm with the <b>DBCENTURY</b> environment variable.) The value must be an actual date; for example, February 30 is illegal. You can use a different date format if you indicate this format with the <b>GL_DATE</b> or <b>DBDATE</b> environment variable. For more information about environment variables, see the <i>Informix® Guide to SQL: Reference</i> and the <i>Informix® GLS User's Guide</i> . |
| DECIMAL, MONEY, FLOAT             | Value that can include a leading and/or trailing currency symbol and thousands and decimal separators Your locale files or the <b>DBMONEY</b> environment variable can specify a currency format.  |
| NULL                              | Nothing between the delimiters   |
| ROW types (named or unnamed)      | ROW type must have its values surrounded by parentheses and a field delimiter that separates each element. For more information, see <a href="#">Loading Complex Data Types on page 657</a> .  |
| Simple large objects (TEXT, BYTE) | TEXT and BYTE columns are loaded directly from the LOAD TO file. For more information, see <a href="#">Loading Simple Large Objects on page 656</a> .  |

| Type of Data                             | Input Format  |
|--|---|
| Smart large objects (CLOB, BLOB)         | CLOB and BLOB columns are loaded from a separate operating-system file. The field for the CLOB or BLOB column in the LOAD FROM file contains the name of this separate file. For more information, see <a href="#">Loading Smart Large Objects on page 656</a> .  |
| Time                                     | Character string in <i>year-month-day hour:minute:second.fraction</i> format You cannot use data type keywords or qualifiers for DATETIME or INTERVAL values. The year must be a 4-digit number, and the month must be a 2-digit number. The <b>DBTIME</b> or <b>GL_DATETIME</b> environment variable can specify other end-user formats.   |
| User-defined data formats (opaque types) | Associated opaque type must have an import support function defined if special processing is required to copy the data in the LOAD FROM file to the internal format of the opaque type. An import binary support function might also be required for data in binary format. The LOAD FROM file data must be in the format that the import or import binary support function expects. The associated opaque type must have an assign support function if special processing is required before writing the data in the database. See <a href="#">Loading Opaque-Type Columns on page 657</a> . |

For more information on **DB\*** environment variables, refer to the *Informix® Guide to SQL: Reference*. For more information on **GL\*** environment variables, refer to the *Informix® GLS User's Guide*.

If you are using a nondefault locale, the formats of DATE, DATETIME, MONEY, and numeric column values in the LOAD FROM file must be compatible with the formats that the locale supports for these data types. For more information, see the *Informix® GLS User's Guide*.

The following example shows the contents of an input file named **new\_custs**:

```
0|Jeffery|Padgett|Wheel Thrills|3450 El Camino|Suite 10|Palo Alto|CA|94306||
0|Linda|Lane|Palo Alto Bicycles|2344 University||Palo Alto|CA|94301|
(415)323-6440
```

This data file conveys the following information:

- Indicates a serial field by specifying a zero (0)
- Uses the pipe (|), the default delimiter
- Assigns NULL values to the **phone** field for the first row and the **address2** field for the second row

The NULL values are shown by two delimiters with nothing between them.

The following statement loads the values from the **new\_custs** file into the **customer** table that **jason** owns:

```
LOAD FROM 'new_custs' INSERT INTO jason.customer;
```

If you include any of the following special characters as part of the value of a field, you must precede the character with a backslash (\) escape symbol:

- Backslash
- Delimiter

- Newline character anywhere in the value of a VARCHAR or NVARCHAR column
- Newline character at end of a value for a TEXT value

Do not use the backslash character ( \ ) as a field separator. It serves as an escape character to inform the LOAD statement that the next character is to be interpreted as part of the data, rather than as having special significance.

Fields that correspond to character columns can contain more characters than the defined maximum allows for the field. The extra characters are ignored.

If you are loading files that contain VARCHAR data types, note the following information:

- If you give the LOAD statement data in which the character fields (including VARCHAR) are longer than the column size, the excess characters are disregarded.
- Use the backslash ( \ ) to escape embedded delimiter and backslash characters in all character fields, including VARCHAR.
- Do not use the following characters as delimiting characters in the LOAD FROM file: digits ( 0 to 9), the letters a to f, and A to F, the backslash ( \ ) character, or the NEWLINE (CTRL-J) character.

---

## Loading Simple Large Objects

The database server loads simple large objects (BYTE and TEXT columns) directly from the LOAD FROM file. Keep the following restrictions in mind when you load BYTE and TEXT data:

- You cannot have leading and trailing blanks in BYTE fields.
- Use the backslash ( \ ) to escape the special significance of literal delimiter and backslash characters in TEXT fields.
- Data being loaded into a BYTE column must be in ASCII-hexadecimal form. BYTE columns cannot contain preceding blanks.
- Do not use the following characters as delimiting characters in the LOAD FROM file: digits ( 0 to 9), the letters a to f, and A to F, the backslash ( \ ) character, or the NEWLINE (CTRL-J) character.

For loading TEXT columns in a non-default locale, the database server handles any required code-set conversions for the data. See also the *Informix® GLS User's Guide*.

If you are unloading files that contain BYTE or TEXT data types, objects smaller than 10 kilobytes are stored temporarily in memory. You can adjust the 10-kilobyte setting to a larger setting with the **DBBLOBBUF** environment variable. Simple large objects that are larger than the default or the setting of **DBBLOBBUF** are stored in a temporary file. For more information about the **DBBLOBBUF** environment variable, see the *Informix® Guide to SQL: Reference*.

---

## Loading Smart Large Objects

The database server loads smart large objects (BLOB and CLOB columns) from a separate operating-system file on the client computer. For information on the structure of this file, see [Unloading Smart Large Objects on page 1034](#).

In a LOAD FROM file, a CLOB or BLOB column value appears as follows:

```
start_off,length,client_path
```

In this format, *start\_off* is the starting offset (in hexadecimal) of the smart-large-object value within the client file, *length* is the length (in hexadecimal) of the BLOB or CLOB value, and *client\_path* is the pathname for the client file. No blank spaces can appear between these values.

For example, to load a CLOB value that is 512 bytes long and is at offset 256 in the `/usr/apps/clob9ce7.318` file, the database server expects the CLOB value to appear as follows in the LOAD FROM file:

```
|100,200,/usr/apps/clob9ce7.318|
```

If the whole client file is to be loaded, a CLOB or BLOB column value appears as follows in the LOAD FROM file:

```
client_path
```

For example, to load a CLOB value that occupies the entire file `/usr/apps/clob9ce7.318`, the database server expects the CLOB value to appear as follows in the LOAD FROM file:

```
|/usr/apps/clob9ce7.318|
```

In DB-Access, the USING clause is valid within files executed from DB-Access. In interactive mode, DB-Access prompts you for a password, so the USING keyword and *validation\_var* are not used.

For CLOB columns, the database server handles any required code-set conversions for the data. See also the *Informix® GLS User's Guide*.

## Loading Complex Data Types

In a LOAD FROM file, complex data types appear as follows:

- Collections are introduced with the appropriate constructor (SET, MULTISET, or LIST), and their elements are enclosed in braces ({} ) and separated with a comma, as follows:

```
constructor{val1 , val2 , ... }
```

For example, to load the SET values {1, 3, 4} into a column whose data type is SET(INTEGER NOT NULL), the corresponding field of the LOAD FROM file appears as:

```
|SET{1 , 3 , 4}|
```

- Row types (named and unnamed) are introduced with the ROW constructor and their fields are enclosed with parentheses and separated with a comma, as follows:

```
ROW(val1 , val2 , ... )
```

For example, to load the ROW values (1, 'abc'), the corresponding field of the LOAD FROM file appears as:

```
|ROW(1 , abc)|
```

## Loading Opaque-Type Columns

Some opaque data types require special processing when they are inserted. For example, if an opaque data type contains spatial or multirepresentational data, it might provide a choice of how to store the data: inside the internal structure or, for large objects, in a smart large object.

This processing is accomplished by calling a user-defined support function called **assign()**. When you execute the LOAD statement on a table whose rows contain one of these opaque types, the database server automatically invokes the **assign()** function for the type. The **assign()** function can make the decision of how to store the data. For more information about the **assign()** support function, see the *Informix® User-Defined Routines and Data Types Developer's Guide*.

## DELIMITER Clause

Use the DELIMITER clause to specify the delimiter that separates the data contained in each column in a row in the input file. You can specify TAB (CTRL-I) or a blank space (= ASCII 32) as the delimiter symbol. You cannot use the following items as the delimiter symbol:

- Backslash ( \ )
- NEWLINE character (CTRL-J)
- Hexadecimal numbers (0 to 9, a to f, A to F)

If you omit this clause, the database server checks the **DBDELIMITER** environment variable. For information about how to set the **DBDELIMITER** environment variable, see the *Informix® Guide to SQL: Reference*.

If the **DBDELIMITER** environment variable has not been set, the default delimiter is the pipe ( | ).

The following example specifies the semicolon ( ; ) as the delimiting character. The example uses Windows™ file-naming conventions.

```
LOAD FROM 'C:\data\loadfile' DELIMITER ';'
INSERT INTO orders;
```

## INSERT INTO Clause

Use the INSERT INTO clause to specify the table, synonym, or view in which to load the new data.

You must specify the column names only if one of the following conditions is true:

- You are not loading data into all columns.
- The input file does not match the default order of the columns (the order specified when the table was created).

The INTO clause cannot specify a table object that the CREATE EXTERNAL TABLE statement defined.

The following example identifies the **price** and **discount** columns as the only columns in which to add data. The example uses Windows™ file naming conventions.

```
LOAD FROM 'C:\tmp\prices' DELIMITER ','
INSERT INTO norman.worktab(price,discount)
```

## LOCK TABLE statement

Use the LOCK TABLE statement to control access to a table by other processes.

### Syntax

#### LOCK TABLE

*owner.*

*table synonym*

**IN**

**SHARE EXCLUSIVE**

**MODE**

| Element        | Description                             | Restrictions   | Syntax                                  |
|----------------|---|--|---|
| <i>owner</i>   | Owner of <i>synonym</i> or <i>table</i> | Must be the owner of the specified object                  | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> | Synonym for the table to be locked      | Synonym and the table to which it points must exist        | <a href="#">Identifier on page 1456</a> |
| <i>table</i>   | Table to be locked                      | See first paragraph of <a href="#">Usage on page 659</a> . | <a href="#">Identifier on page 1456</a> |

### Usage

This statement is an extension to the ANSI/ISO standard for SQL.

You can use LOCK TABLE to lock a table if either of the following is true:

- You are the owner of the table.
- You have Select privilege on the table or on a column in the table, either from a direct grant or from a grant to PUBLIC or to your current role.

The LOCK TABLE statement fails if the table is already locked in EXCLUSIVE mode by another process, or if you request an EXCLUSIVE lock while another user has locked the same table in SHARE mode.

The SHARE keyword locks a table in *shared mode*. Shared mode gives other processes *read* access to the table but denies *write* access. Other processes cannot update or delete data if a table is locked in shared mode.

The EXCLUSIVE keyword locks a table in *exclusive mode*. This mode denies other processes both read and write access to the table. Exclusive-mode locking automatically occurs during the following statements:

- ALTER FRAGMENT
- ALTER INDEX
- ALTER TABLE
- CREATE INDEX
- DROP INDEX
- RENAME COLUMN
- RENAME TABLE
- START VIOLATIONS TABLE
- STOP VIOLATIONS TABLE
- TRUNCATE

### The **ONLINE** keyword in some DDL operations

During certain ALTER FRAGMENT, DROP INDEX, and CREATE INDEX operations, including the ONLINE keyword can reduce the risk of run time errors when a concurrent session attempts to access the same table. For more information about the locking behavior of DDL statements that support the ONLINE keyword option, see these topics:

- [Using the ONLINE keyword in ATTACH operations on page 31](#)
- [Using the ONLINE keyword in DETACH operations on page 38](#)
- [Using the ONLINE keyword in MODIFY operations on page 68](#)
- [The ONLINE keyword of CREATE INDEX on page 279](#)
- [The ONLINE keyword of DROP INDEX on page 516.](#)

### **LOCK TABLE** statement behavior on secondary servers

You can set an exclusive lock on a table from an updatable secondary server in a high-availability cluster. For exclusive mode locks requested from a secondary server, sessions can read the table but not update it. This behavior is similar to shared access mode on a secondary server; that is, when one session has an exclusive lock on a given table, no other session can obtain a shared or exclusive lock on that table.

On read-only secondary servers, the session issuing the LOCK TABLE statement does not lock the table and the database server does not return an error to the client.

Shared mode locks in a cluster behave the same as for a standalone server. After a LOCK TABLE statement runs successfully, users can read the table but cannot modify it until the lock is released.

## Concurrent Access to Tables with Shared Locks

After the LOCK TABLE statement that specifies the IN SHARE MODE keywords executes successfully, other users can read the table but cannot modify its data until the lock is released. In databases that support transaction logging, the SELECT statement can implicitly place a shared lock on each tables that is listed in the FROM clause, in order to prevent other users from modifying those tables until the query is committed or rolled back.

## Concurrent Access to Tables with Exclusive Locks

After the LOCK TABLE statement with the IN EXCLUSIVE MODE option executes successfully, no other user can obtain a lock on the specified table. When you attempt a DDL operation on that table, however, you might receive RSAM error -106 if the same table is being accessed by a concurrent session (for example, by opening a cursor). This error can also affect implicit locks that certain DDL statements place on tables automatically.

This is possible because table locks do not preclude table access. An exclusive lock prevents other users from obtaining a lock, but it cannot prevent them from opening the table for write operations that wait for the exclusive lock to be released, or for Dirty Read operations on the table. You can set the **IFX\_DIRTY\_WAIT** environment variable to specify that the DDL operation wait for a specified number of seconds for Dirty Read operations to commit or rollback.

When one or more rows in a table are locked by an exclusive lock, the effect on other users partly depends on their transaction isolation level. Other users in all isolation levels except the Dirty Read isolation level might encounter locking errors, such as transactions that fail because the lock was not released within a specified time limit, or a deadlock situation.

On tables where row-level locking affects some of the rows, the risk of locking conflicts can be reduced by enabling transactions to read the most recently committed version of the data in the row-level locked table, rather than waiting for the transaction that holds the lock on that row to be committed or rolled back. This can be accomplished in several different ways, including these:

- From an individual session, issue this SQL statement

```
SET ISOLATION TO COMMITTED READ LAST COMMITTED;
```

- For all sessions using Committed Read or Read Committed isolation levels, set the USELASTCOMMITTED configuration parameter to 'ALL' or to 'COMMITTED READ', or else issue the SET ENVIRONMENT USELASTCOMMITTED statement with 'ALL' or 'COMMITTED READ' as the session environment option.
- For all sessions using Dirty Read or Read Uncommitted isolation levels, set the USELASTCOMMITTED configuration parameter to 'ALL' or to 'DIRTY READ', or else issue the SET ENVIRONMENT USELASTCOMMITTED statement with 'ALL' or 'DIRTY READ' as the session environment option.

- For users for whom a *user.sysdbopen()* procedure is defined in the database, the DBA can define that procedure to include the SET ENVIRONMENT USELASTCOMMITTED statement with 'ALL' or 'COMMITTED READ' as the session environment option, and also issue the SET ISOLATION statement to set Committed Read as the isolation level.
- For users for whom no *user.sysdbopen()* procedure exists in the database, the DBA can define a PUBLIC.*sysdbopen* procedure that specifies the same SET ENVIRONMENT USELASTCOMMITTED and SET ISOLATION statements.

This LAST COMMITTED isolation feature is useful only when row-level locking is in effect, rather than when another session holds an exclusive lock on the entire table. This feature is disabled for the specified table when LOCK TABLE applies a table-level lock. See [The LAST COMMITTED Option to Committed Read on page 977](#) for more information about this LAST COMMITTED feature for concurrent access to tables in which some rows are locked by exclusive locks, and for restrictions on the kinds of tables that can support this feature.

## Databases with transaction logging

If your database was created with transaction logging, the LOCK TABLE statement succeeds only if it executes within a transaction. You must issue a BEGIN WORK statement before you can execute a LOCK TABLE statement.

Transactions are implicit in an ANSI-compliant database. The LOCK TABLE statement succeeds if the specified table is not already locked by another process.

The following guidelines apply to the use of the LOCK TABLE statement within transactions:

- You cannot lock system catalog tables.
- You cannot switch between shared and exclusive table locking within a transaction. For example, once you lock the table in shared mode, you cannot upgrade the lock mode to exclusive.
- If you issue a LOCK TABLE statement before you access a row in the table, and PDQ is not in effect, no row locks are set for the table. In this way, you can override row-level locking and avoid exceeding the maximum number of locks that are defined in the database server configuration. (But if PDQ is in effect, you might run out of locks with error -134 unless the LOCKS parameter of your ONCONFIG file specifies a large enough number of locks.)
- All row and table locks release automatically after a transaction is completed. The UNLOCK TABLE statement fails in a database that uses transaction logging.
- The same user can explicitly use LOCK TABLE to lock up to 32 tables concurrently. (Use SET ISOLATION to specify an appropriate isolation level, such as Repeatable Read, if you need to lock rows from more than 32 tables during a single transaction.)

The following example shows how to change the locking mode of a table in a database that was created with transaction logging:

```
BEGIN WORK;
LOCK TABLE orders IN EXCLUSIVE MODE;
...
COMMIT WORK;
BEGIN WORK;
LOCK TABLE orders IN SHARE MODE;
...
COMMIT WORK;
```

**Warning:** It is recommended that you not use nonlogging tables in a transaction. If you need to use a nonlogging table in a transaction, either lock the table in exclusive mode or set the isolation level to Repeatable Read to prevent concurrency problems.

## Databases without transaction logging

In a database that was created without transaction logging (by omitting the WITH LOG keywords in the CREATE DATABASE statement), table locks that were set by the LOCK TABLE statement are released after any of the following events:

- An UNLOCK TABLE statement executes.
- The user closes the database.
- The user exits from the application.

To change the lock mode on a table, release the lock with the UNLOCK TABLE statement and then issue a new LOCK TABLE statement.

The following example shows how to change the lock mode of a table in an unlogged database:

```
LOCK TABLE orders IN EXCLUSIVE MODE;
. . .
UNLOCK TABLE orders;
. . .
LOCK TABLE orders IN SHARE MODE;
```

## Locking Granularity

The default granularity for locking a table is at the *page* level, or whatever you specify (either PAGE or ROW) in the **IFX\_TABLE\_LOCKMODE** environment variable, or if that is not set, by setting DEF\_TABLE\_LOCKMODE in the ONCONFIG file. The LOCK MODE clause of the CREATE TABLE or ALTER TABLE statement can override the default locking granularity by specifying PAGE or ROW. Only row-level locks support the LAST COMMITTED feature of Informix®.

The LOCK TABLE statement, however, always locks the entire table, overriding any other locking granularity specification for the table.

In all of these contexts, the term "lock mode" means the *locking granularity*. In the context of the SET LOCK MODE statement, however, "lock mode" refers to the behavior of the database server when a process attempts to access a row or a table that another process has locked.

---

## MERGE statement

Use the MERGE statement to transfer data from a source table into a target table by combining UPDATE or DELETE operations with INSERT operations in a single SQL statement. You can also use this statement to join the source and target tables, and then perform only UPDATE operations, only DELETE operations, or only INSERT operations on the target table.

The MERGE statement supports the ANSI/ISO standard for SQL with Informix® extensions.

### Syntax

#### MERGE

*, directive*

#### INTO

*target\_table target\_view target\_synonym*

| <i>target_table</i> ,<br><i>target_view</i> ,<br><i>target_synonym</i>  | The name or synonym of a table or updatable view in which to insert, update, or delete data    | See <a href="#">Restrictions on Source and Target Tables on page 669</a> .  | <a href="#">Database Object Name on page 1450</a>   |

## Usage

The MERGE statement of Informix® is a data manipulation language (DML) statement that joins a source table object with a target table or view. The *condition* that you specify after the ON keyword determines which rows from the source object are used in UPDATE or DELETE operations on the target, and which rows are used in INSERT operations on the target. The MERGE statement does not modify its source object.

The condition must be followed by the WHEN MATCHED THEN keywords of the Delete or the Update clause, or by the WHEN NOT MATCHED THEN keywords of the Insert clause, or by both the Update (or Delete) and Insert clauses.

- If you specify both the Update clause and the Insert clause, the MERGE statement can perform both INSERT and UPDATE operations on the target object.
- If you specify both the Delete clause and the Insert clause, the MERGE statement can perform both INSERT and DELETE operations on the target object.
- If you specify no Insert clause, no INSERT operations are performed, but the Update clause must specify an UPDATE operation (or else the Delete clause must specify a DELETE operation) on the target object for source rows that match the condition.
- If you specify no Update clause and no Delete clause, no UPDATE or DELETE operations are performed, but the Insert clause must specify an INSERT operation on the target object for source rows that do not match the condition.

The MERGE statement fails with an error if no Delete clause, no Update clause, and no Insert clause is specified.

The MERGE statement can have the following effects on the target object:

- If the Update clause is included, the MERGE statement updates rows in the target table or view according to the specifications of the SET clause with data from rows in the source table for which the condition evaluates to true.
- If the Delete clause is included, the MERGE statement deletes from the target table or view the rows for which the condition evaluates to true.
- If the Insert clause is included, the MERGE statement inserts new rows into the target table or view according to the specifications of the VALUES clause with data from rows in the source table for which the condition evaluates to false.

A single MERGE statement, however, can have no more than two of these three effects, because the Delete clause and the Update clause are mutually exclusive.

For operations on large tables, make sure that these resources are available on your system:

- A sufficient number of locks
- Sufficient temporary dbspace storage for the intermediate join results
- Sufficient dbspace storage for the results of the MERGE statement.

In a high-availability cluster configuration, you can issue the MERGE statement from a primary server or from an updatable secondary server.

### Optimizer Directives and Subqueries

You can optionally specify one or more query optimizer directives after the MERGE keyword, such as access method directives, join order directives, and join method directives to specify how the source and target tables are joined. The goal-oriented directives like EXPLAIN and AVOID\_EXECUTE are also valid in the MERGE statement.

Within the MERGE statement, subqueries can also include optimizer directives to control other aspects of the execution plan. Subqueries are valid in the following contexts in the MERGE statement:

- In the *condition* of the ON clause
- In the SET clause of the Update clause
- In the VALUES clause of the Insert clause
- In the USING clause if it specifies a source query, which can include a subquery in any context where the SELECT statement supports a subquery.

The MERGE statement fails with an error, however, if it includes a subquery that references the target table.

In a database that supports external directives, the query optimizer can also apply external directives to the outer join of the source and target tables, or to subqueries within the MERGE statement.

## The ON Condition

The *condition* that follows the ON keyword specifies a join filter for the source and target table objects. This ON clause filter determines the matched rows and unmatched rows in the MERGE statement, based on the outer join of the target and source tables.

- If the MERGE statement includes the Update clause, and the ON clause condition evaluates to true, then the corresponding rows are updated in the target.
- If the MERGE statement includes the Delete clause, and the ON clause condition evaluates to true, then the corresponding rows are deleted from the target.
- If the MERGE statement includes the Insert clause, and the ON clause condition evaluates to false, then the corresponding source rows are inserted into the target.

Update operations of the MERGE statement on rows that match the condition obey the UPDATE statement rules for the SET clause. For details of the syntax for specifying the updated values in the target table, see [SET Clause on page 1042](#).

Delete operations of MERGE on rows that match the condition obey the DELETE statement rules. For details of deleting values from the target table, see [Using the WHERE Keyword to Specify a Condition on page 491](#).

Insert operations on rows that do not match the condition obey the INSERT statement rules for the VALUES clause. For details of the syntax for specifying the inserted values in the target table, see [VALUES Clause on page 643](#).

## Error Handling

If an error occurs while the MERGE statement is executing, the entire statement is rolled back.

For databases that support transaction logging, you can include error-handling logic that includes the ROLLBACK TO SAVEPOINT statement in a transaction that includes the MERGE statement and that defines one or more savepoints. After a partial rollback of the transaction to a savepoint, the effects of the INSERT, DELETE, or UPDATE operations of the MERGE statement persist in the target table if the MERGE statement precedes the savepoint in the lexical order of statements for that savepoint level of the transaction. The effects of MERGE are rolled back, however, if the MERGE statement follows the specified savepoint within the transaction.

In an ANSI-compliant database, data manipulation language (DML) statements are always in a transaction. These databases do not support the MERGE statement outside a transaction.

## Constraint Checking

Enabled data-integrity constraints on the target object are enforced in MERGE operations.

- If the checking mode is set to DEFERRED, the constraints are not checked until after the transaction is committed.
- If the constraint-checking mode for the target table is set to IMMEDIATE, then unique and referential constraints are checked after all the UPDATE (or DELETE) and INSERT operations are complete. The NOT NULL and check constraints are checked during the UPDATE, DELETE, and INSERT operations.

For information on setting the constraint-checking mode, see the topic [SET Transaction Mode statement on page 1007](#).

If a referential constraint on the target table was defined with the ON DELETE CASCADE keywords, the DELETE clause of the MERGE statement also performs cascading deletes on rows of child tables of the target table.

A Delete merge fails, however, if an enabled referential constraint has established a parent-child relationship between the target and source tables, if the constraint was defined with the ON DELETE CASCADE keywords. The MERGE statement cannot perform cascading deletes on rows of its source table. For more information, see the topic [Restrictions on DELETE When Tables Have Cascading Deletes on page 490](#).

If the START VIOLATIONS statement has defined an active violations table on the target table, then the MERGE statement can have the following effects on the target, violations, and diagnostic tables:

- The conforming rows in the target table that match the join condition are either deleted or updated.
- The target table also receives the conforming unmatched rows that MERGE successfully inserts.
- The violation table receives the nonconforming rows.
- A diagnostic table receives information about why the nonconforming rows failed to satisfy a constraint or a unique index during operations of the MERGE statement on the target table.

To enable a violations table and a diagnostic table on the target table, the SET Database Object Mode statement must set the constraints or unique indexes of the target table to ENABLED or FILTERING mode. For more information, see the topics [Relationship to the SET Database Object Mode statement on page 1013](#) and [SET Database Object Mode statement on page 871](#).

### Using the MERGE Statement with Triggers

The target object can be a table on which an Update, Delete, or Insert trigger is defined. If both an Update trigger and an Insert trigger (or both a Delete trigger and an Insert trigger) are enabled on the target table, MERGE can act as the triggering event for both triggers, if the MERGE statement performs both UPDATE (or DELETE) and INSERT operations on the target.

If the MERGE statement includes operations that activate both Update (or Delete) and Insert triggers, the BEFORE trigger actions of both triggers are executed when the MERGE operation starts. Similarly, the AFTER trigger actions of both triggers are executed at the end of the MERGE operation. The FOR EACH ROW trigger actions are activated for each row processed.

Just as for any DML statement, the database server treats all the triggers that are activated by the same MERGE statement as a single trigger, and the resulting trigger action is the merged-action list. All the rules that govern a trigger action apply to the merged list as one list, and no distinction is made between the two original triggers. For more information, see [Actions of Multiple Triggers on page 421](#).

The target object, however, cannot be a view on which an enabled INSTEAD OF trigger is defined. Before you can use that view as the target of a MERGE statement, you must disable or drop the INSTEAD OF trigger.

In the definition of a trigger, the MERGE statement cannot be specified directly as a triggered action. An SPL trigger routine that is called in a triggered action, however, can issue the MERGE statement.

### Security Policies and Secure Auditing

If the source object or any of its columns is protected by a label-based access control (LBAC) security policy, the user who issues the MERGE statement must have a security label (or must hold a security policy exemption) that provides sufficient credentials to read the source table in MERGE operations.

If the target object or any of its columns is protected by a label-based security policy, the user who issues the MERGE statement must have a security label (or must hold a security policy exemption) that provides sufficient credentials to write

in the target object columns that the SET clause or the VALUES clause specifies, or to delete rows from the target that include protected data.

If both the source and the target table are protected, they must be protected by the same security policy. The MERGE statement cannot join tables that are protected by different LBAC security policies.

On Informix® instances that use the secure-auditing facility to record activity that could potentially alter or reveal data or the auditing configuration, no specific audit event mnemonic is defined in audit trails for the MERGE statement:

- Activities specified by the Delete clause are recorded as DELETE events.
- Activities specified by the Insert clause are recorded as INSERT events.
- Activities specified by the Update clause are recorded as UPDATE events.

## Restrictions on Source and Target Tables

Which table objects can be the source or target of the MERGE statement depends on attributes of the table object, and on what access privileges are held by the user who issues the MERGE statement.

The target table must be local to the database to which the current session is connected, but you can specify a remote a table as the source table, or in subqueries of the SET clause for UPDATE operations, and in subqueries of the VALUES clause for INSERT operations.

Sections that follow identify additional restrictions on the source and target tables.

### Restrictions on the Source Table

The source object can be the name or synonym of a STANDARD, RAW, TEMP, EXTERNAL, or collection-derived table, or a view. It can be in the same database as the target object, or in a different database of the local Informix® instance, or it can be a remote table that is managed by a different Informix® instance.

If the source is a collection-derived table that is defined by the result of a query, the USING clause can declare names for derived columns that the SET and VALUES clauses of the MERGE statement can reference.

The user who issues the MERGE statement must hold the Connect access privilege (or a higher privilege) on the database of the source object, and must also hold the Select privilege (or a higher privilege) on the source object. The user can be granted these access privileges individually, or can hold them as a member of the PUBLIC group, or through the current or default role of the user, if the role or PUBLIC holds those privileges.

If the source object or any of its columns is protected by a label-based security policy, the user who issues the MERGE statement must have a security label (or must hold a security policy exemption) that provides sufficient credentials to read

the source object. If the credentials of the user are insufficient to read protected columns, according to the standard label-based access control (LBAC) rules, then the MERGE statement can process only a subset of the source data. If this subset is empty, the MERGE statement cannot insert any values from the source object into the target table.

The following restrictions apply to the source table object:

- The source cannot be a view on which an enabled SELECT trigger is defined.
- The source cannot be a typed table in the same table hierarchy as the target table.
- In a Delete merge, the source cannot have a child-table relationship with the target, as defined by an enabled referential constraint, if that constraint was defined with the ON DELETE CASCADE keywords. (Child-table relationships have no effect on the Delete merge, however, unless a target table constraint specifies cascading deletes.)

### Restrictions on the Target Table

The target table object must be in a database of the same Informix® instance to which the current session is connected. It can be the name or synonym of a STANDARD, RAW, or TEMP table, or an updatable view. If the target is a supertable within a table hierarchy, the Delete clause also deletes the corresponding rows in all the subtables of the target table.

The user who issues the MERGE statement must hold the Connect access privilege (or a higher privilege) on the database of the target object, and must also hold the Insert privilege and the Update or Delete privilege on the target object, if the MERGE statement includes the corresponding Insert, Update, or Delete clause.

The following restrictions apply to the target table of the MERGE statement. If that table has any of the following attributes, the MERGE operation returns an error.

- The target cannot be a typed table in the same table hierarchy as the source table.
- The target cannot be a Virtual Table Interface (VTI) table.
- The target cannot be an object that the CREATE EXTERNAL TABLE statement defined.
- The target cannot be in a database of a remote Informix® instance.
- The target cannot be a system catalog table.
- The target cannot be a view on which an enabled INSTEAD OF trigger is defined.
- The target cannot be a read-only view.
- The target cannot be a pseudo-table (a memory-resident object in a system database, such as the **sysmaster** or **sysadmin** databases).
- The target cannot be a data source of any subquery of the same MERGE statement, including subqueries in the ON clause, in the SET clause, or in the VALUES clause.
- If the MERGE statement includes the DELETE clause, the target cannot have a parent-table relationship with the source table, if this relationship is defined by an enabled referential constraint that specifies the ON DELETE CASCADE keywords.

### Restriction on the combined row length

The source table and the target table in the MERGE statement cannot have a total combined row length ( = row size of source table + row size of target table ) greater than 32,767 bytes. Otherwise, the MERGE statement fails with an error, as in the following example:

```

CREATE TABLE t1
  (f1 INT,
   f2 VARCHAR(10),
   lv1 LVARCHAR(5000),
   lv2 LVARCHAR(4000),
   lv3 LVARCHAR(8000));
CREATE TABLE t2
  (f1 INT,
   f2 VARCHAR(10),
   lv1 LVARCHAR(5000),
   lv2 LVARCHAR(4000),
   lv3 LVARCHAR(8000));

INSERT INTO t1 (f1,f2) VALUES (1,'t1 1');
INSERT INTO t1 (f1,f2) VALUES (2,'t1 2');
INSERT INTO t1 (f1,f2) VALUES (3,'t1 3');
INSERT INTO t1 (f1,f2,lv1) VALUES (7,'t1 7',
  'loooooooooooooooooooooong');

INSERT INTO t2 (f1,f2) VALUES (3,'t2 3');
INSERT INTO t2 (f1,f2) VALUES (4,'t2 4');
INSERT INTO t2 (f1,f2) VALUES (5,'t2 5');
INSERT INTO t2 (f1,f2) VALUES (6,'t2 6');

MERGE INTO t2 AS o USING t1 AS n ON o.f1 = n.f1
  WHEN NOT MATCHED THEN INSERT ( o.f1,o.f2)
  VALUES ( n.f1,n.f2);

```

The MERGE statement above fails, because the sum of the row lengths of the source and target tables exceeds the upper limit of 32,767 bytes.

For MERGE operations that include only the INSERT clause (but no DELETE clause nor UPDATE clause), you can circumvent this row length limit by replacing the MERGE statement with INSERT INTO . . . SELECT statements. For the same tables and data values in the MERGE example above, the following INSERT statements run successfully:

```

INSERT INTO t2(f1, f2)
  SELECT t1.f1, t1.f2 FROM t1
  WHERE NOT EXISTS
    (SELECT f1, f2 FROM t2
     WHERE t2.f1 = t1.f1);

INSERT INTO t2(f1,f2)
  SELECT t1.f1, t1.f2 FROM t1
  LEFT JOIN t2 ON t1.f1 = t2.f1
  WHERE t2.f1 IS NULL;

```

After the two INSERT INTO . . . SELECT operations, table **t2** contains what the row size restriction prevented the previous MERGE example from returning.

### Restrictions on distributed MERGE statements

If the source and target tables are not in the same database, both databases must satisfy the compatibility requirements for cross-database and cross-server DML operations:

- Both databases must be of release versions that support all the data types in the source table and in the target table.
- If one database is ANSI-compliant, the other must also be ANSI-compliant.

- If one database is not ANSI-compliant but uses explicit transaction logging, the other must also support explicit transaction logging. (In this case, their buffered or unbuffered logging modes need not match.)
- If one database does not support transaction logging, the other also must not.
- Both databases must have the same NLSCASE sensitivity setting.

A distributed MERGE statement cannot, for example, specify a source table in a case-sensitive database and a target table in a database created as NLSCASE INSENSITIVE, whether or not either table includes NCHAR or NVARCHAR columns.

Distributed MERGE transactions cannot access the database of another Informix® instance unless both servers define TCP/IP or IPCSTR connections in their DBSERVERNAME or DBSERVERALIASES configuration parameters and in the **sqlhosts** file or SQLHOSTS registry subkey. The requirement, that both participating servers support the same type of connection (either TCP/IP or else IPCSTR), applies to any communication between Informix® instances, even if both reside on the same computer.

### Data types valid in distributed MERGE statements

When the source table and the target tables are in the same database, MERGE statements can access all the data-type categories that the [Data Type on page 1163](#) topics describe, including BYTE and TEXT objects, OPAQUE and DISTINCT types, complex types, and user-defined types (UDTs).

A MERGE statement whose source table is in a database of another Informix® server instance, however, is subject to the restrictions on column data types in other distributed data manipulation language (DML) operations. A cross-server MERGE statement can reference columns with only the following subset of data types:

- Built-in data types that are not opaque or complex
- BOOLEAN
- BSON
- JSON
- LVARCHAR
- DISTINCT of built-in types that are not opaque
- DISTINCT of BOOLEAN
- DISTINCT of BSON
- DISTINCT of JSON
- DISTINCT of LVARCHAR
- DISTINCT of the DISTINCT types in this list.

Cross-server distributed MERGE operations can support these DISTINCT types only if the DISTINCT types are cast explicitly to built-in types, and all of the DISTINCT types, their data type hierarchies, and their casts are defined exactly the same way in the source database and in the target database.

Cross-server operations can also return the IDSSECURITYLABEL data type from a table protected by row-level LBAC security, if the user issuing the MERGE statement holds sufficient LBAC credentials. Accessing a table protected only by column-level LBAC security requires similar credentials, but in that case the table has no IDSSECURITYLABEL column.

Cross-server DML operations cannot reference a column or expression of a complex, large-object, nor user-defined data type (UDT), nor of an unsupported DISTINCT or built-in opaque type. For additional information about the data types that Informix® supports in cross-server DML operations, see [Data Types in Cross-Server Transactions on page 781](#).

Distributed MERGE operations in which the source table and the target table are in a different databases of the same Informix® server instance can access the same data types that are listed above for cross-server MERGE statements. They can also access the following additional data types that are not supported in cross-server MERGE operations:

- Most of the *built-in opaque data types*, as listed in [Data Types in Cross-Database Transactions on page 779](#)
- DISTINCT of the built-in types that are referenced in the line above
- DISTINCT of any of the data types that are listed in either of the two lines above
- Opaque UDTs that can be cast explicitly to built-in data types.

Cross-database INSERT operations can support these DISTINCT and opaque UDTs only if all the opaque UDTs and DISTINCT types are cast explicitly to built-in types, and all of the opaque UDTs, DISTINCT types, data type hierarchies, and casts are defined exactly the same way in each participating database.

If the target and source tables are in different databases, whether of the same server instance or of different server instances, the MERGE statement fails if it references a table, view, or synonym that includes a column of any of the following opaque or complex data types:

- IMPEXP, IMPEXPBIN, LOLIST, or SENDRECV built-in opaque type
- DISTINCT of any of those opaque data types
- Any complex type, including COLLECTION, LIST, MULTISSET, or SET, and named or unnamed ROW types.

## Handling Duplicate Rows

While MERGE is executing, the same row in the target table cannot be updated or deleted more than once. No attempt is made to update or delete any row in the target that did not already exist before the MERGE statement was executed. That is, there are no updates or deletes of rows that the same MERGE statement inserted into the target.

The following example of the MERGE statement uses the transaction table **new\_sale** as the source table from which to insert or update rows in the fact table **sale**. The join condition in this example tests whether the **new\_sale.cust\_id** column value matches the **sale.cust\_id** column value.

```
MERGE INTO sale USING new_sale AS n
ON sale.cust_id = n.cust_id
WHEN MATCHED THEN UPDATE
    SET sale.salecount = sale.salecount + n.salecount
WHEN NOT MATCHED THEN INSERT (cust_id, salecount)
VALUES (n.cust_id, n.salecount);
```

To execute this MERGE statement, the database server joins the target and source tables, and then applies the specified equality condition to process the result of the join:

- For rows that satisfy the condition (because the **sale.cust\_id** value matches the **new\_sale.cust\_id** value), MERGE updates the **sale.salecount** column value, according to the SET clause specification.
- For rows that do not satisfy the condition (because no row in the **sale** table has the same **cust\_id** value as **new\_sale.cust\_id**), MERGE inserts new rows containing the **new\_sale.cust\_id** and **new\_sale.salecount** values into the **sale** table, according to the VALUES clause specification.

For the MERGE statement in the previous example, suppose that the **sale** target table contains the two records and that the **new\_sale** source table contains the three records.

**Table 9. Records in 'sale' Table**

| <b>cust_id</b> | <b>sale_count</b> |
|----------------|-------------------|
| Tom            | 129               |
| Julie          | 230               |

**Table 10. Records in 'new\_sale' Table**

| <b>cust_id</b> | <b>sale_count</b> |
|----------------|-------------------|
| Tom            | 20                |
| Julie          | 3                 |
| Julie          | 10                |

When merging **new\_sale** into **sale** by specifying the expression `sale.cust_id = new_sale.cust_id` as the matching condition, the MERGE statement returns an error, because it attempts to update one of the records in the **sale** target table more than once.

### Data Types in Distributed MERGE Operations

If the source table or view (or any table object referenced in the source query) specifies a table object in a database of a Informix® instance other than the local instance that manages the database of the target table, the MERGE statement can access columns of only the following data types in the remote database:

- Built-in data types that are not opaque
- BOOLEAN
- LVARCHAR
- DISTINCT of the built-in data types that are not opaque
- DISTINCT of BOOLEAN
- DISTINCT of LVARCHAR
- DISTINCT of any DISTINCT data type that appears in this list.

Cross-server distributed MERGE operations can support these DISTINCT types only if the DISTINCT types are cast explicitly to built-in types, and all of the DISTINCT types, their data type hierarchies, and their casts are defined exactly the same way

in each participating database. For additional information about the data types that Informix® supports in cross-server DML operations, see [Data Types in Cross-Server Transactions on page 781](#).

MERGE operations cannot access a database of another Informix® instance unless both server instances support either a TCP/IP or an IPCSTR connection, as defined in their DBSERVERNAME or DBSERVERALIASES configuration parameters and in the **sqlhosts** file or SQLHOSTS registry subkey. This connection-type requirement applies to any communication between Informix® instances, even if both database servers reside on the same computer.

Distributed MERGE operations that access table objects in other databases of the local Informix® instance, however, can access all of the cross-server data types in the preceding list, and these additional data types:

- Most built-in opaque data types, as listed in [Data Types in Cross-Database Transactions on page 779](#)
- DISTINCT of the same built-in opaque types
- DISTINCT of any of the data types in either of the two preceding lines
- Opaque user-defined data types (UDTs) that are explicitly cast to built-in data types.

The MERGE statement also supports Distributed Relational Database Architecture™ (DRDA®) protocols in common client APIs. For the Informix® data types that MERGE can return from a remote database through DRDA® protocols, see the *Informix® Administrator's Guide* for lists of the Informix® data types that are supported (and that are not supported) by DRDA®.

## Examples of MERGE Statements

Examples in this section include MERGE statements that illustrate join conditions and various DML operations on the result set of the join.

### Examples

The following MERGE statement includes the Update and Insert clauses, and uses an equality predicate as the join condition:

```
MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num
WHEN MATCHED THEN
  UPDATE SET c.fname = e.fname,
            c.lname = e.lname,
            c.company = e.company,
            c.address1 = e.address1,
            c.address2 = e.address2,
            c.city = e.city,
            c.state = e.state,
            c.zipcode = e.zipcode,
            c.phone = e.phone
WHEN NOT MATCHED THEN
  INSERT (c.fname, c.lname, c.company, c.address1, c.address2,
         c.city, c.state, c.zipcode, c.phone)
  VALUES
    (e.fname, e.lname, e.company, e.address1, e.address2,
     e.city, e.state, e.zipcode, e.phone);
```

The next example specifies multiple predicates in the ON clause:

```

MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num
     AND c.fname=e.fname AND c.lname=e.lname
WHEN MATCHED THEN
  UPDATE SET c.fname = e.fname,
             c.lname = e.lname,
             c.company = e.company,
             c.address1 = e.address1,
             c.address2 = e.address2,
             c.city = e.city,
             c.state = e.state,
             c.zipcode = e.zipcode,
             c.phone = e.phone
WHEN NOT MATCHED THEN
  INSERT
    (c.fname, c.lname, c.company, c.address1, c.address2,
     c.city, c.state, c.zipcode, c.phone)
  VALUES
    (e.fname, e.lname, e.company, e.address1, e.address2,
     e.city, e.state, e.zipcode, e.phone);

```

The following MERGE statement performs an Update join, with no Insert clause:

```

MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num
WHEN MATCHED THEN
  UPDATE SET c.fname = e.fname,
             c.lname = e.lname,
             c.company = e.company,
             c.address1 = e.address1,
             c.address2 = e.address2,
             c.city = e.city,
             c.state = e.state,
             c.zipcode = e.zipcode,
             c.phone = e.phone ;

```

The following MERGE statement includes only the Delete clause after the join condition:

```

MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num
  WHEN MATCHED THEN
    DELETE ;

```

The next MERGE example includes only the Insert clause:

```

MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num AND c.fname=e.fname
     AND c.lname=e.lname
WHEN NOT MATCHED THEN
  INSERT
    (c.fname, c.lname, c.company, c.address1, c.address2,
     c.city, c.state, c.zipcode, c.phone)
  VALUES
    (e.fname, e.lname, e.company, e.address1, e.address2,
     e.city, e.state, e.zipcode, e.phone);

```

The next example illustrates that the WHEN MATCHED and WHEN NOT MATCHED specifications can appear in any order:

```

MERGE INTO customer c
  USING ext_customer e
  ON c.customer_num=e.customer_num AND c.fname=e.fname AND c.lname=e.lname
WHEN NOT MATCHED THEN
  INSERT
    (c.fname, c.lname, c.company, c.address1, c.address2,
     c.city, c.state, c.zipcode, c.phone)
  VALUES
    (e.fname, e.lname, e.company, e.address1, e.address2,
     e.city, e.state, e.zipcode, e.phone)
WHEN MATCHED THEN UPDATE
  SET c.fname = e.fname,
      c.lname = e.lname,
      c.company = e.company,
      c.address1 = e.address1,
      c.address2 = e.address2,
      c.city = e.city,
      c.state = e.state,
      c.zipcode = e.zipcode,
      c.phone = e.phone ;

```

The following MERGE statement specifies as its source a derived table that the query in the USING clause defines:

```

MERGE INTO customer c
  USING (SELECT * from ext_customer e1, orders e2
         WHERE e1.customer_num=e2.customer_num ) e
  ON c.customer_num=e.customer_num AND c.fname=e.fname
  AND c.lname=e.lname
WHEN NOT MATCHED THEN
  INSERT (c.fname, c.lname, c.company, c.address1, c.address2,
         c.city, c.state, c.zipcode, c.phone)
  VALUES (e.fname, e.lname, e.company, e.address1, e.address2,
         e.city, e.state, e.zipcode, e.phone)
WHEN MATCHED THEN
  UPDATE SET c.fname = e.fname,
            c.lname = e.lname,
            c.company = e.company,
            c.address1 = e.address1,
            c.address2 = e.address2,
            c.city = e.city,
            c.state = e.state,
            c.zipcode = e.zipcode,
            c.phone = e.phone ;

```

## OPEN statement

Use the OPEN statement to activate a cursor.

**Syntax****OPEN***cursor\_id*<sup>328</sup><sup>329</sup> *cursor\_id\_var***USING***, parameter\_var*<sup>329</sup>**SQL DESCRIPTOR**'*descriptor*' *descriptor\_var***DESCRIPTOR** *sqlda\_pointer*<sup>328</sup> <sup>329</sup> **WITH REOPTIMIZATION**

| Element               | Description  | Restrictions   | Syntax   |
|-----------------------|--|--|--|
| <i>cursor_id</i>      | Name of a cursor   | Must have been declared by the DECLARE statement   | <a href="#">Identifier on page 1456</a>        |
| <i>cursor_id_var</i>  | Host variable = <i>cursor_id</i>   | Must be a character data type  | Language specific                              |
| <i>descriptor</i>     | Name of a system-descriptor area   | Must have been allocated   | <a href="#">Quoted String on page 1424</a>     |
| <i>descriptor_var</i> | Host variable that identifies the system-descriptor area   | System-descriptor area must have been allocated  | <a href="#">Quoted String on page 1424</a>     |
| <i>parameter_var</i>  | Host variable whose contents replace a question ( ? ) mark placeholder in a prepared SQL statement   | Must be a character or collection data type  | Language specific                              |
| <i>sqlda_pointer</i>  | Pointer to <b>sqlda</b> structure defining data type and memory location of values to replace question ( ? ) marks in a prepared statement | Cannot begin with a dollar ( \$ ) sign nor with a colon ( : ). You must use an <b>sqlda</b> structure with dynamic SQL statements. | <a href="#">DESCRIBE statement on page 495</a> |

**Usage**

Use this statement with Informix® ESQL/C or with SPL.

A *cursor* is an identifier associated with an SQL statement that returns an ordered set of values. The OPEN statement activates a cursor that the DECLARE statement defined.

Cursor can be classified by their associated SQL statements:

- A *Select cursor*: a cursor that is associated with a SELECT statement
- A *Function cursor*: a cursor that is associated with the EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement

328. Informix® extension

329. ESQL/C only

- An *Insert cursor*: a cursor that is associated with the INSERT statement
- A *Collection cursor*: a Select or Insert cursor that operates on a collection variable.

In UDRs written in the SPL language, the OPEN statement can reference only Select or Function cursors, and these must specify the identifier of the cursor, rather than a variable that stores the *cursor\_id*. The OPEN statement cannot reference a direct cursor that the FOREACH statement of SPL has declared.

The specific actions that the database server takes differ, depending on the statement with which the cursor is associated. In ESQL/C, when you associate one of the previous statements with a cursor directly (that is, you do not prepare the statement and associate the statement identifier with the cursor), the OPEN statement implicitly prepares the statement. (This is not a feature of OPEN in SPL routines, where the DECLARE statement associates a cursor with the identifier of an existing prepared statement, rather than directly with SQL statement text.)

In an ANSI-compliant database, you receive an error code if you try to open a cursor that is already open.

## Opening a Select Cursor

When you open either a Select cursor or an update cursor that is created with the SELECT FOR UPDATE syntax, the SELECT statement is passed to the database server with any values that are specified in the USING clause. The database server processes the query to the point of locating or constructing the first row of the active set. The following example illustrates a simple OPEN statement in Informix® ESQL/C:

```
EXEC SQL declare s_curs cursor for select * from orders;
EXEC SQL open s_curs;
```

An SPL routine cannot reference an update cursor in the OPEN statement.

## Opening an Update Cursor Inside a Transaction

If you are working in a database with explicit transactions, you must open an update cursor within a transaction. This requirement is waived if you declared the cursor using the WITH HOLD option.

## Opening a Function Cursor

When you open a Function cursor, the EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement is passed to the database server with any values that are specified in the USING clause.

The values in the USING clause are passed as arguments to the user-defined function. This user-defined function must be declared to accept values. (If the statement was previously prepared, the statement was passed to the database server when it was prepared.) The database server executes the function to the point where it returns the first set of values.

The following example illustrates a simple OPEN statement in Informix® ESQL/C:

```
EXEC SQL declare s_curs cursor for
  execute function new_func(arg1,arg2)
  into :ret_val1, :ret_val2;
EXEC SQL open s_curs;
```

## Reopening a Select or Function Cursor

The database server evaluates the values that are specified in the USING clause of the OPEN statement only when it opens a Select cursor or Function cursor. While the cursor is open, subsequent changes to program variables in the USING clause do not change the active set of the cursor.

In a database that is ANSI-compliant, you receive an error code if you try to open a cursor that is already open.

In a database that is not ANSI-compliant, a subsequent OPEN statement closes the cursor and then reopens it. When the database server reopens the cursor, it creates a new active set, based on the current values of the variables in the USING clause. If the variables have changed since the previous OPEN statement, reopening the cursor can generate an entirely different active set.

Even if the values of the variables are unchanged, the values in the active set can be different, as in the following situations:

- If the user-defined function takes a different execution path from the previous OPEN statement on a Function cursor
- If data in the table was modified since the previous OPEN statement on a Select cursor

The database server can process most queries dynamically, without pre-fetching all rows when it opens the Select or Function cursor. Therefore, if other users are modifying the table at the same time that the cursor is being processed, the active set might reflect the results of these actions.

For some queries, the database server evaluates the entire active set when it opens the cursor. These queries include those with the following features:

- Queries that require sorting: those with an ORDER BY clause or with the DISTINCT or UNIQUE keyword
- Queries that require hashing: those with a join or with the GROUP BY clause

For these queries, any changes that other users make to the table while the cursor is being processed are not reflected in the active set.

## Errors Associated with Select and Function Cursors

Because the database server is seeing the query for the first time, it might detect errors. In this case, it does not actually return the first row of data, but it resets the **SQLCODE** variable and the **sqlca.sqlcode** field of the **sqlca**. The value is either negative or zero, as the following table describes.

### Code Value

#### Significance

#### Negative

An error was detected in the SELECT statement

#### Zero

The SELECT statement is valid

Unlike ESQL/C routines, SPL routines do not have direct access to the **sqlca** structure. An ESQL/C routine must invoke the built-in **SQLCODE** function explicitly to access the return code of the SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE statement associated with the cursor that OPEN references.

If the SELECT, SELECTFOR UPDATE, EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement is valid, but no rows match its criteria, the first FETCH statement returns a value of 100 (**SQLNOTFOUND**), meaning that no rows were found.

**Tip:** When you encounter an **SQLCODE** error, a corresponding **SQLSTATE** error value also exists. For information about how to view the message text, refer to [Using the SQLSTATE Error Status Code on page 582](#).

## Opening an Insert Cursor (ESQL/C)

When you open an Insert cursor, the cursor passes the INSERT statement to the database server, which checks the validity of the keywords and column names. The database server also allocates memory for an insert buffer to hold new data. (See [DECLARE statement on page 467](#).)

An OPEN statement for a cursor that is associated with an INSERT statement cannot include a USING clause.

## Example of Opening an Insert Cursor

The following Informix® ESQL/C example illustrates an OPEN statement with an Insert cursor:

```
EXEC SQL prepare s1 from
    'insert into manufact values ('npr', 'napier)';
EXEC SQL declare in_curs cursor for s1;
EXEC SQL open in_curs;
EXEC SQL put in_curs;
EXEC SQL close in_curs;
```

## Reopening an Insert Cursor

When you reopen an Insert cursor that is already open, you effectively flush the insert buffer; any rows that are stored in the insert buffer are written into the database table. The database server first closes the cursor, which causes the flush and then reopens the cursor. For information about how to check errors and count inserted rows, see [Error Checking on page 707](#).

In an ANSI-compliant database, you receive an error code if you try to open a cursor that is already open.

## Opening a Collection Cursor (ESQL/C)

You can declare both Select and Insert cursors on collection variables. Such cursors are called *Collection cursors*. You must use the OPEN statement to activate these cursors.

Use the name of a collection variable in the USING clause of the OPEN statement. For more information on the use of OPEN ... USING with a collection variable, see [Fetching from a Collection Cursor on page 569](#) and [Inserting into a Collection Cursor on page 705](#).

## USING Clause

The USING clause is required when the cursor is associated with a prepared statement that includes question-mark (?) placeholders, as follows:

- A SELECT statement with input parameters in its WHERE clause
- An EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement with input parameters as arguments to its user-defined function
- An INSERT statement with input parameters in its VALUES clause (in ESQL/C).

In SPL routines, you must specify these parameters as SPL variables.

In ESQL/C, you can supply values for these parameters in one of the following ways:

- You can specify one or more host variables.
- You can specify a system-descriptor area.
- You can specify a pointer to an **sqllda** structure.

For more information, see [PREPARE statement on page 687](#).

If you know the number and the order of parameters to be supplied at runtime and their data types, you can define the parameters that are needed by the statement as host variables in your program. You pass parameters to the database server positionally, by opening the cursor with the USING keyword, followed by the names of the variables in their sequential order. These variables are matched with the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement question-mark ( ? ) placeholders in a one-to-one correspondence, from left to right.

You cannot include indicator variables of ESQL/C in the list of variables. To use an indicator variable, you must include the SELECT or EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement text as part of the DECLARE statement, rather than the identifier of a prepared statement.

You must supply one host variable name for each placeholder. The data type of each variable must be compatible with the corresponding type that the prepared statement requires. The following Informix® ESQL/C code fragment opens a Select cursor and specifies host variables in the USING clause:

```
printf (select_1, "%s %s %s %s %s",
        "SELECT o.order_num, sum(total price)",
        "FROM orders o, items i",
        "WHERE o.order_date > ? AND o.customer_num = ?",
        "AND o.order_num = i.order_num",
        "GROUP BY o.order_num");
EXEC SQL prepare statement_1 from :select_1;
EXEC SQL declare q_curs cursor for statement_1;
EXEC SQL open q_curs using :o_date, :o.customer_num;
```

The following example illustrates the USING clause of the OPEN statement with an EXECUTE FUNCTION statement in the Informix® ESQL/C code fragment:

```
stcopy ("EXECUTE FUNCTION one_func(?, ?)", exfunc_stmt);
EXEC SQL prepare exfunc_id from :exfunc_stmt;
EXEC SQL declare func_curs cursor for exfunc_id;
EXEC SQL open func_curs using :arg1, :arg2;
```

## Specifying a System Descriptor Area (ESQL/C)

If you do not know the number of parameters to be supplied at runtime or their data types, you can associate input values from a system-descriptor area. A system-descriptor area describes the data type and memory location of one or more values to replace question-mark ( ? ) placeholders.

A system-descriptor area conforms to the X/Open standards.

Use the SQL DESCRIPTOR keywords to introduce the name of a system descriptor area as the location of the parameters.

The COUNT field in the system-descriptor area corresponds to the number of dynamic parameters in the prepared statement. The value of COUNT must be less than or equal to the number of item descriptors that were specified when the system-descriptor area was allocated with the ALLOCATE DESCRIPTOR statement. You can obtain the value of a field with the GET DESCRIPTOR statement and set the value with the SET DESCRIPTOR statement.

The following example shows the OPEN ... USING SQL DESCRIPTOR statement:

```
EXEC SQL allocate descriptor 'desc1';
...
EXEC SQL open selcurs using sql descriptor 'desc1';
```

As the example indicates, the system descriptor area must be allocated before you reference it in the OPEN statement.

## Specifying a Pointer to an sqlda Structure (ESQL/C)

If you do not know the number of parameters to be supplied at runtime, or their data types, you can associate input values from an **sqlda** structure. An **sqlda** structure lists the data type and memory location of one or more values to replace question-mark ( ? ) placeholders.

Use the DESCRIPTOR keyword to introduce a pointer to the **sqlda** structure as the location of the parameters.

The **sqlda** value specifies the number of input values that are described in occurrences of **sqlvar**. This number must correspond to the number of dynamic parameters in the prepared statement.

## Example of Specifying a Pointer to an sqlda Structure

The following example shows an OPEN ... USING DESCRIPTOR statement:

```
struct sqlda *sdp;
...
EXEC SQL open selcurs using descriptor sdp;
```

## Using the WITH REOPTIMIZATION Option (ESQL/C)

Use the WITH REOPTIMIZATION keywords to reoptimize your query plan. When you prepare SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE statements, the database server uses a query plan to optimize the query. If you later modify the data associated with the prepared statement, you can compromise the effectiveness of the query plan for that statement. In other words, if you change the data, you might deoptimize your query. To ensure optimization of your query, you can prepare the statement again, or open the cursor again using the WITH REOPTIMIZATION option.

You should generally use the WITH REOPTIMIZATION option, because it provides the following advantages over preparing a statement again:

- Rebuilds only the query plan, rather than the entire statement
- Uses fewer resources
- Reduces overhead
- Requires less time

The WITH REOPTIMIZATION option forces the database server to optimize the query-design plan before it processes the OPEN cursor statement.

The following examples use the WITH REOPTIMIZATION keywords:

```
EXEC SQL open selcurs using descriptor sdp with reoptimization;
```

## Relationship Between OPEN and FREE

The database server allocates resources to prepared statements and open cursors. If you execute a FREE *statement\_id* or FREE *statement\_id\_var* statement, you can still open the cursor associated with the freed statement ID. If you release resources with a FREE *cursor\_id* or FREE *cursor\_id\_var* statement, however, you cannot use the cursor unless you declare the cursor again.

Similarly, if you use the SET AUTOFREE statement for one or more cursors, when the program closes the specific cursor, the database server automatically frees the cursor-related resources. In this case, you cannot use the cursor unless you declare the cursor again.

## DDL Operations on Tables Referenced by Cursors

Various DDL statements can drop, rename, or alter the schema of a table that is referenced directly (or indirectly, by the identifier of a prepared statement) in the DECLARE statement that defines a cursor. Subsequent OPEN operations on the cursor might fail with error -710, or might produce unexpected results. Changing the number of columns or the data type of a column has this effect, and the user typically must reissue the DESCRIBE statement, the PREPARE statement, and (for cursors associated with routines) the UPDATE STATISTICS statement for any SPL routines that reference a table whose schema has been modified.

These restrictions do not apply, however, if an index is added or dropped when automatic recompilation is enabled for prepared objects and for SPL routines that reference tables that ALTER TABLE, CREATE INDEX, or DROP INDEX operations have modified. This is the default behavior of Informix®. For more information about enabling or disabling automatic recompilation after schema changes, see the description of the IFX\_AUTO\_REPREPARE option to the SET ENVIRONMENT statement. For more information about the AUTO\_REPREPARE configuration parameter, see your .

When the AUTO\_REPREPARE configuration parameter and the IFX\_AUTO\_REPREPARE session environment variable are set to disable recompilation of prepared objects, however, adding an index to a table that is referenced directly or indirectly in a DECLARE statement can similarly invalidate the associated cursor. Subsequent OPEN statements that specify the invalid cursor fail, even if they include the WITH REOPTIMIZATION keywords. If an index is added to the table that is associated with a cursor while automatic recompilation is disabled, you must prepare the statement again and declare the cursor again before you can open the cursor. For cursors associated with calls to SPL routines, you must run the UPDATE STATISTICS statement for routines that reference tables to which an index has been added or dropped. You cannot simply reopen a cursor that is based on a prepared statement that is no longer valid.

## OUTPUT statement

Use the OUTPUT statement to send the results of a query to an operating-system file or to a program.

### Syntax

#### OUTPUT TO

*filename*

#### PIPE

*program*

#### WITHOUT HEADINGS

SELECT Statement<sup>330</sup>

| Element         | Description   | Restrictions  | Syntax  |
|-----------------|---|---|---|
| <i>filename</i> | Path and filename where query results are written. The default path is the current directory. | Can specify a new or existing file. If the file exists, query results overwrite the current contents of the file. | Must conform to the rules of your operating system. |
| <i>program</i>  | Name of a program to receive the query results as input                                       | Program must exist, must be known to the operating system, and must be able to read the results of a query.       | Must conform to the rules of your operating system. |

### Usage

The OUTPUT statement writes query results in an operating-system file, or pipes query results to another program. You can optionally specify whether column headings are omitted from the query output. This statement is an extension to the ANSI/ISO standard for SQL. You can use this statement only with DB-Access.

---

## Sending Query Results to a File

To send the results of a query to an operating-system file, specify the full pathname for the file. If the file already exists, the output overwrites the current contents.

The following examples show how to send the result of a query to an operating-system file. The example uses UNIX™ file naming conventions.

```
OUTPUT TO /usr/april/query1
SELECT * FROM cust_calls WHERE call_code = 'L'
```

330. See [SELECT statement on page 768](#)

## Displaying Query Results Without Column Headings

### About this task

To display the results of a query without column headings, use the WITHOUT HEADINGS keywords.

## Sending Query Results to Another Program

You can use the keyword PIPE to send the query results to another program, as the following example shows:

```
OUTPUT TO PIPE more
SELECT customer_num, call_dtime, call_code
FROM cust_calls;
```

## PREPARE statement

Use the PREPARE statement to parse, validate, and generate an execution plan for one or more SQL statements at runtime.

### Syntax

#### PREPARE

*statement\_id*

<sup>331</sup>*statement\_id\_var*

#### FROM

'*statement\_text*'

<sup>331</sup>*statement\_var*

<sup>332</sup>*char\_expression*

| Element                 | Description   | Restrictions   | Syntax                                       |
|-------------------------|---|--|--|
| <i>char_expression</i>  | Expression that evaluates to the text of a single SQL statement | Statement must be a SELECT, EXECUTE FUNCTION, or EXECUTE PROCEDURE   | <a href="#">Expression on page 1193</a>      |
| <i>statement_id</i>     | Identifier declared here for the prepared object                | Must be unique in the routine among names of cursors and prepared objects (and in SPL, among variables)            | <a href="#">Identifier on page 1456</a>      |
| <i>statement_id_var</i> | Host variable storing <i>statement_id</i>                       | Must have been previously declared as a character data type  | Language specific                            |
| <i>statement_text</i>   | Text of the SQL statement(s) to prepare                         | See <a href="#">Preparing Multiple SQL Statements on page 697</a> and <a href="#">Statement Text on page 690</a> . | <a href="#">Quoted String on page 1424</a> . |

331. ESQL/C only

332. SPL only

| Element              | Description  | Restrictions  | Syntax            |
|----------------------|--|---|-------------------|
| <i>statement_var</i> | Host variable storing the text of one or more SQL statements | Must be a character data type. Not valid if the SQL statement(s) contains the Collection-Derived Table segment. | Language specific |

## Usage

Use this statement in ESQL/C or SPL routines.

The PREPARE statement enables your program to assemble the text of one (or for ESQL/C, more than one) SQL statement at runtime, to declare an identifier for the resulting *prepared object*, and to make it executable. This dynamic form of SQL is accomplished in three steps:

1. The PREPARE statement accepts statement text as input, either as a quoted string, or an ESQL/C character variable, or (in SPL) as the value to which a character expression evaluates. Statement text can contain question-mark ( ? ) placeholders to represent values that are to be defined when the statement is executed.
2. The OPEN statement (and in ESQL/C routines, the EXECUTE statement) can supply the required input values and execute the prepared statement once or many times.
3. Resources allocated to the prepared statement can be released later using the FREE statement.

For more information about the replacement of placeholders in prepared statements with runtime values, see the section [Preparing Statements That Receive Parameters on page 694](#).

The same collating order that is current when you create a prepared object is also used when that object is executed, even if the execution-time collation of the session (or of **DB\_LOCALE**) is different.

#### **Related information**

[Overloading the Name of a Function on page 247](#)

## Restrictions

The number of prepared objects in a single program is limited by available memory. These include statement identifiers declared in PREPARE statements (*statement\_id* or *statement\_id\_var*) and declared cursors. To avoid exceeding the limit, use the FREE statement to release some statements or cursors.

In SPL routines, a prepared object can include the text of no more than one SQL statement, and that statement must be either an EXECUTE FUNCTION, EXECUTE PROCEDURE, or SELECT statement, but the SELECT statement cannot include the INTO *variable*, INTO TEMP, or FOR UPDATE clause.

An expression that specifies the statement text in an SPL routine must evaluate to a CHAR, LVARCHAR, NCHAR, NVARCHAR, or VARCHAR data type. You must explicitly cast to one of these types an expression of any other text data type, such as a UDT.

For restrictions in ESQL/C routines on the SQL statements in the character string, see [Restricted Statements in Single-Statement Prepares on page 693](#) and [Restricted Statements in Multistatement Prepared Objects on page 698](#).

## Declaring a Statement Identifier

PREPARE sends the statement text to the database server, which analyzes the statement text. If the text contains no syntax errors, the database server translates it to an internal form. This translated statement is saved for later execution in a data structure that the PREPARE statement allocates. The name of the structure is the value that is assigned to the statement identifier in the PREPARE statement. Subsequent SQL statements can refer to the structure by using the same statement identifier that was used in the PREPARE statement.

A subsequent FREE statement releases the database server resources that were allocated to the statement. After you release these resources with FREE, you cannot use the statement identifier in a DECLARE statement or (in ESQL/C) with the EXECUTE statement until you prepare the statement again.

The database server resources for the prepared objects that an SPL routine defines are released automatically when the routine exits.

## Scope of Statement Identifiers

An ESQL/C program can consist of one or more source-code files. By default, the scope of reference of a statement identifier is global to the program. Therefore, a statement identifier that is prepared in one file can be referenced from another file.

In a multiple-file program, if you want to limit the scope of reference of a statement identifier to the file in which it is prepared, preprocess all the files with the **-local** command-line option.

## Releasing a Statement Identifier

A statement identifier can represent only one SQL statement or (in ESQL/C) one semicolon-separated list of SQL statements at a time. A new PREPARE statement can specify an existing statement identifier if you want to bind the identifier to a different SQL statement text.

The PREPARE statement supports dynamic statement-identifier names, which allow you to prepare a statement identifier as an identifier or (in ESQL/C) as a host variable of a data type that can contain a character string. The first example that follows shows a statement identifier that was specified as a host variable. The second specifies a statement identifier as a character string.

```
stcopy ("query2", stmtid);
EXEC SQL prepare :stmtid from 'select * from customer';

EXEC SQL prepare query2 from 'select * from customer';
```

The variable must be a character data type. In C, it must be declared as `char`.

In an SPL routine, statement identifiers that the PREPARE statement declares are automatically defined in the local scope. Do not attempt to declare a statement identifier as having local or global scope. A statement identifier defined in one SPL routine is not visible to any other SPL routine that the same session calls. SPL statement identifiers share the same namespace as SPL variables and cursor names.

## Statement Text

Statement text can be specified in the PREPARE statement

- as a quoted string
- or as text that is stored in an ESQL/C program variable
- or (in SPL routines) as a character expression.

The following restrictions apply to the statement text:

- The text can contain only SQL statements. It cannot contain statements or comments from the host programming language.
- The text can contain comments preceded by a double hyphen (--), or that are enclosed in braces ( { } ) or in C-style slash and asterisk ( /\* \*/ ) delimiters.

These symbols introduce or enclose SQL comments. For more information on SQL comment symbols, see [How to Enter SQL Comments on page 3](#).

- The text can contain either a single SQL statement or (in ESQL/C routines) a series of statements that are separated by semicolon ( ; ) symbols.

For a list of SQL statements that cannot be prepared, see [Restricted Statements in Single-Statement Prepares on page 693](#). For more information on how to prepare multiple SQL statements, see [Preparing Multiple SQL Statements on page 697](#).

- The text cannot include an embedded SQL statement prefix or terminator, such as a dollar sign ( \$ ) or the words EXEC SQL.
- Host-language variables are not recognized as such in prepared text.

Therefore, you cannot prepare a SELECT (or EXECUTE FUNCTION or EXECUTE PROCEDURE) statement that includes an INTO clause, because the INTO clause requires a host-language variable.

- The only identifiers that you can use are names that are defined in the database, such as names of tables and columns. For more information on how to use identifiers in statement text, see [Preparing Statements with SQL Identifiers on page 695](#).
- Use a question mark ( ? ) as a placeholder to indicate where data is supplied when the statement executes, as in this Informix® ESQL/C example:

```
EXEC SQL prepare new_cust from
    'insert into customer(fname,lname) values(?,?)';
```

For more information on how to use question marks as placeholders, see [Preparing Statements That Receive Parameters on page 694](#).

If the prepared statement contains the Collection-Derived Table segment or the Informix® ESQL/C collection variable, some additional limitations exist on how you can assemble the text for the PREPARE statement. For information about dynamic SQL, see the *Informix® ESQL/C Programmer's Manual*. SPL routines cannot use dynamic SQL statements to process prepared statements that contain the Collection-Derived Table segment.

## Example of a PREPARE statement in an SPL routine

The HCL Informix® SPL language supports single-statement prepared objects.

For example, the following SQL and SPL statements perform these tasks:

1. Create the **cities** table.
2. Populates the **cities** table with four rows of data.
3. Creates the **order\_city** SPL routine that defines a prepared statement and a cursor to query the **cities** table:

```
CREATE TABLE cities    -- defines a table
(
  id INT,
  city_name CHAR(50)
);

INSERT INTO cities VALUES (1, 'Chicago');
INSERT INTO cities VALUES (2, 'New York');
INSERT INTO cities VALUES (3, 'San Francisco');
INSERT INTO cities VALUES (4, 'Atlanta');
```

```

UPDATE STATISTICS HIGH;

CREATE PROCEDURE order_city() -- defines a UDR
RETURNING INT, CHAR(50);
DEFINE c_num INT;
DEFINE c_name CHAR(50);
DEFINE c_query VARCHAR(250);
LET c_query =
  "SELECT id, city_name FROM cities ORDER BY city_name;";

PREPARE c_stmt FROM c_query;
DECLARE c_cur CURSOR FOR c_stmt;

OPEN c_cur ;
while (1 = 1)
  FETCH c_cur INTO c_num, c_name;
  IF (SQLCODE != 100) THEN
    RETURN c_num, c_name WITH RESUME;
  ELSE
    EXIT;
  END IF
END WHILE

CLOSE c_cur;
FREE c_cur;
FREE c_stmt;

END PROCEDURE;

```

The following SQL statement invokes the **order\_city** routine:

```
EXECUTE PROCEDURE order_city();
```

If the **order\_city** function is called from the **dbaccess** utility, this output is displayed:

```

(expression) (expression)

      4 Atlanta
      1 Chicago
      2 New York
      3 San Francisco

```

For an overview with detailed examples of how to create and use prepared objects and Dynamic SQL in SPL routines, see this article: [Dynamic SQL support in Informix® Dynamic Server Stored Procedure Language](#)

## Preparing and Executing User-Defined Routines

The way to prepare a user-defined routine (UDR) depends on whether the UDR is a user-defined procedure or a user-defined function:

- To prepare a user-defined procedure, prepare the EXECUTE PROCEDURE statement that executes the procedure.

To execute the prepared procedure, use the EXECUTE statement.

- To prepare a user-defined function, prepare the EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement that executes the function.

You cannot include the INTO clause of EXECUTE FUNCTION (or EXECUTE PROCEDURE) in the PREPARE statement.

How to execute a prepared user-defined function depends on whether it returns only one group or multiple groups of values. Use the EXECUTE statement for user-defined functions that return only one group of values.

To execute user-defined functions that return more than one group of return values, you must associate the EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement with a cursor.

## Restricted Statements in Single-Statement Prepares

In general, you can prepare any data manipulation language (DML) statement.

In Informix®, you can prepare any single SQL statement except for the following statements:

- ALLOCATE COLLECTION
- ALLOCATE DESCRIPTOR
- ALLOCATE ROW
- CLOSE
- CONNECT
- CREATE FUNCTION FROM
- CREATE PROCEDURE FROM
- CREATE ROUTINE FROM
- DEALLOCATE COLLECTION
- DEALLOCATE DESCRIPTOR
- DEALLOCATE ROW
- DECLARE
- DESCRIBE
- DISCONNECT
- EXECUTE
- EXECUTE IMMEDIATE
- FETCH
- FLUSH
- FREE
- GET DESCRIPTOR
- GET DIAGNOSTICS
- INFO
- LOAD
- OPEN
- OUTPUT
- PREPARE
- PUT

- SET AUTOFREE
- SET CONNECTION
- SET DEFERRED\_PREPARE
- SET DESCRIPTOR
- UNLOAD
- WHENEVER

You can prepare a SELECT statement. If SELECT includes the INTO TEMP clause, an ESQL/C program can execute the prepared statement with an EXECUTE statement. If it does not include the INTO TEMP clause, the statement returns rows of data. Use DECLARE, OPEN, and FETCH cursor statements to retrieve the rows.

In ESQL/C, a prepared SELECT statement can include a FOR UPDATE clause. This clause is used with the DECLARE statement to create an update cursor. The next example shows a SELECT statement with a FOR UPDATE clause in Informix® ESQL/C:

```

sprintf(up_query, "%s %s %s",
        "select * from customer ",
        "where customer_num between ? and ? ",
        "for update");
EXEC SQL prepare up_sel from :up_query;
EXEC SQL declare up_curs cursor for up_sel;
EXEC SQL open up_curs using :low_cust,:high_cust;

```

## Preparing Statements When Parameters Are Known

In some prepared statements, all necessary information is known at the time the statement is prepared. The following example in Informix® ESQL/C shows two statements that were prepared from constant data:

```

sprintf(redo_st, "%s %s",
        "drop table workt1; ",
        "create table workt1 (wtk serial, wtv float)" );
EXEC SQL prepare redotab from :redo_st;

```

## Preparing Statements That Receive Parameters

In some statements, parameters are unknown when the statement is prepared because a different value can be inserted each time the statement is executed. In these statements, you can use a question-mark ( ? ) placeholder where a parameter must be supplied when the statement is executed.

The PREPARE statements in the following Informix® ESQL/C examples show some uses of question-mark ( ? ) placeholders:

```

EXEC SQL prepare s3 from
        'select * from customer where state matches ?';
EXEC SQL prepare in1 from 'insert into manufact values (?,?,?)';
sprintf(up_query, "%s %s",
        "update customer set zipcode = ?"
        "where current of zip_cursor");
EXEC SQL prepare update2 from :up_query;

```

```
EXEC SQL prepare exfunc from
    'execute function func1 (?, ?)';
```

You can use a placeholder to defer evaluation of a value until runtime only for an expression, but not for an SQL identifier, except as noted in [Preparing Statements with SQL Identifiers on page 695](#).

The following example of the Informix® ESQL/C code fragment prepares a statement from a variable that is named **demoquery**. The text in the variable includes one question-mark ( ? ) placeholder. The prepared statement is associated with a cursor and, when the cursor is opened, the USING clause of the OPEN statement supplies a value for the placeholder:

```
EXEC SQL BEGIN DECLARE SECTION;
    char queryvalue [6];
    char demoquery [80];
EXEC SQL END DECLARE SECTION;

EXEC SQL connect to 'stores_demo';
sprintf(demoquery, "%s %s",
    "select fname, lname from customer ",
    "where lname > ? ");
EXEC SQL prepare quid from :demoquery;
EXEC SQL declare democursor cursor for quid;
strcpy("C", queryvalue);
EXEC SQL open democursor using :queryvalue;
```

The USING clause is available in both OPEN statements that are associated with a cursor and EXECUTE statements (all other prepared statements).

You can use a question-mark ( ? ) placeholder to represent the name of the Informix® ESQL/C or SPL collection variable.

## Preparing Statements with SQL Identifiers

In general, you must specify SQL identifiers explicitly in the statement text when you prepare the statement. In a few special cases, however, you can use the question-mark ( ? ) placeholder for an SQL identifier:

- For the database name in the DATABASE statement.
- For the dbspace name in the IN *dbspace* clause of the CREATE DATABASE statement.
- For the cursor name in statements that use cursor names.

## Obtaining SQL Identifiers from User Input

If a prepared statement requires identifiers, but the identifiers are unknown when you write the prepared statement, you can construct a statement that receives SQL identifiers from user input.

The following Informix® ESQL/C example prompts the user for the name of a table and uses that name in a SELECT statement. Because this name is unknown until runtime, the number and data types of the table columns are also unknown. Therefore, the program cannot allocate host variables to receive data from each row in advance. Instead, this program fragment describes the statement into an **sqllda** descriptor and fetches each row with the descriptor. The fetch puts each row into memory locations that the program provides dynamically.

If a program retrieves all the rows in the active set, the FETCH statement would be placed in a loop that fetched each row. If the FETCH statement retrieves more than one data value (column), another loop exists after the FETCH, which performs some action on each data value:

```
#include <stdio.h>
EXEC SQL include sqllda;
EXEC SQL include sqltypes;
char *malloc( );

main()
{
    struct sqllda *demodesc;
    char tablename[19];
    int i;
EXEC SQL BEGIN DECLARE SECTION;
    char demoselect[200];
EXEC SQL END DECLARE SECTION;

    /* This program selects all the columns of a given tablename.
       The tablename is supplied interactively. */

EXEC SQL connect to 'stores_demo';
printf( "This program does a select * on a table\n" );
printf( "Enter table name: " );
scanf( "%s", tablename );
sprintf(demoselect, "select * from %s", tablename );

EXEC SQL prepare iid from :demoselect;
EXEC SQL describe iid into demodesc;

/* Print what describe returns */

for ( i = 0; i < demodesc->sqld; i++ )
    prsqllda (demodesc->sqlvar + i);

/* Assign the data pointers. */

for ( i = 0; i < demodesc->sqld; i++ )
{
    switch (demodesc->sqlvar[i].sqltype & SQLTYPE)
    {
        case SQLCHAR:
            demodesc->sqlvar[i].sqltype = CCHARTYPE;
            /* make room for null terminator */
            demodesc->sqlvar[i].sqlllen++;
            demodesc->sqlvar[i].sqldata =
                malloc( demodesc->sqlvar[i].sqlllen );
            break;

        case SQLSMINT:    /* fall through */
        case SQLINT:      /* fall through */
        case QLSERIAL:
            demodesc->sqlvar[i].sqltype = CINTTYPE;
            demodesc->sqlvar[i].sqldata =
                malloc( sizeof( int ) );
            break;

        /* And so on for each type. */
    }
}
```

```

    }
}

/* Declare and open cursor for select . */
EXEC SQL declare d_curs cursor for iid;
EXEC SQL open d_curs;

/* Fetch selected rows one at a time into demodesc. */
for( ; ; )
{
    printf( "\n" );
    EXEC SQL fetch d_curs using descriptor demodesc;
    if ( sqlca.sqlcode != 0 )
        break;
    for ( i = 0; i < demodesc->sqld; i++ )
    {
        switch (demodesc->sqlvar[i].sqltype)
        {
            case CCHARTYPE:
                printf( "%s: \"%s\n", demodesc->sqlvar[i].sqlname,
                    demodesc->sqlvar[i].sqldata );
                break;
            case CINTTYPE:
                printf( "%s: %d\n", demodesc->sqlvar[i].sqlname,
                    *((int *) demodesc->sqlvar[i].sqldata) );
                break;
            /* And so forth for each type... */
        }
    }
}

EXEC SQL close d_curs;
EXEC SQL free d_curs;
/* Free the data memory. */

for ( i = 0; i < demodesc->sqld; i++ )
    free( demodesc->sqlvar[i].sqldata );
free( demodesc );

printf( "Program Over.\n");
}

prsqlda(sp)
    struct sqlvar_struct *sp;

{
    printf( "type = %d\n", sp->sqltype);
    printf( "len = %d\n", sp->sqlllen);
    printf( "data = %lx\n", sp->sqldata);
    printf( "ind = %lx\n", sp->sqlind);
    printf( "name = %s\n", sp->sqlname);
}

```

## Preparing Multiple SQL Statements

In ESQL/C, you can execute several SQL statements as one action if you include them in the same PREPARE statement. Multistatement text is processed as a unit; actions are not treated sequentially. Therefore, multistatement text cannot include statements that depend on actions that occur in a previous statement in the text. For example, you cannot create a table and insert values into that table in the same prepared statement block.

If a statement in a multistatement prepare returns an error, the whole prepared statement stops executing. The database server does not execute any remaining statements. In most situations, compiled products return error-status information on the error, but do not indicate which statement in the text causes an error. You can use the `sqlca.sqlerrd[4]` field in the `sqlca` to find the offset of the errors.

In a multistatement prepare, if no rows are returned from a WHERE clause in the following statements, the database server returns `SQLNOTFOUND (100)`:

- UPDATE WHERE
- SELECT INTO TEMP WHERE
- INSERT INTO WHERE
- DELETE FROM WHERE

In the next example, four SQL statements are prepared into a single Informix® ESQL/C string called **query**. Individual statements are delimited with semicolons.

A single PREPARE statement can prepare the four statements for execution, and a single EXECUTE statement can execute the statements that are associated with the **qid** statement identifier:

```

sprintf (query, "%s %s %s %s %s %s %s",
    "update account set balance = balance + ? ",
    "where acct_number = ?;",
    "update teller set balance = balance + ? ",
    "where teller_number = ?;",
    "update branch set balance = balance + ? ",
    "where branch_number = ?;",
    "insert into history values (?, ?);";
EXEC SQL prepare qid from :query;

EXEC SQL begin work;
EXEC SQL execute qid using
    :delta, :acct_number, :delta, :teller_number,
    :delta, :branch_number, :timestamp, :values;
EXEC SQL commit work;

```

Here the semicolons (;) are required as SQL statement-terminator symbols between each SQL statement in the text that **query** holds.

## Restricted Statements in Multistatement Prepared Objects

In addition to the statements listed as exceptions in [Restricted Statements in Single-Statement Prepares on page 693](#), you cannot use the following statements in the text of a multiple-statement prepared object:

- CLOSE DATABASE
- CREATE DATABASE
- DATABASE
- DROP DATABASE
- RENAME DATABASE
- SELECT (*with one exception*)

The following types of statements are also not valid in a multistatement prepare:

- Statements that can cause the current database to close during the execution of the multistatement sequence
- Statements that include references to TEXT or BYTE host variables

In general, you cannot use the SELECT statement in a multistatement prepare. The only form of the SELECT statement allowed in a multistatement prepare is a SELECT statement with an INTO temporary table clause.

## Using Prepared Statements for Efficiency

To increase performance efficiency, you can use the PREPARE statement and an EXECUTE statement in a loop to eliminate overhead that redundant parsing and optimizing cause. For example, an UPDATE statement that is located within a WHILE loop is parsed each time the loop runs. If you prepare the UPDATE statement outside the loop, the statement is parsed only once, eliminating overhead and speeding statement execution. The following example shows how to prepare Informix® ESQL/C statements to improve performance:

```
EXEC SQL BEGIN DECLARE SECTION;
char disc_up[80];
int cust_num;
EXEC SQL END DECLARE SECTION;
main()
{
    sprintf(disc_up, "%s %s", "update customer ",
           "set discount = 0.1 where customer_num = ?");
    EXEC SQL prepare up1 from :disc_up;
    while (1)
    {
        printf("Enter customer number (or 0 to quit): ");
        scanf("%d", cust_num);
        if (cust_num == 0)
            break;
        EXEC SQL execute up1 using :cust_num;
    }
}
```

Like the SQL statement cache, prepared statements can reduce how often the same query plan is reoptimized, thereby conserving resources in some contexts. The section [Prepared Statements and the Statement Cache on page 1002](#) discusses the use of prepared DML statements, cursors, and the SQL statement cache as combined or alternative techniques for improving query performance.

## DDL Operations on Tables Referenced in Prepared Objects

Various DDL statements can drop, rename, or alter the schema of a table that a prepared object references, but subsequent attempts to execute the prepared object might fail with error -710, or might produce unexpected results.

These restrictions do not necessarily apply, however, if an index is added or dropped when automatic recompilation is enabled for prepared objects and routines that directly reference tables that ALTER TABLE, CREATE INDEX, or DROP INDEX operations have modified. This is the default behavior of Informix®. For more information about using the SET ENVIRONMENT IFX\_AUTO\_REPREPARE statement to enable or disable automatic recompilation after changes to the schema of a table, and for contexts where the database server issues error -710 even when automatic recompilation is enabled, see [IFX\\_AUTO\\_REPREPARE session environment option on page 927](#).

When the AUTO\_REPREPARE configuration parameter and the IFX\_AUTO\_REPREPARE session environment variable are set to disable automatic recompilation, however, adding an index to a table that a prepared statement references indirectly can similarly invalidate the prepared statement. A subsequent OPEN statement fails if the cursor refers to the invalid prepared statement, even if the OPEN statement includes the WITH REOPTIMIZATION keywords. If an index on an indirectly referenced table is added after the statement was prepared while automatic recompilation is disabled, you must prepare the statement again and declare the cursor again. You cannot simply reopen the cursor if it is based on a prepared statement that is no longer valid.

For information about more advanced concepts that relate to the PREPARE statement, see the *Informix® ESQL/C Programmer's Manual*.

## PUT statement

Use the PUT statement to store a row in an insert buffer for later insertion into the database.

**Syntax****PUT***cursor\_id\_var cursor\_id***FROM***, output\_var***INDICATOR***indicator\_var**\$indicator\_var**:indicator\_var***USING****SQL DESCRIPTOR***'descriptor ' descriptor\_var***DESCRIPTOR***sqlda\_pointer*

| Element               | Description   | Restrictions   | Syntax   |
|-----------------------|---|--|--|
| <i>cursor_id</i>      | Name of a cursor  | Must be open   | <a href="#">Identifier on page 1456</a>        |
| <i>cursor_id_var</i>  | Host variable = <i>cursor_id</i>  | Must be a character type;<br>cursor must be open     | Language specific                              |
| <i>descriptor</i>     | Name of a system-descriptor area  | Must already be allocated                            | <a href="#">Quoted String on page 1424</a>     |
| <i>descriptor_var</i> | Host-variable that contains <i>descriptor</i>   | Must already be allocated                            | <a href="#">Quoted String on page 1424</a>     |
| <i>indicator_var</i>  | Host variable to receive a return code if corresponding <i>output_var</i> receives a NULL value       | Cannot be a DATETIME or INTERVAL data type           | Language specific                              |
| <i>output_var</i>     | Host variable whose contents replace a question-mark ( ? ) placeholder in a prepared INSERT statement | Must be a character data type                        | Language specific                              |
| <i>sqlda_pointer</i>  | Pointer to an <b>sqlda</b> structure  | First character cannot be the ( \$ ) or ( : ) symbol | <a href="#">DESCRIBE statement on page 495</a> |

**Usage**

This statement is an extension to the ANSI/ISO standard for SQL. You can use this statement with ESQL/C.

PUT stores a row in an *insert buffer* that is created when the cursor is opened.

If the buffer has no room for the new row when the statement executes, the buffered rows are written to the database in a block, and the buffer is emptied. As a result, some PUT statement executions cause rows to be written to the database, and some do not. You can use the FLUSH statement to write buffered rows to the database without adding a new row. The CLOSE statement writes any remaining rows before it closes an Insert cursor.

If the current database uses explicit transactions, you must execute a PUT statement within a transaction.

The following example uses a PUT statement in Informix® ESQL/C:

```
EXEC SQL prepare ins_mcode from
    'insert into manufact values(?,?)';
EXEC SQL declare mcode cursor for ins_mcode;
EXEC SQL open mcode;
EXEC SQL put mcode from :the_code, :the_name;
```

The PUT statement is not an X/Open SQL statement. Therefore, you get a warning message if you compile a PUT statement in X/Open mode.

## Supplying Inserted Values

The values in the inserted row can come from one of the following sources:

- Constant values that are written into the INSERT statement
- Program variables that are named in the INSERT statement
- Program variables in the FROM clause of the PUT statement
- Values that are prepared in memory addressed by an **sqlda** structure or a system-descriptor area and then specified in the USING clause of the PUT statement

The system descriptor area or **sqlda** structure that *descriptor* or *sqlda\_pointer* references must define a data type and memory location of each value that corresponds to a question-mark ( ? ) placeholder in a prepared INSERT statement.

## Using Constant Values in INSERT

The VALUES clause lists the values for the inserted columns. One or more of these values can be constants (that is, numbers or character strings).

When *all* the inserted values are constants, the PUT statement has a special effect. Instead of creating a row and putting it in the buffer, the PUT statement merely increments a counter. When you use a FLUSH or CLOSE statement to empty the buffer, one row and a repetition count are sent to the database server, which inserts that number of rows. In the following Informix® ESQL/C example, 99 empty customer records are inserted into the **customer** table. Because all values are constants, no disk output occurs until the cursor closes. (The constant zero for **customer\_num** causes generation of a SERIAL value.) The following example inserts 99 empty customer records into the customer table:

```
int count;
EXEC SQL declare fill_c cursor for
    insert into customer(customer_num) values(0);
EXEC SQL open fill_c;
for (count = 1; count <= 99; ++count)
    EXEC SQL put fill_c;
EXEC SQL close fill_c;
```

## Naming Program Variables in INSERT

When you associate the INSERT statement with a cursor (in the DECLARE statement), you create an Insert cursor. In the INSERT statement, you can name program variables in the VALUES clause. When each PUT statement is executed, the contents of the program variables at that time are used to populate the row that is inserted into the buffer.

If you are creating an Insert cursor (using DECLARE with INSERT), you must use only program variables in the VALUES clause. Variable names are not recognized in the context of a prepared statement; you associate a prepared statement with a cursor through its statement identifier.

The following Informix® ESQL/C example illustrates the use of an Insert cursor. The code includes the following statements:

- The DECLARE statement associates a cursor called **ins\_curs** with an INSERT statement that inserts data into the **customer** table.  
The VALUES clause specifies a data structure that is called **cust\_rec**; the Informix® ESQL/C preprocessor converts **cust\_rec** to a list of values, one for each component of the structure.
- The OPEN statement creates a buffer.
- A user-defined function (not defined within this example) obtains customer information from user input and stores it in **cust\_rec**.
- The PUT statement composes a row from the current contents of the **cust\_rec** structure and sends it to the row buffer.
- The CLOSE statement inserts into the **customer** table any rows that remain in the row buffer and closes the Insert cursor:

```
int keep_going = 1;
EXEC SQL BEGIN DECLARE SECTION
    struct cust_row { /* fields of a row of customer table */ } cust_rec;
```

```

EXEC SQL END DECLARE SECTION
EXEC SQL declare ins_curs cursor for
    insert into customer values (:cust_row);
EXEC SQL open ins_curs;
while ( (sqlca.sqlcode == 0) && (keep_going) )

{
keep_going = get_user_input(cust_rec); /* ask user for new customer */
  if (keep_going )                    /* user did supply customer info
*/
  {
    cust_rec.customer_num = 0;        /* request new serial value */
    EXEC SQL put ins_curs;
  }
  if (sqlca.sqlcode == 0)             /* no error from PUT */
    keep_going = (prompt_for_y_or_n("another new customer") == 'Y')
  }
EXEC SQL close ins_curs;

```

Use an indicator variable if the data to be inserted might be NULL.

## Naming Program Variables in PUT

When the INSERT statement is prepared (see [PREPARE statement on page 687](#)), you cannot use program variables in its VALUES clause, but you can represent values by a question-mark ( ? ) placeholder. List the program variables in the FROM clause of the PUT statement to supply the missing values.

The following Informix® ESQL/C example lists host variables in a PUT statement:

```

char answer [1] = 'y';
EXEC SQL BEGIN DECLARE SECTION;
  char ins_comp[80];
  char u_company[20];
EXEC SQL END DECLARE SECTION;

main()
{
  EXEC SQL connect to 'stores_demo';
  EXEC SQL prepare ins_comp from
    'insert into customer (customer_num, company) values (0, ?)';
  EXEC SQL declare ins_curs cursor for ins_comp;
  EXEC SQL open ins_curs;

  while (1)
  {
    printf("\n\nEnter a customer: ");
    gets(u_company);
    EXEC SQL put ins_curs from :u_company;
    printf("Enter another customer (y/n) ? ");
    if (answer = getch() != 'y')
      break;
  }
  EXEC SQL close ins_curs;

```

```
EXEC SQL disconnect all;
}
```

Indicator variables are optional, but you should use an indicator variable if the possibility exists that *output\_var* might contain a NULL value. If you specify the indicator variable without the INDICATOR keyword, you cannot put a blank space between *output\_var* and *indicator\_var*.

## Using the USING Clause

If you do not know the number of parameters to be supplied at runtime or their data types, you can associate input values from a system-descriptor area or an **sqlda** structure. Both of these descriptor structures describe the data type and memory location of one or more values to replace question-mark ( ? ) placeholders.

Each time the PUT statement executes, the values that the descriptor structure describes are used to replace question-mark ( ? ) placeholders in the INSERT statement. This process is similar to using a FROM clause with a list of variables, except that your program has full control over the memory location of the data values.

## Specifying a System-Descriptor Area

The SQL DESCRIPTOR option specifies the name of a system-descriptor area.

The **COUNT** field in the system-descriptor area corresponds to the number of dynamic parameters in the prepared statement. The value of **COUNT** must be less than or equal to the number of item descriptors that were specified when the system-descriptor area was allocated with the ALLOCATE DESCRIPTOR statement. You can obtain the value of a field with the GET DESCRIPTOR statement and set the value with the SET DESCRIPTOR statement.

A system-descriptor area conforms to the X/Open standards.

The following Informix® ESQL/C example shows how to associate values from a system-descriptor area:

```
EXEC SQL allocate descriptor 'desc1';
...
EXEC SQL put selcurs using sql descriptor 'desc1';
```

## Specifying an sqlda Structure

Use the **DESCRIPTOR** option to introduce the name of a pointer to an **sqlda** structure. The following Informix® ESQL/C example shows how to associate values from an **sqlda** structure:

```
EXEC SQL put selcurs using descriptor pointer2;
```

## Inserting into a Collection Cursor

A Collection cursor allows you to access the individual elements of a collection variable. To declare a Collection cursor, use the DECLARE statement and include the Collection-Derived Table segment in the INSERT statement that you associate with the cursor. Once you open the Collection cursor with the OPEN statement, the cursor can put elements in the collection variable.

To put elements, one at a time, into the Insert cursor, use the PUT statement and the FROM clause. The PUT statement identifies the Collection cursor that is associated with the collection variable. The FROM clause identifies the element value to be inserted into the cursor. The data type of any host variable in the FROM clause must match the element type of the collection.

**Important:** The collection variable stores the elements of the collection. However, it has no intrinsic connection with a database column. Once the collection variable contains the correct elements, you must then save the variable into the actual collection column with the INSERT or UPDATE statement.

Suppose you have a table called **children** with the following schema:

```
CREATE TABLE children
(
  age      SMALLINT,
  name     VARCHAR(30),
  fav_colors SET(VARCHAR(20) NOT NULL)
);
```

The following Informix® ESQL/C program fragment shows how to use an Insert cursor to put elements into a collection variable called **child\_colors**:

```
EXEC SQL BEGIN DECLARE SECTION;
  client collection child_colors;
  char *favorites[]
  (
    "blue",
    "purple",
    "green",
    "white",
    "gold",
    0
  );
  int a = 0;
  char child_name[21];
EXEC SQL END DECLARE SECTION;

EXEC SQL allocate collection :child_colors;

/* Get structure of fav_colors column for untyped
 * child_colors collection variable */
EXEC SQL select fav_colors into :child_colors
  from children where name = :child_name;
/* Declare insert cursor for child_colors collection
 * variable and open this cursor */
EXEC SQL declare colors_curs cursor for
  insert into table(:child_colors)
  values (?);
EXEC SQL open colors_curs;
/* Use PUT to gather the favorite-color values
 * into a cursor */
while (fav_colors[a])
{
  EXEC SQL put colors_curs from :favorites[:a];
  a++
```

```

...
}
/* Flush cursor contents to collection variable */
EXEC SQL flush colors_curs;
EXEC SQL update children set fav_colors = :child_colors;

EXEC SQL close colors_curs;
EXEC SQL deallocate collection :child_colors;

```

After the FLUSH statement executes, the collection variable, **child\_colors**, contains the elements {"blue", "purple", "green", "white", "gold"}. The UPDATE statement at the end of this program fragment saves the new collection into the **fav\_colors** column of the database. Without this UPDATE statement, the new collection would not be added to the collection column.

[DEALLOCATE COLLECTION statement on page 464](#)

## Writing Buffered Rows

To open an Insert cursor, the OPEN statement creates an insert buffer. The PUT statement puts a row into this insert buffer. The buffered rows are inserted into the database table as a block only when necessary; this process is called *flushing the buffer*. The buffer is flushed after any of the following events:

- Buffer is too full to hold the new row at the start of a PUT statement.
- A FLUSH statement executes.
- A CLOSE statement closes the cursor.
- An OPEN statement specifies an already open cursor, closing it before reopening it. (This implicit CLOSE statement flushes the buffer.)
- A COMMIT WORK statement executes.
- Buffer contains BYTE or TEXT data (flushed after a single PUT statement).

If the program terminates without closing an Insert cursor, the buffer remains unflushed. Rows that were inserted into the buffer since the last flush are lost. Do not rely on the end of the program to close the cursor and flush the buffer.

## Error Checking

The **sqlca** structure contains information on the success of each PUT statement as well as information that lets you count the rows that were inserted. The result of each PUT statement is contained in the following fields of the **sqlca**: **sqlca.sqlcode**, **SQLCODE**, and **sqlca.sqlerrd[2]**.

Data buffering with an Insert cursor means that errors are not discovered until the buffer is flushed. For example, an input value that is incompatible with the data type of the column for which it is intended is discovered only when the buffer is

flushed. When an error is discovered, buffered rows that were not inserted before the error are *not* inserted; they are lost from memory.

The **SQLCODE** field is set to 0 if no error occurs; otherwise, it is set to an error code. The third element of the **sqlerrd** array is set to the number of rows that were successfully inserted into the database:

- If any row is put into the insert buffer, but *not* written to the database, **SQLCODE** and **sqlerrd** are set to 0 (**SQLCODE** because no error occurred, and **sqlerrd** because no rows were inserted).
- If a block of buffered rows is written to the database during the execution of a PUT statement, **SQLCODE** is set to 0 and **sqlerrd** is set to the number of rows that was successfully inserted into the database.
- If an error occurs while the buffered rows are written to the database, **SQLCODE** indicates the error, and **sqlerrd** contains the number of successfully inserted rows. (The uninserted rows are discarded from the buffer.)

**Tip:** When you encounter an **SQLCODE** error, a **SQLSTATE** error value also exists. See the GET DIAGNOSTICS statement for details of how to obtain the message text.

### To count the number of pending and inserted rows in the database

1. Prepare two integer variables (for example, **total** and **pending**).
2. When the cursor is opened, set both variables to 0.
3. Each time a PUT statement executes, increment both **total** and **pending**.
4. Whenever a PUT or FLUSH statement executes or the cursor closes, subtract the third field of the **SQLERRD** array from **pending**.

At any time, (**total** - **pending**) represents the number of rows actually inserted. If no statements fail, **pending** contains zero after the cursor is closed. If an error occurs during a PUT, FLUSH, or CLOSE statement, the value that remains in **pending** is the number of uninserted (discarded) rows.

## RELEASE SAVEPOINT statement

Use the RELEASE SAVEPOINT statement to destroy a specified savepoint. The RELEASE SAVEPOINT statement is compliant with the ANSI/ISO standard for SQL.

## Syntax

### RELEASE SAVEPOINT *savepoint*

| Element          | Description                           | Restrictions                              | Syntax                                  |
|------------------|---------------------------------------|---|---|
| <i>savepoint</i> | Name of the savepoint to be destroyed | Must exist in the current savepoint level | <a href="#">Identifier on page 1456</a> |

## Usage

 **Restriction:** After this statement executes successfully, rollback to the specified savepoint (or to any other savepoint between the RELEASE SAVEPOINT statement and the specified savepoint) is no longer possible.

The RELEASE SAVEPOINT statement destroys the specified savepoint. Any savepoints set between that savepoint and the RELEASE SAVEPOINT statement in the current savepoint level are also destroyed. Any other savepoints, however, that were set earlier than the specified savepoint in the current savepoint level continue to be active.

The RELEASE SAVEPOINT statement fails with an error in the following contexts:

- No SQL transaction is open.
- No savepoint with the specified name exists in the current savepoint level.
- The statement is part of a triggered action.
- The statement is part of an XA transaction.
- The autocommit transaction mode of the client API is enabled.
- The statement is part of a cross-server distributed SQL transaction in which one of the participating database servers does not support savepoints.
- The statement is issued within a UDR that is invoked within a DML statement.

The identifier of any savepoint that RELEASE SAVEPOINT destroys can be reused in a subsequent SAVEPOINT statement of the same savepoint level, even if the released savepoint was set by a SAVEPOINT statement that included the UNIQUE keyword.

Because savepoints are program objects, not database objects, the RELEASE SAVEPOINT statement has no direct effect on the database or on its system catalog tables. RELEASE SAVEPOINT can affect user tables and the system catalog indirectly, however, if it changes the scope of a subsequent ROLLBACK TO SAVEPOINT operation that cancels uncommitted changes to the database within a different portion of the current savepoint level, as the next example illustrates.

The following program fragment sets and then releases a savepoint called `sp45`:

```
BEGIN WORK;
CREATE DATABASE third_base IN db3 WITH BUFFERED LOG;
SAVEPOINT sp46;
CREATE TABLE tab1 ( col1 INT, col2 CHAR(24));
SAVEPOINT sp45 UNIQUE;
...
CREATE TABLE tab2 ( col1 INT8, col2 LVARCHAR(24000));
SAVEPOINT sp44;
...
```

```
RELEASE SAVEPOINT sp45;
ROLLBACK TO SAVEPOINT;
```

The effect of the `RELEASE SAVEPOINT` statement in this example is to destroy two savepoints, `sp45` and `sp44`. If the only remaining savepoint in the current savepoint level is `sp46`, the subsequent `ROLLBACK TO SAVEPOINT` statement cancels the DDL statements that created **tab1** and **tab2**, and any DML operations on those tables that preceded the `ROLLBACK` statement. The rollback does not, however, cancel the `CREATE DATABASE` statement that created the **third\_base** database. Without the `RELEASE SAVEPOINT` statement, the `CREATE TABLE` statement that created **tab1** would not have been cancelled, because Informix® would have treated **sp44** as the default savepoint that the `TO SAVEPOINT` clause of the `ROLLBACK` statement references.

---

## RENAME COLUMN statement

Use the `RENAME COLUMN` statement to change the name of a column. The `RENAME COLUMN` statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### RENAME COLUMN

*owner.*

*table.old\_column*

**TO***new\_column*

| Element           | Description   | Restrictions   | Syntax                                  |
|-------------------|---|--|---|
| <i>new_column</i> | Name that you declare here to replace <i>old_column</i> | Must be unique among column names in <i>table</i> . See also <a href="#">How Triggers Are Affected on page 711</a> . | <a href="#">Identifier on page 1456</a> |
| <i>old_column</i> | Column to rename  | Must exist within table  | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>      | Owner of the table                                      | Must be the owner of table   | <a href="#">Owner name on page 1488</a> |
| <i>table</i>      | Table that contains <i>old_column</i>                   | Must be registered in the current database   | <a href="#">Identifier on page 1456</a> |

### Usage

You can rename a column of a table if any of the following conditions are true:

- You own the table or have Alter privilege on the table.
- You have the DBA privilege on the database.

The column can be in a table object that the CREATE EXTERNAL TABLE statement defined.

### Example

The following example assigns the new name of **c\_num** to the **customer\_num** column in the **customer** table:

```
RENAME COLUMN customer.customer_num TO c_num;
```

---

#### Related reference

[RENAME TABLE statement on page 717](#)

[ALTER TABLE statement on page 99](#)

[CREATE TABLE statement on page 335](#)

[CREATE VIEW statement on page 452](#)

#### Related information

[CREATE TRIGGER statement on page 405](#)

## How Views and Check Constraints Are Affected

If you rename a column that appears in a view, the text of the view definition in the **sysviews** system catalog table is updated to reflect the new column name. If you rename a column that appears in a check constraint, the text of the check constraint in the **syschecks** system catalog table is updated to reflect the new column name.

## How Triggers Are Affected

If you rename a column that appears within the definition a trigger, it is replaced with the new name only in the following instances:

- When it appears as part of a correlation name inside the FOR EACH ROW action clause of a trigger
- When it appears as part of a correlation name in the INTO clause of an EXECUTE FUNCTION (or EXECUTE PROCEDURE) statement
- When it appears as a triggering column in the UPDATE clause

When the trigger executes, if the database server encounters a column name that no longer exists in the table, an error is returned.

## RENAME CONSTRAINT statement

Use the RENAME CONSTRAINT statement to rename the constraint. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****RENAME CONSTRAINT**

*owner* .

*old\_constraint* **TO** *new\_constraint*

| Element               | Description  | Restrictions  | Syntax                                  |
|-----------------------|--|---|---|
| <i>new_constraint</i> | New name that you declare here for <i>old_constraint</i> | Name must be unique to the database                                 | <a href="#">Identifier on page 1456</a> |
| <i>old_constraint</i> | Constraint name that <i>new_constraint</i> replaces      | Must exist, but it cannot be a constraint on a system catalog table | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>          | Owner of <i>old_constraint</i>                           | Must be the owner of <i>old_constraint</i>                          | <a href="#">Owner name on page 1488</a> |

**Usage**

You can rename a constraint if any of the following is true:

- You are the owner of the constraint.
- You have the DBA privilege on the database.

When you rename a constraint, the database server changes the constraint name in the **sysconstraints** and **sysobjstate** system catalog tables.

**RENAME DATABASE statement**

Use the RENAME DATABASE statement to change the name of a database. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****RENAME DATABASE**

*owner* .

*old\_database* **TO** *new\_database*

| Element             | Description  | Restrictions   | Syntax                                     |
|---------------------|--|--|--|
| <i>new_database</i> | New name that you declare here for <i>old_database</i> | Must be unique among database names of the current database server; must not be opened by any user when this statement is issued | <a href="#">Database Name on page 1449</a> |
| <i>old_database</i> | Name that <i>new_database</i> replaces                 | Must exist on current database server, but it cannot be the name of the current database<br><br>Cannot be a tenant database.     | <a href="#">Database Name on page 1449</a> |

| Element      | Description                  | Restrictions                      | Syntax                                  |
|--------------|------------------------------|-----------------------------------|---|
| <i>owner</i> | Owner of <i>old_database</i> | Must be the owner of the database | <a href="#">Owner name on page 1488</a> |

## Usage

You can rename a database if any of the following is true:

- You created the database.
- You have the DBA privilege on the database.
- The database is not a tenant database. Tenant databases cannot be renamed.

The RENAME DATABASE statement fails with error -9874, however, if the specified database contains any of the following objects:

- a virtual table
- a virtual index
- an R-tree index
- a DataBlade® that references the current name of the database in a user-defined primary access method or in a user-defined secondary access method.

You can only rename databases of the database server to which you are currently connected.

You cannot rename a database from inside an SPL routine.

---

[CREATE DATABASE statement on page 201](#)

## RENAME INDEX statement

Use the RENAME INDEX statement to change the name of an existing index. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### RENAME INDEX

*owner*.

*old\_index* **TO** *new\_index*

| Element          | Description                                  | Restrictions   | Syntax                                  |
|------------------|--|--|---|
| <i>new_index</i> | New name that you declare here for the index | Name must be unique to the database (or to the session, if <i>old_index</i> is on a temporary table) | <a href="#">Identifier on page 1456</a> |

| Element          | Description                               | Restrictions   | Syntax                                  |
|------------------|---|--|---|
| <i>old_index</i> | Index name that <i>new_index</i> replaces | Must exist, but it cannot be any of the following: <ul style="list-style-type: none"> <li>• An index on a system catalog table</li> <li>• A Virtual-Index Interface (VII)</li> </ul> | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>     | Owner of index                            | Must be the owner of <i>old_index</i>  | <a href="#">Owner name on page 1488</a> |

## Usage

You can rename an index if you are the owner of the index or have the DBA privilege on the database.

When you rename an index, the database server changes the index name in the **sysindexes**, **sysconstraints**, **sysobjstate**, and **sysfragments** system catalog tables. (But for an index on a temporary table, no system catalog tables are updated.)

You can rename a system-generated index that implements a primary-key or foreign-key constraint. When you rename a system-generated index, the index is not automatically dropped if you drop the corresponding constraint. The name of a system-generated index consists of a white space, a number, an underscore, and a number. Omit the white space at the beginning of the system-generated index name in the RENAME INDEX statement. For example, to rename an index that is named " 100\_1" to idx1, run the following statement:

```
RENAME INDEX 100_1 TO idx1;
```

You can include the owner name before the system-generated index name, for example:

```
RENAME INDEX jmm.100_1 TO idx1;
```

Indexes on system catalog tables cannot be renamed.

By default, SPL routines that use the renamed index are reoptimized when they are next executed after the index is renamed. When automatic recompilation is disabled, however, SPL routines that use the renamed index are automatically recompiled on their next use if the renamed index is associated with a directly referenced table. If the table is only referenced indirectly, however, execution can fail with error -710. For more information about enabling or disabling automatic recompilation after changes to the schema of a referenced table, see the [IFX\\_AUTO\\_REPREPARE session environment option on page 927](#). For more information about the AUTO\_REPREPARE configuration parameter, see your .

[CREATE INDEX statement on page 253](#)

[DROP INDEX statement on page 515](#)

## RENAME SECURITY statement

Use the RENAME SECURITY statement to change the name of an existing security object. The object can be a security policy, or a security label, or a security label component.

**Syntax****RENAME SECURITY****POLICY**LABEL *policy*.**LABEL COMPONENT***old\_name* **TO** *new\_name*

| Element         | Description  | Restrictions   | Syntax                                  |
|-----------------|--|--|---|
| <i>new_name</i> | New name that you declare here for the security object | Must be unique among identifiers of security objects in the database, and must be different from <i>old_name</i> | <a href="#">Identifier on page 1456</a> |
| <i>old_name</i> | Current® name that <i>new_name</i> replaces            | Must exist in the database as the identifiers of a security object   | <a href="#">Identifier on page 1456</a> |
| <i>policy</i>   | Security policy of the <i>old_name</i> label           | Must be the security policy for which <i>old_name</i> is a security label  | <a href="#">Identifier on page 1456</a> |

**Usage**

This statement is an extension to the ANSI/ISO standard for SQL.

Only DBSECADM can issue this statement. The RENAME SECURITY statement replaces the *old\_name* with the specified *new\_name* in the table of the system catalog in which the renamed security object is registered:

- **syssecpolicies.secpolicyname** for security policies
- **sysseclabels.seclabelname** for security labels
- **sysseclabelcomponents.compname** for security label components.

This statement does not, however, change the numeric value of the **syssecpolicies.secpolicyid**, **sysseclabels.seclabelid**, nor **sysseclabelcomponents.compoid** of the renamed security object.

The keyword or keywords that follow the SECURITY keyword identify the type of security object that is being renamed. In the following example, the new identifier **honesty** replaces **best** as the name of a security policy:

```
RENAME SECURITY POLICY best TO honesty;
```

In the following example, the new identifier **transparent** replaces **opaque** as the name of a label for the **honesty** security policy:

```
RENAME SECURITY LABEL honesty.opaque TO transparent;
```

In the next example, the new identifier **accountant** replaces **architect** as the name of a security label component:

```
RENAME SECURITY LABEL COMPONENT architect TO accountant;
```

## RENAME SEQUENCE statement

Use the RENAME SEQUENCE statement to change the name of a sequence. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### RENAME SEQUENCE

*owner*.

*old\_sequence* **TO** *new\_sequence*

| Element             | Description   | Restrictions   | Syntax                                  |
|---------------------|---|--|---|
| <i>new_sequence</i> | New name that you declare here for an existing sequence | Must be unique among the names of sequences, tables, views, and synonyms in the database | <a href="#">Identifier on page 1456</a> |
| <i>old_sequence</i> | Current® name of a sequence                             | Must exist in the current database   | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>        | Owner of the sequence                                   | Must be the owner of the sequence  | <a href="#">Owner name on page 1488</a> |

### Usage

To rename a sequence, you must be the owner of the sequence, have the ALTER privilege on the sequence, or have the DBA privilege on the database.

You cannot use a synonym to specify the name of the sequence.

In a database that is not ANSI compliant, the name of *new\_sequence* (or in an ANSI-compliant database, the combination of *owner.new\_sequence*) must be unique among sequences, tables, views, and synonyms in the database.

**Related reference**[DROP SEQUENCE statement on page 529](#)[ALTER SEQUENCE statement on page 95](#)[CREATE SEQUENCE statement on page 326](#)[CREATE SYNONYM statement on page 330](#)[DROP SYNONYM statement on page 530](#)[GRANT statement on page 592](#)[REVOKE statement on page 727](#)[INSERT statement on page 638](#)[UPDATE statement on page 1037](#)[SELECT statement on page 768](#)[NEXTVAL and CURRVAL Operators on page 1243](#)

## RENAME TABLE statement

Use the RENAME TABLE statement to change the name of a table. The RENAME TABLE statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****RENAME TABLE***owner.**old\_table***TO***new\_table*

| Element          | Description                         | Restrictions   | Syntax                                  |
|------------------|-------------------------------------|--|---|
| <i>new_table</i> | New name for <i>old_table</i>       | Must be unique among the names of sequences, tables, views, and synonyms in the database | <a href="#">Identifier on page 1456</a> |
| <i>old_table</i> | Name that <i>new_table</i> replaces | Must be the name (not the synonym) of a table that is registered in the current database | <a href="#">Identifier on page 1456</a> |
| <i>owner</i>     | Current® owner of the table         | Must be the owner of the table.  | <a href="#">Owner name on page 1488</a> |

**Usage**

To rename a table, you must be the owner of the table, or have the ALTER privilege on the table, or have the DBA privilege on the database.

An error occurs if *old\_table* is a synonym, rather than the name of a table.

The *old\_table* can be an object that the CREATE EXTERNAL TABLE statement defined.

The renamed table remains in the current database. You cannot use the RENAME TABLE statement to move a table from the current database to another database, nor to rename a table that resides in another database.

You cannot change the table *owner* by renaming the table. An error occurs if you try to specify an *owner*. qualifier for the new name of the table.

When the table owner is changed, you must specify both the old owner and new owner.

In an ANSI-compliant database, if you are not the owner of *old\_table*, you must specify *owner.old\_table* as the old name of the table.

If *old\_table* is referenced by a view in the current database, the view definition is updated in the **sysviews** system catalog table to reflect the new table name. For further information on the **sysviews** system catalog table, see the *Informix® Guide to SQL: Reference*.

If *old\_table* is a triggering table, the database server takes these actions:

- Replaces the name of the table in the trigger definition but does not replace the table name where it appears inside any triggered actions
- Returns an error if the new table name is the same as a correlation name in the REFERENCING clause of the trigger definition

When the trigger executes, the database server returns an error if it encounters a table name for which no table exists.

### Using RENAME TABLE to Reorganize a Table

The RENAME TABLE statement can be a useful alternative to the ALTER TABLE statement when you need to reorganize the schema of an existing table. Suppose, for example, that you decide to change the order of columns in the **items** table of the **stores** demonstration database. You can reorganize the **items** table to move the **quantity** column from the fifth position to the third position by following these steps:

1. Create a new table, **new\_table**, that contains the column **quantity** in the third position.
2. Fill the table with data from the current **items** table.
3. Drop the old **items** table.
4. Rename **new\_table** with the identifier **items**.

The following example uses the RENAME TABLE statement as the last step:

```
CREATE TABLE new_table
(
  item_num      SMALLINT,
  order_num     INTEGER,
  quantity      SMALLINT,
  stock_num     SMALLINT,
  manu_code     CHAR(3),
  total_price   MONEY(8)
);
INSERT INTO new_table
```

```

SELECT item_num, order_num, quantity, stock_num,
       manu_code, total_price FROM items;
DROP TABLE items;
RENAME TABLE new_table TO items;

```

---

## RENAME TRUSTED CONTEXT statement

Use the RENAME TRUSTED CONTEXT statement to change the name of a trusted-context object.

This statement is an extension to the ANSI/ISO standard for SQL. You must hold the database security administrator (DBSECADM) role to rename a trusted context.

### Syntax

#### RENAME TRUSTED CONTEXT

*old\_name* **TO** *new\_name*

**R**  
**D e**  
**e s**  
**s t**  
**E c r i**

### Usage

The *new\_name* and the *old\_name* cannot include qualifiers, such as *owner*, *database*, or *dbserver*.

After the RENAME TRUSTED CONTEXT statement successfully executes, all references to the *old\_name* will be replaced by *new\_name* in these tables in the **sysuser** database of the Informix® database server instance:

- **systrustedcontext**
- **sysctxattributes**
- **sysctxusers**.

In addition, applications that attempt to establish a connection to the database by referencing the *old\_name* will fail, unless the *old\_name* has been declared as the identifier of a new trusted-context object.

If you rename the trusted context while trusted connections for this context are active, those connections remain trusted until they terminate, or until the next reuse attempt. If an attempt is made to switch the user on these trusted connections, however, an error is returned.

### Example

The following example of a complete RENAME TRUSTED CONTEXT statement replaces the security-object identifier cntx1 with cntx2 as the new name for the cntx1 trusted context:

```
RENAME TRUSTED CONTEXT cntx1 TO cntx2;
```

This example fails under either of the following circumstances:

- if cntx1 is not the name of a trusted-context object of the current database server instance,
- or if cntx2 is already the name of an existing trusted-context object of the same database server.

## RENAME USER statement (UNIX™, Linux™)

Use the RENAME USER statement to change the name of an internal user of a non-root installation of the database server.

This statement is an extension to the ANSI/ISO standard for the SQL language.

### Syntax

#### RENAME USER

*old\_name*TO*new\_name*

| Element         | Description  | Restrictions                                   | Syntax                                  |
|-----------------|--|--|---|
| <i>old_name</i> | Authorization identifier of a specific user that you are renaming. | Must be an existing authorization identifier   | <a href="#">Owner name on page 1488</a> |
| <i>new_name</i> | Authorization identifier of a specific user.                       | Cannot be an existing authorization identifier | <a href="#">Owner name on page 1488</a> |

## Usage

Only a DBSA can run the RENAME USER statement. With a non-root installation, the user who installs the server is the equivalent of the DBSA, unless the user delegates DBSA privileges to a different user.

Do not rename a user while the user is active on a connection. Running the statement does not transfer any database or table level privileges granted to the old user name to the new user name.

Execution of the RENAME USER statement can be audited with the RNUR audit code.

The USERMAPPING configuration parameter must be set to BASIC or ADMIN.

You must also enter values in the SYSUSERMAP table of the **sysusers** database to map users with the appropriate user properties so that the mapped user statements of SQL to work correctly.

## Example

### Example

The following statement renames the user **bill** to **bob**:

```
RENAME USER bill TO bob;
```

| Element        | Description   | Restrictions                                | Syntax                                  |
|----------------|---|---|---|
| <i>revoker</i> | Authorization identifier of the grantor of the privileges to be revoked | Must be grantor of the specified privileges | <a href="#">Owner name on page 1488</a> |
| <i>role</i>    | Role from which you revoke another role                                 | Must exist                                  | <a href="#">Owner name on page 1488</a> |
| <i>user</i>    | User whose role (or default role) you cancel                            | Must exist                                  | <a href="#">Owner name on page 1488</a> |

## Usage

To cancel privileges on one or more fragments of a table that has been fragmented by expression, see [REVOKE FRAGMENT statement on page 755](#).

You can revoke privileges if any of the following conditions is true for the privileges that you are attempting to revoke on some database object:

- You granted them and did not designate another user as grantor.
- The GRANT statement specified you as grantor.
- You are revoking privileges from PUBLIC on an object that you own, and those privileges were granted by default when you created the object.
- You have database-level DBA privileges and you specify in the AS clause the name of a user who was grantor of the privilege.

The REVOKE statement can cancel any of the following access privileges or roles that a user, or PUBLIC, or a role currently holds:

- Privileges on the database (but a role cannot hold database-level privileges)
- Privileges on a table, synonym, view, or sequence object
- Privileges on a user-defined data type (UDT), a user-defined routine (UDR), or on the SPL language
- A non-default role, or the default role of PUBLIC or of a user.

You cannot revoke privileges from yourself. You cannot revoke grantor status from another user. To revoke a privilege that was granted to another user by the AS *grantor* clause of the GRANT statement, you must have the DBA privilege, and you must use the AS clause to specify that user as *revoker*.

## Delimiting *revoker*, *role*, and *user* identifiers

The REVOKE statement syntax diagram is simplified, because

- 337. See [Role Name on page 742](#)
- 338. See [Routine-Level Privileges on page 737](#)
- 339. See [Language-Level Privileges on page 739](#)
- 340. See [Type-Level Privileges on page 736](#)
- 341. See [Sequence-Level Privileges on page 740](#)
- 342. See [Security Administration Options on page 746](#)

- the quotation-mark delimiters that can enclose the *revoker*, *role*, or *user* names are optional,
- and you can also substitute double ( " ) quotation marks for single ( ' ) quotation marks to delimit those identifiers. Both delimiters must be the same character.

If you enclose *revoker*, *role*, or *user* in quotation marks, the name is case sensitive, and the database server stores it in the system catalog exactly as you enter it in the REVOKE statement. For example, the following statement revokes the DBA privilege from user `sam`.

```
REVOKE DBA FROM "sam";
```

If another user who holds the DBA privilege has the authorization identifier `sam`, they would not be affected by the REVOKE example, because their case sensitive user name does not match the delimited name. In a database that was not created as MODE ANSI, however, the following example revokes the DBA privilege of both users `sam` and `sam`:

```
REVOKE DBA FROM sam;
```

In an ANSI-compliant database, if you do not use quotation marks as delimiters, that identifier is stored in uppercase letters. In locales that support letter case, authorization identifiers for distinct users or roles that differ only in letter case might produce unexpected results, if GRANT and REVOKE statements use both delimited and undelimited *user* and *role* specifications to manage access privileges.

## Revoking database server access from mapped users (UNIX™, Linux™)

Use the REVOKE ACCESS FROM statement to remove surrogate user properties from specific mapped users.

Only user **informix** or a DBSA can run the REVOKE ACCESS FROM statement.

The REVOKE ACCESS FROM statement does not affect any access privileges of the Informix® user account name that accesses the database server through an OS-level account on the host computer.

Example:

User **informix** or a DBSA can run the following statement on a system that supports mapped users, and one of the mapped users is user **bob**:

```
REVOKE ACCESS FROM bob;
```

This statement entirely removes the access of user **bob** to the database server, except when one or both of the following is true:

- PUBLIC is mapped to surrogate user properties. In this case, user **bob** still retains the same access privileges that the PUBLIC group holds.
- User **bob** is also a user account on the Informix® host computer with database server access.

**Related reference**

[Surrogate user properties \(UNIX, Linux\) on page 625](#)

## Database-level privileges

Three concentric layers of database-level privileges, Connect, Resource, and DBA, authorize increasing power over database access and control. Only a user with the DBA privilege can grant or revoke database-level privileges.

Database-Level Privileges

**DBA RESOURCE CONNECT**

Because of the hierarchical organization of the privileges (as outlined in the privilege definitions that are described later in this section), if you revoke either the Resource or the Connect privilege from a user with the DBA privilege, the statement has no effect. If you revoke the DBA privilege from a user who has the DBA privilege, the user retains the Connect privilege on the database. To deny database access to a user with the DBA or Resource privilege, you must first revoke the DBA or the Resource privilege and then revoke the Connect privilege in a separate REVOKE statement.

Similarly, if you revoke the Connect privilege from a user who has the Resource privilege, the statement has no effect. If you revoke the Resource privilege from a user, the user retains the Connect privilege on the database.

Only users or PUBLIC can hold database-level privileges. You cannot revoke these privileges from a role, because a role cannot hold database level privileges.

The following table lists the keyword for each database-level privilege.

| Privilege | Effect  |
|-----------|---|
| DBA       | <p>Has all the capabilities of the Resource privilege and can perform the following additional operations:</p> <ul style="list-style-type: none"> <li>• Grant any database-level privilege, including the DBA privilege, to another user.</li> <li>• Grant any table-level privilege to another user or to a role.</li> <li>• Grant a role to a user or to another role.</li> <li>• Revoke a privilege whose grantor you specify as the <i>revoker</i> in the AS clause of the REVOKE statement.</li> <li>• Restrict the Execute privilege to DBAs when registering a UDR.</li> <li>• Execute the SET SESSION AUTHORIZATION statement.</li> <li>• Create any database object.</li> <li>• Create tables, views, and indexes, designating another user as owner of these objects.</li> <li>• Alter, drop, or rename database objects, regardless of who owns it.</li> <li>• Execute the DROP DISTRIBUTIONS option of the UPDATE STATISTICS statement.</li> <li>• Execute DROP DATABASE and RENAME DATABASE statements.</li> </ul> |
| RESOURCE  | <p>Lets you extend the structure of the database. In addition to the capabilities of the Connect privilege, the holder of the Resource privilege can perform the following operations:</p> <ul style="list-style-type: none"> <li>• Create new tables.</li> <li>• Create new indexes.</li> <li>• Create new user-defined routines.</li> <li>• Create new data types.</li> </ul>   |
| CONNECT   | <p>If you have this privilege, you can query and modify data, and modify the database schema if you own the database object that you want to modify. A user holding the Connect privilege can perform the following operations:</p> <ul style="list-style-type: none"> <li>• Connect to the database with the CONNECT statement or another connection statement.</li> <li>• Execute SELECT, INSERT, UPDATE, and DELETE statements, provided that the user has the necessary table-level privileges.</li> <li>• Create views, provided that the user has the Select privilege on the underlying tables.</li> <li>• Create synonyms.</li> <li>• Create temporary tables and create indexes on temporary tables.</li> <li>• Alter or drop a table or an index, if the user owns the table or index (or has the Alter, Index, or References privilege on the table).</li> <li>• Grant privileges on a table, if the user owns the table (or was given privileges on the table with the WITH GRANT OPTION keyword).</li> </ul>       |

**Tip:** To determine which users have DBA privileges on a database, run this query from DB-Access or your application:

```
select username,usertype from sysusers;
```

The output shows user names (for example, public and informix) followed by one of the following codes:

- D = DBA privilege
- C = Connect privilege
- R = Resource privilege

## Table-Level Privileges

Table-level privileges, also called *table privileges*, specify which operations a user or role can perform on a table or view in the database. You can use a synonym to specify the table or view on which you grant or revoke table privileges.

Select, Update, and References privileges can be granted on a subset of the columns of a table or view, but can be revoked only for all columns. If Select privileges are revoked from a user for a table that is referenced in the SELECT statement defining a view that the same user owns, then that view is dropped, unless it also includes columns from tables in another database.

For table objects that the CREATE EXTERNAL TABLE statement has registered in the current database, only the Select privilege and the Insert privilege are supported; no other table or column access privileges can be granted or revoked.

Use the following syntax to specifying which table-level privileges to revoke from one or more users or roles:

Table-Level Privileges

**ALL**

**PRIVILEGES**

,

**INSERT DELETE UPDATE**

<sup>343</sup> **SELECT ALTER INDEX REFERENCES**

**UNDER**

**ON**

*owner.*

*table view synonym*

| Element  | Description  | Restrictions                             | Syntax                                  |
|--|--|--|---|
| <i>owner</i>                                   | Name of the user who owns the <i>table</i> , <i>view</i> , or <i>synonym</i> | Must be a valid authorization identifier | <a href="#">Owner name on page 1488</a> |
| <i>synonym</i> ,<br><i>table</i> , <i>view</i> | Synonym, table, or view on which privileges are granted                      | Must exist in the current database       | <a href="#">Identifier on page 1456</a> |

In one REVOKE statement, you can list one or more of the following keywords to specify the privileges on the specified table to be revoked from the users or roles.

343. Informix® extension

| Privilege  | Effect after REVOKE   |
|------------|---|
| INSERT     | User cannot insert rows.  |
| DELETE     | User cannot delete rows.  |
| SELECT     | User cannot display data retrieved by a SELECT statement.   |
| UPDATE     | User cannot change column values.   |
| INDEX      | User cannot create permanent indexes. You must have the Resource privilege to take advantage of the Index privilege. (But any user who has the Connect privilege can create indexes on temporary tables.)   |
| ALTER      | The holder cannot add or delete columns, modify column data types, add or delete constraints, change the locking mode of a table from PAGE to ROW, nor add or drop a corresponding named ROW type table. The user also cannot enable or disable indexes, constraints, nor triggers, as described in <a href="#">SET Database Object Mode statement on page 871</a> .                            |
| Privilege  | Effect after REVOKE   |
| REFERENCES | User cannot reference columns in referential constraints. You must also have the Resource privilege on the database to take advantage of the References privilege on tables. (You can add, however, a referential constraint during an ALTER TABLE statement. without holding the Resource privilege on the database.) Revoking the References privilege disallows cascading DELETE operations. |
| UNDER      | User cannot create subtables under a typed table.   |
| ALL        | This removes all of the table privileges that are listed above. (Here the PRIVILEGES keyword is optional. )   |

See also [Table-Level Privileges on page 597](#).

If a user receives the same privilege from two different grantors and one grantor revokes the privilege, the grantee still has the privilege until the second grantor also revokes the privilege. For example, if both you and a DBA grant the Update privilege on your table to **ted**, both you and the DBA must revoke the Update privilege to prevent **ted** from updating your table.

If user **ted** holds the same privileges through a role or as PUBLIC, however, this REVOKE operation does not prevent **ted** from exercising the Update privilege.

## When to Use REVOKE Before GRANT

You can use combinations of REVOKE and GRANT to replace PUBLIC with specific users as grantees, and to remove table-level privileges on some columns.

## Replacing PUBLIC with Specified Users

If a table owner grants a privilege to PUBLIC, the owner cannot revoke the same privilege from any specific user. For example, assume PUBLIC has default Select privileges on your **customer** table. Suppose that you issue the following statement in an attempt to exclude **ted** from accessing your table:

```
REVOKE ALL ON customer FROM ted;
```

This statement results in ISAM error message 111, `No record found`, because the system catalog tables (**syscolauth** or **sysstabauth**) contain no table-level privilege entry for a user named **ted**. This REVOKE operation does not prevent **ted** from keeping all the table-level privileges given to PUBLIC on the **customer** table.

To restrict table-level privileges, first revoke the privileges with the PUBLIC keyword, then re-grant them to some appropriate list of users and roles. The following statements revoke the Index and Alter privileges from all users for the **customer** table, and then grant these privileges specifically to user **mary**:

```
REVOKE INDEX, ALTER ON customer FROM PUBLIC;
GRANT INDEX, ALTER ON customer TO mary;
```

## Restricting Access to Specific Columns

Unlike GRANT, the REVOKE statement has no syntax to specify privileges on a subset of columns in a table. To revoke the Select, Update, or References privilege on a column from a user, you must revoke the privilege for all the columns of the table. To provide access to some of the columns on which you previously had granted privileges, issue a new GRANT statement to restore the appropriate privilege on specific columns.

The next example cancels Select privileges for PUBLIC on certain columns:

```
REVOKE SELECT ON customer FROM PUBLIC;
GRANT SELECT (fname, lname, company, city) ON customer TO PUBLIC;
```

In the next example, **mary** first receives the ability to reference four columns in **customer**, then the table owner restricts references to two columns:

```
GRANT REFERENCES (fname, lname, company, city) ON customer TO mary;
REVOKE REFERENCES ON customer FROM mary;
GRANT REFERENCES (company, city) ON customer TO mary;
```

## Effect of the ALL Keyword

The ALL keyword revokes all table-level privileges. If any or all of the table-level privileges do not exist for the revokee, REVOKE with the ALL keyword executes successfully but returns the following **SQLSTATE** code:

```
01006--Privilege not revoked
```

For example, assume that user **hal** has the Select and Insert privileges on the **customer** table. User **jocelyn** wants to revoke all table-level privileges from user **hal**. So user **jocelyn** issues the following REVOKE statement:

```
REVOKE ALL ON customer FROM hal;
```

This statement executes successfully but returns **SQLSTATE** code 01006. The **SQLSTATE** warning is returned because both of the following are true:

- The statement succeeds in revoking the Select and Insert privileges from user **hal** because user **hal** had those privileges.
- **SQLSTATE** code 01006 is returned because user **hal** lacked other privileges implied by the ALL keyword, but these privileges were not revoked.

The ALL keyword instructs the database server to revoke everything possible, including nothing. If the user from whom privileges are revoked has no privileges on the table, the REVOKE ALL statement still succeeds, because it revokes everything possible from the user (in this case, no privileges at all).

## Effect of the ALL Keyword on UNDER Privilege

If you revoke ALL privileges on a typed table, the Under privilege is included in the privileges that are revoked. If you revoke ALL privileges on a table that is not based on a ROW type, the Under privilege is not included among the privileges that are revoked. (The Under privilege can be granted only on a typed table.)

## Effect of Uncommitted Transactions

The REVOKE statement places an exclusive row lock on the entry in the **systables** system catalog table for the table on which privileges are revoked. This lock is not released until the transaction that contains the REVOKE statement terminates. When another transaction attempts to prepare a SELECT statement against this table while the first transaction is open, the concurrent transaction fails, because the **systables** row for the specified table remains exclusively locked. The attempt to prepare the SELECT statement cannot succeed until after the first transaction is either committed or rolled back.

## Type-Level Privileges

You can revoke two privileges on data types:

- The Usage privilege on a user-defined data type
- The Under privilege on a named ROW type

Type-Level Privileges

**USAGE ON TYPE***type\_name*

**UNDER ON TYPE***row\_type*

| Element          | Description   | Restrictions | Syntax   |
|------------------|---|--------------|--|
| <i>row_type</i>  | Named ROW type for which to revoke Under privilege    | Must exist   | Data Type, p. <a href="#">Data Type on page 1163</a> |
| <i>type_name</i> | User-defined type for which to revoke Usage privilege | Must exist   | Data Type, p. <a href="#">Data Type on page 1163</a> |

## Usage Privilege

Any user can reference a built-in data type in an SQL statement, but not a DISTINCT data type that is based on a built-in data type. The creator of a user-defined data type or a DBA must explicitly grant the Usage privilege on the UDT, including a DISTINCT data type based on a built-in data type.

REVOKE with the USAGE ON TYPE keywords removes the Usage privilege that you granted earlier to another user, to PUBLIC, or to a role.

The following statement revokes from user **mark** the privilege of using the **widget** user-defined type:

```
REVOKE USAGE ON TYPE widget FROM mark;
```

## Under Privilege

You own any named ROW data type that you create. If you want other users to be able to create subtypes under this named ROW type, you must grant these users the Under privilege on your named ROW type. If you later want to remove the ability of these users to create subtypes under the named ROW type, you must revoke the Under privilege from these users. A REVOKE statement with the UNDER ON TYPE keywords removes the Under privilege that you granted earlier to these users.

For example, suppose that you created a ROW type named **rtype1**:

```
CREATE ROW TYPE rtype1 (cola INT, colb INT);
```

If you want another user named **kathy** to be able to create a subtype under this named ROW type, you must grant the Under privilege on this named ROW type to user **kathy**:

```
GRANT UNDER ON TYPE rtype1 TO kathy;
```

Now user **kathy** can create another ROW type under the **rtype1** ROW type even though **kathy** is not the owner of the **rtype1** ROW type:

```
CREATE ROW TYPE rtype2 (colc INT, cold INT) UNDER rtype1;
```

If you later want to remove the ability of user **kathy** to create subtypes under the **rtype1** ROW type, enter the following statement:

```
REVOKE UNDER ON TYPE rtype1 FROM kathy;
```

## Routine-Level Privileges

If you revoke the Execute privilege on a UDR from a user, that user can no longer execute that UDR in any way. For details of how a user can execute a UDR, see [Routine-Level Privileges on page 603](#).

## Routine-Level Privileges

**EXECUTE ON***SPL\_routine***PROCEDURE FUNCTION ROUTINE***routine*(Routine Parameter List <sup>344</sup>

)

**SPECIFIC****ROUTINE FUNCTION PROCEDURE**Specific Name <sup>345</sup>

| Element            | Description            | Restrictions                   | Syntax                                  |
|--------------------|------------------------|--------------------------------|---|
| <i>routine</i>     | A user-defined routine | Must exist                     | <a href="#">Identifier on page 1456</a> |
| <i>SPL_routine</i> | An SPL routine         | Must be unique in the database | <a href="#">Identifier on page 1456</a> |

In an ANSI-compliant database, the *owner* name must qualify the *routine* name, unless the user who issues the REVOKE statement is the owner of the routine.

The following example cancels the Execute privilege of user **mark** on the **delete\_order** routine that is owned by **luke**:

```
REVOKE EXECUTE ON ROUTINE luke.delete_order FROM mark;
```

In Informix®, any negator function for which you grant the Execute privilege requires a separate, explicit, REVOKE statement.

When you create a UDR under any of the following circumstances, PUBLIC is not granted Execute privilege by default.

Therefore you must explicitly grant the Execute privilege before you can revoke it:

- You create the UDR in an ANSI-compliant database.
- You have DBA privilege and specify DBA after the CREATE keyword to restrict the Execute privilege to users with the DBA database-level privilege.
- The **NODEFDAC** environment variable is set to **yes** to prevent the PUBLIC group from receiving any access privileges by default that are not explicitly granted.

Setting **NODEFDAC** to **yes** also prevents PUBLIC from receiving table access privileges by default when a new table is created in a database that was not created as mode ANSI. The **NODEFDAC** setting, however, cannot prevent the PUBLIC group from being granted the same privileges by a user who holds the necessary access privileges on the new UDR or on the new table.

If you create a UDR with none of the above conditions in effect, however, PUBLIC can execute your UDR without the GRANT EXECUTE statement. To limit who can execute your UDR, revoke Execute privilege FROM PUBLIC, and grant it to users (see [User List on page 741](#)) or roles (see [Role Name on page 742](#)).

344. See [Routine Parameter List on page 1514](#)

345. See [Specific Name on page 1521](#)

In Informix®, if two or more UDRs have the same name, use a keyword from this list to specify which of those UDRs a user list can no longer execute.

### **Keyword**

#### **UDR for Which Execution by the User is Prevented**

#### **SPECIFIC**

The UDR identified by *specific name*

#### **FUNCTION**

Any function with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

#### **PROCEDURE**

Any procedure with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

#### **ROUTINE**

Functions or procedures with the specified *routine name* (and parameter types that match *routine parameter list*, if specified)

## Language-Level Privileges

To register or drop a UDR written in the SPL, C, or Java™ languages, a user must hold the Usage privilege on the programming language in which the routine is written.

This is the syntax of the USAGE ON LANGUAGE clause for specifying a language-level privilege to revoke:

Language-Level Privileges

### **USAGE ON LANGUAGE**

#### **SPL C JAVA**

Each REVOKE USAGE ON LANGUAGE statement can specify no more than one programming language.

When a user registers a UDR that is written in the SPL, C, or Java™ language, the database server verifies that the user has the Usage privilege on the language in which the UDR is written. If the user does not, the CREATE FUNCTION or CREATE PROCEDURE statement fails with an error. If the IFX\_EXTEND\_ROLE configuration parameter has enabled the built-in EXTEND role, only users who also hold that role can register or drop UDRs written in the C language or in the Java™ language, even if the users hold USAGE ON LANGUAGE privileges for those languages.

To revoke the Usage privilege on a programming language from a user or role, issue a REVOKE statement that includes the USAGE ON LANGUAGE keywords and a keyword that specifies the programming language. If this statement succeeds, any user or role that you specify in the FROM clause can no longer register UDRs that are written in the specified language. For example, if you revoke the default Usage privilege on SPL from PUBLIC, the ability to create SPL routines is taken away from

all users (except those who have been individually granted the Usage privilege on the SPL language, or who hold that Usage privilege through a role:

```
REVOKE USAGE ON LANGUAGE SPL FROM PUBLIC;
```

You can issue a GRANT USAGE ON LANGUAGE statement to restore Usage privilege on SPL to a restricted group, such as to the role named **developers**:

```
GRANT USAGE ON LANGUAGE SPL TO developers;
```

## Sequence-Level Privileges

Although Informix® implements sequence objects as tables, only the following subset of the table privileges (as described in [Table-Level Privileges on page 597](#)) can be granted or revoked on a sequence:

- Select privilege
- Alter privilege

Use the following syntax to specify privileges to revoke on a sequence object:

Sequence-Level Privileges

**ALL**

, **ALTER SELECT**

**ON**

'owner.'

*sequence synonym*

| Element         | Description                             | Restrictions             | Syntax                                  |
|-----------------|---|--------------------------|---|
| <i>owner</i>    | Owner of the sequence or of its synonym | Must be the owner        | <a href="#">Owner name on page 1488</a> |
| <i>sequence</i> | Sequence on which to revoke privileges  | Must exist               | <a href="#">Identifier on page 1456</a> |
| <i>synonym</i>  | Synonym for a sequence object           | Must point to a sequence | <a href="#">Identifier on page 1456</a> |

The sequence must reside in the current database. (You can qualify the *sequence* or *synonym* identifier with a valid *owner* name, but the name of a remote *database* (or *database@server*) is not valid as a qualifier.) Syntax to revoke sequence-level privileges is an extension to the ANSI/ISO standard for SQL.

## Alter Privilege

You can revoke the Alter privilege on a sequence from another user, from PUBLIC, or from a role. The Alter privilege enables a specified user or role to modify the definition of a sequence with the ALTER SEQUENCE statement or to rename the sequence with the RENAME SEQUENCE statement.

The following REVOKE statement cancels any Alter privilege that was granted individually to user **mark** on the **cust\_seq** sequence object:

```
REVOKE ALTER ON cust_seq FROM mark;
```

## Select Privilege

You can revoke the Select privilege on a sequence from another user, from PUBLIC, or from a role. Select privilege enables a user or role to use the *sequence.CURRVAL* and *sequence.NEXTVAL* in SQL statements to access and to increment the value of a sequence.

The following REVOKE statement cancels any Select privilege that was granted individually to user **mark** on the **cust\_seq** sequence object:

```
REVOKE SELECT ON cust_seq FROM mark;
```

## ALL Keyword

You can use the ALL keyword to revoke both Alter and Select privileges from another user, from PUBLIC, or from a role.

The following example cancels any Alter and Select privileges that user **mark** holds on the **cust\_seq** sequence object:

```
REVOKE ALL ON cust_seq FROM mark;
```

Whether **mark** can still access **cust\_seq** after this statement executes depends on whether the user still holds Alter or Select privileges on **cust\_seq** that were granted to PUBLIC, or if he holds a role to which unrevoked privileges on **cust\_seq** have been granted.

## User List

The authorization identifiers (or the PUBLIC keyword) that follow the FROM keyword of REVOKE specify who loses the revoked privileges or revoked roles. If you use the PUBLIC keyword as the user list, the REVOKE statement revokes the specified privileges or roles from PUBLIC, thereby revoking them from all users to whom the privileges or roles have not been explicitly granted, or who do not hold some other role through which they have received the role or privilege.

The *user list* can consist of the authorization identifier of a single user or of multiple users, separated by commas. If you use the PUBLIC keyword as the user list, the REVOKE statement revokes the specified privileges from all users.

User List

**PUBLIC**

, user 'user'

| Element     | Description   | Restrictions                             | Syntax                                  |
|-------------|---|--|---|
| <i>user</i> | Login name of a user whose privilege or role you are revoking | Must be a valid authorization identifier | <a href="#">Owner name on page 1488</a> |

Spell the user names in the list exactly as they were spelled in the GRANT statement. You can optionally use quotation marks around each user name in the list to preserve the lettercase. In an ANSI-compliant database, if you do not use quotation

marks to delimit *user*, the name of the user is stored in uppercase letters unless the **ANSIOWNER** environment variable was set to 1 before the database server was initialized.

When you specify login names, you can use the REVOKE statement and the GRANT statement to secure various types of database objects selectively. For examples, see [When to Use REVOKE Before GRANT on page 734](#).

## Role Name

Only the DBA or a user who was granted a role WITH GRANT OPTION can revoke a role or its privileges. Users cannot revoke roles from themselves.

Role Name

*'role' role*

| Element     | Description  | Restrictions  | Syntax                                  |
|-------------|--|---|---|
| <i>role</i> | A role with one of these attributes: <ul style="list-style-type: none"> <li>• Loses an existing privilege or role</li> <li>• Is lost by a user or by another role</li> </ul> | Must exist. If enclosed between quotation marks, <i>role</i> is case sensitive. | <a href="#">Owner name on page 1488</a> |

Immediately after the REVOKE keyword, the name of a *role* specifies a role to be revoked from the user list. After the FROM keyword, however, the name of a *role* specifies a role from which access privilege (or another role) is to be revoked. The same FROM clause can include both *user* and *role* names if no other REVOKE options conflict with the *user* or *role* specifications. Syntax to revoke privileges on a role or from a role are extensions to the ANSI/ISO standard for SQL.

When you include a *role* after the FROM keyword of the REVOKE statement, the specified privilege (or another role) is revoked from that role, but users who have that role retain any privileges or roles that were granted to them individually.

If you enclose *role* between quotation marks, the name is case sensitive and is stored exactly as you typed it. In an ANSI-compliant database, if you do not use quotation marks as delimiters, the *role* is stored in uppercase letters.

When you revoke a role that was granted to a user with the WITH GRANT OPTION keywords, you revoke both the role and the option to grant it.

The following examples show the effects of REVOKE *role*:

- Remove users or remove another role from inclusion in the specified role:

```
REVOKE accounting FROM mary;
REVOKE payroll FROM accounting;
```

- Remove one or more access privileges from a role:

```
REVOKE UPDATE ON employee FROM accounting;
```

When you revoke table-level privileges from a role, you cannot include the RESTRICT or CASCADE keywords.

## Revoking a Default Role

The DBA or the owner of the database can define a *default role* for one or more users or for PUBLIC with the GRANT DEFAULT ROLE statement. Unlike a non-default role, which does not take effect until the SET ROLE statement activates the role, a default role takes effect automatically when the user connects to the database. The default role can specify a set of access privileges for all the users who are granted that default role. Conversely, the REVOKE DEFAULT ROLE statement cancels the current default role as the default role for the specified *user-list*, as in the following program fragment:

```
CREATE ROLE accounting;
GRANT USAGE ON LANGUAGE SPL TO accounting;
GRANT ALL PRIVILEGES ON receivables TO accounting;
GRANT DEFAULT ROLE accounting TO mary;
. . .
REVOKE DEFAULT ROLE FROM mary;
```

The last statement removes from user **mary** any access privileges that they hold only through her default role. In this example, the default role was **accounting**, but because at a given point in time there can be only one default role for an individual user (or for the PUBLIC group), the name of the default role is not specified in the REVOKE DEFAULT ROLE statement. If **mary** issues the SET ROLE DEFAULT statement, it has no effect until they are granted some new default role.

After you execute REVOKE DEFAULT ROLE specifying one or more users or PUBLIC, any privileges that those users held only through the default role are cancelled. (But this statement does not revoke any privileges that were granted to a user individually, or privileges that were granted to a user through another role, or privileges that PUBLIC holds.)

After REVOKE DEFAULT ROLE successfully cancels the default role of *user*, the default role of *user* becomes NULL, and the default role information is removed from the system catalog. (In this context, NULL and NONE are synonyms.)

No warning is issued if REVOKE DEFAULT ROLE specifies a user who has not been granted a default role.

No options besides the *user-list* are valid after the FROM keyword in the REVOKE DEFAULT ROLE statement.

## Revoking the EXTEND Role

The REVOKE EXTEND FROM *user-list* statement cancels the EXTEND role of the specified users. In databases where the IFX\_EXTEND\_ROLE configuration parameter is enabled, revoking this role prevents the specified users from creating or dropping external UDRs. Whether or not a user holds the EXTEND role has no effect on creating or dropping UDRs written in the SPL language.

Only the Database Server Administrator (DBSA), by default user **informix**, can grant the built-in EXTEND role to one or more users or to PUBLIC by issuing the GRANT EXTEND TO *user-list* statement. (Because EXTEND is a built-in role, a user who holds it does not need to activate it with the SET ROLE statement, and the DROP ROLE statement cannot destroy the EXTEND role.)

If the IFX\_EXTEND\_ROLE configuration parameter is set to ON or to 1, users who do not hold the EXTEND role cannot create or drop UDRs that are written in the C or Java™ languages, both of which support shared libraries. The following example revokes the EXTEND role from user **max**:

```
REVOKE EXTEND FROM 'max';
```

This prevents user **max** from creating or dropping external UDRs, even if **max** is the owner of a UDR that he subsequently attempts to drop.

In databases for which this security feature is not needed, the DBSA can disable this restriction on who can create or drop external UDRs by setting the `IFX_EXTEND_ROLE` parameter to `OFF` or to `0` in the `ONCONFIG` file. But whether `IFX_EXTEND_ROLE` is enabled or disabled, users who create or drop external UDRs must also hold the following access privileges:

- Either the Resource privilege or the DBA privilege on the database in which the UDR is registered.
- The Usage privilege on the external programming language in which the UDR is written,

See [Database-level privileges on page 731](#) for information about the Resource privilege. See [Language-Level Privileges on page 607](#) for the syntax of the `GRANT USAGE ON LANGUAGE C` and the `GRANT USAGE ON LANGUAGE JAVA` statements of SQL.

## Revoking privileges granted WITH GRANT OPTION

If you revoke from *user* privileges or a role that you granted using the `WITH GRANT OPTION` keywords, you sever the chain of privileges granted by that *user*.

Thus, when you revoke privileges from users or from a role, you also revoke the same privilege resulting from `GRANT` statements in the following contexts:

- Issued by your grantee
- Allowed because your grantee specified the `WITH GRANT OPTION` clause
- Allowed because subsequent grantees granted the same privilege or role using the `WITH GRANT OPTION` clause

The `WITH GRANT OPTION` clause is only valid in `GRANT` statements that assign privileges to specific users. The grantee cannot be the `PUBLIC` group or a role.

The following examples show the revocation of privileges. Suppose you, as the owner of the table **items**, issue the following statements to grant access privileges to user **mary**:

```
REVOKE ALL ON items FROM PUBLIC;
GRANT SELECT, UPDATE ON items TO mary WITH GRANT OPTION;
```

User **mary** then uses their new privilege to grant users **cathy** and **paul** access to the **items** table:

```
GRANT SELECT, UPDATE ON items TO cathy;
GRANT SELECT ON items TO paul;
```

Later you revoke privileges on the **items** table from user **mary**:

```
REVOKE SELECT, UPDATE ON items FROM mary;
```

This single statement effectively revokes all privileges on the **items** table from users **mary**, **cathy**, and **paul**.

The `CASCADE` keyword has the same effect as this default condition.

## The AS Clause

Without the AS clause, the user who executes the REVOKE statement must be the grantor of the privilege that is being revoked. The DBA or the owner of the object can use the AS clause to specify another user (who must be the grantor of the privilege) as the revoker of the privileges.

For example, if user **falstaff** is the owner of table **CONS\_table**, and has granted

The AS clause provides the only mechanism by which discretionary access privileges can be revoked on a database object whose *owner* is an authorization identifier, such as **informix**, that is not also a valid user account known to the operating system.

For contexts where the AS *revoker* clause is required, rather than optional, see [Revoking the Execute privilege from PUBLIC on page 606](#).

## Effect of CASCADE Keyword on UNDER Privileges

If you revoke the Under privilege on a typed table with the CASCADE option, the Under privilege is removed from the specified user, and any subtables created under the typed table by that user are dropped from the database.

If you revoke the Under privilege on a named ROW type with the CASCADE option when that data type is in use, the REVOKE fails. This exception to the default behavior of the CASCADE option occurs because the database server supports the DROP ROW TYPE statement with the RESTRICT keyword only.

For example, assume that user **jeff** creates a ROW type named **rtype1** and grants the Under privilege on that ROW type to user **mary**. User **mary** now creates a ROW type named **rtype2** under ROW type **rtype1** and grants the Under privilege on ROW type **rtype2** to user **andy**. Then user **andy** creates a ROW type named **rtype3** under ROW type **rtype2**.

If user **jeff** now tries to revoke the Under privilege on ROW type **rtype1** from user **mary** with the CASCADE option, the REVOKE statement fails, because ROW type **rtype2** is still in use by ROW type **rtype3**.

## Controlling the Scope of REVOKE with the RESTRICT Option

The RESTRICT keyword causes the REVOKE statement to fail when any of the following dependencies exist:

- A view depends on a Select privilege that you are attempting to revoke.
- A foreign-key constraint depends on a References privilege that you attempt to revoke.
- You attempt to revoke a privilege from a user who subsequently granted this privilege to another user or to a role.

REVOKE does not fail if it specifies a user who has the right to grant the privilege to others but has not exercised that right. For example, assume that user **clara** specifies WITH GRANT OPTION when they grant the Select privilege on the **customer** table to user **ted**. Further assume that user **ted**, in turn, grants the Select privilege on the **customer** table to user **tania**. The following statement that **clara** issued has no effect, because **ted** has used his authority to grant the Select privilege:

```
REVOKE SELECT ON customer FROM ted RESTRICT;
```

In contrast, if user **ted** does not grant the Select privilege to **tania** or to any other user, the same REVOKE statement succeeds. Even if **ted** does grant the Select privilege to another user, either of the following statements succeeds:

```
REVOKE SELECT ON customer FROM ted CASCADE;
REVOKE SELECT ON customer FROM ted;
```

## Security Administration Options

In conjunction with the GRANT statement, the REVOKE statement supports the discretionary access control (DAC) data security feature of Informix® by specifying which users or roles hold privileges that are required to access the database or objects within the database.

The Security Administration Options of the REVOKE statement, like their counterparts for the GRANT statement, support an additional set of data security features, called label-based access control (LBAC). These features enable Informix® to allow or withhold access to protected data on the basis of a comparing a row security label or column security label that is contained in the data object to the user security label and other credentials that have been granted to the user who is seeking access.

Security Administration Options

DBSECADM Clause<sup>347</sup>

EXEMPTION Clause<sup>348</sup>

SECURITY LABEL Clause<sup>349</sup>

SETSESSIONAUTH Clause<sup>350</sup>

Use of these REVOKE statement security administration options is restricted:

- Only the Database Server Administrator (DBSA), by default user **informix**, can use the REVOKE DBSECADM statement to revoke the DBSECADM role.
- Only a user who holds the DBSECADM role can issue the REVOKE EXEMPTION, REVOKE SECURITY LABEL, or REVOKE SETSESSIONAUTH statements.

## DBSECADM Clause

The REVOKE DBSECADM statement prevents the user to whom the DBSECADM role was granted from issuing DDL statements that can create, alter, rename, or drop security objects, including security policies, security labels, and security components.

346. Informix® extension

347. See [DBSECADM Clause on page 746](#)

348. See [EXEMPTION Clause on page 748](#)

349. See [SECURITY LABEL Clause on page 750](#)

350. See [SETSESSIONAUTH Clause on page 753](#)

DBSECADM Clause

**DBSECADM FROM**

**USER**

*user*

| Element     | Description                              | Restrictions                                   | Syntax                                  |
|-------------|--|--|---|
| <i>user</i> | User from whom the role is to be revoked | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

The DBSECADM role is a built-in role that only the DBSA can revoke. Unlike user-defined roles, whose scope is the database in which the role is created, the scope of the DBSECADM role is all of the databases of the Informix® instance. It is not necessary for DBSA to reissue the REVOKE DBSECADM statement in other databases of the same server.

Only a user who holds the DBSECADM role can issue the following SQL statements that create or modify security objects:

- ALTER SECURITY LABEL COMPONENT
- CREATE SECURITY LABEL
- CREATE SECURITY LABEL COMPONENT
- CREATE SECURITY POLICY
- DROP SECURITY LABEL
- DROP SECURITY LABEL COMPONENT
- DROP SECURITY POLICY
- RENAME SECURITY LABEL
- RENAME SECURITY LABEL COMPONENT
- RENAME SECURITY POLICY

Only a user who holds the DBSECADM role can use the following SQL statements to reference tables that are protected by a security policy:

- ALTER TABLE ... ADD SECURITY POLICY
- ALTER TABLE ... ADD ... IDSSECURITYLABEL [DEFAULT *label*]
- ALTER TABLE ... ADD ... [COLUMN] SECURED WITH
- ALTER TABLE ... DROP SECURITY POLICY
- ALTER TABLE ... MODIFY ... [COLUMN] SECURED WITH
- ALTER TABLE ... MODIFY ... DROP COLUMN SECURITY
- CREATE TABLE ... COLUMN SECURED WITH
- CREATE TABLE ... IDSSECURITYLABEL [DEFAULT *label*]
- CREATE TABLE ... SECURITY POLICY

The following GRANT and REVOKE statements also cannot be issued by a user who does not hold the DBSECADM role:

- GRANT EXEMPTION
- GRANT SECURITY LABEL
- GRANT SETSESSIONAUTH
- REVOKE EXEMPTION
- REVOKE SECURITY LABEL
- REVOKE SETSESSIONAUTH

The USER keyword that can follow the FROM keyword is optional, and has no effect, but any authorization identifier that the DBSA specifies in the REVOKE DBSECADM statement must be the identifier of an individual user, rather than the identifier of a role. The *user* cannot be the DBSA who issues this REVOKE DBSECADM statement.

In the following example, the DBSA cancels the DBSECADM role of user **niccolo**:

```
REVOKE DBSECADM FROM niccolo;
```

If this statement executes successfully, user **niccolo** can no longer perform the operations listed above.

After the DBSECADM role is revoked, only the DBSA can grant it again to the user from whom it was revoked.

## EXEMPTION Clause

The REVOKE EXEMPTION statement modifies the security credentials of the specified user (or list of users) by enabling one or all of the rules of a specified security policy from which the user had been exempt.

EXEMPTION Clause

### EXEMPTION ON RULE

**IDSLBACREADARRAY IDSLBACREADTREE IDSLBACREADSET**

**IDSLBACWRITEARRAY**

**WRITEDOWN WRITEUP**

**IDSLBACWRITESET IDSLBACWRITETREE ALL**

**FOR***policy*

**FROM**

,

**USER**

*user*

| Element       | Description  | Restrictions                                   | Syntax                                  |
|---------------|--|--|---|
| <i>policy</i> | Security policy for which the exemption is revoked | Must exist in the database                     | <a href="#">Identifier on page 1456</a> |
| <i>user</i>   | User to whom the exemption is to be revoked        | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can issue the REVOKE EXEMPTION statement.

## Rules on Which Exemptions Are Revoked

The keyword that follows the ON keyword specifies the predefined access rule of the security policy (whose identifier follows the FOR keyword) for which an exemption is cancelled. The access rule for which exemption is revoked applies when a table that is protected by the specified policy is accessed by a user from whom the exemption is revoked. For descriptions of the predefined rules for read access and for write access that are associated with a security policy, see the section [Rules Associated with a Security Policy on page 325](#).

The following keywords of the REVOKE EXEMPTION statement identify specific **IDSLBACRULES** rules that this statement can apply to formerly exempt users:

- **IDSLBACREADARRAY** applies to the user the **IDSLBACREADARRAY** rule for the specified security policy. For a user with no exemption, this rule requires that each array component of the user security label must be greater than or equal to the corresponding array component of the data row security label.
- **IDSLBACREADSET** applies to the user the **IDSLBACREADSET** rule for the specified security policy. For a user with no exemption, this rule requires that each set component of the user security label must include the set component of the data row security label
- **IDSLBACREADTREE** applies to the user the **IDSLBACREADTREE** rule for the specified security policy. For a user with no exemption, this rule requires that each tree component of the user security label must include at least one of the elements in the tree component of the data row security label, or else an ancestor of one such element.
- **IDSLBACWRITEARRAY WRITEDOWN** exempts the user from one aspect of the **IDSLBACWRITEARRAY** rule for the specified security policy. The user who loses this exemption cannot write to a row protected by a label that includes an array component level below the level in the label of the user.
- **IDSLBACWRITEARRAY WRITEUP** exempts the user from one aspect of the **IDSLBACWRITEARRAY** rule for the specified security policy. The user who loses this exemption cannot write to a row protected by a label that includes an array component level above the level in the label of the user.
- **IDSLBACWRITEARRAY** (with no **WRITEDOWN** or **WRITEUP** keyword) applies to the user the **IDSLBACWRITEARRAY** rule for the specified security policy. The user who loses this exemption cannot write to a row whose array component level is above or below the level in the label of the user. .

- IDSLBACWRITESET applies to the user the **IDSLBACWRITESET** rule for the specified security policy. For a user with no exemption, that rule requires that each set component of the user security label must include the set component of the data row security label
- IDSLBACWRITETREE applies to the user the **IDSLBACWRITETREE** rule for the specified security policy. For a user with no exemption, that rule requires that each tree component of the user security label must include at least one of the elements in the tree component of the data row security label, or the ancestor of one such element.
- ALL revokes an exemption from all **IDSLBACRULES** rules for the specified security policy.

In the following example, DBSECADM revokes an exemption from all of the rules of the **MegaCorp** security policy from users **manoj** and **sam**:

```
REVOKE EXEMPTION ON RULE ALL FOR MegaCorp FROM manoj, sam;
```

## Security Policies and Grantees of Exemptions

An exemption applies only to the rules of a single security policy, whose name follows the FOR keyword. Because a protected table can have multiple security labels, but no more than one security policy, revocation of an exemption can prevent a user with insufficient security credentials from accessing data in tables that are protected by the specified security policy.

The REVOKE EXEMPTION statement fails with an error if the specified policy does not exist in the database.

The USER keyword that can follow the FROM keyword is optional, and has no effect, but any authorization identifier specified in the REVOKE EXEMPTION statement must be the identifier of an individual user, rather than the identifier of a role. This *user* cannot be the DBSECADM who issues the same REVOKE EXEMPTION statement.

In the following example, DBSECADM revokes an exemption from user **lynette** for rule **IDSLBACREADARRAY** of the **MegaCorp** security policy:

```
REVOKE EXEMPTION ON RULE IDSLBACREADARRAY FOR MegaCorp FROM lynette;
```

This exemption restores the read access rules for all array components for subsequent read operations that user **lynette** attempts on tables protected by security labels of the specified policy.

When the REVOKE EXEMPTION statement successfully cancels an exemption of a user, the database server updates the **syssecpolicyexemptions** table of the system catalog to unregister the revoked exemption (or multiple exemptions, if several users are listed after the FROM keyword).

## SECURITY LABEL Clause

The REVOKE SECURITY LABEL statement cancels a security label (or all the security labels of a specified security policy) held by one or more users.

SECURITY LABEL Clause

**SECURITY LABEL***policy*.

*label* \*

**FROM**

,

**USER**

*user*

**FOR ALL ACCESS**

**FOR READ ACCESS**

**FOR WRITE ACCESS**

| Element       | Description                              | Restrictions   | Syntax                                  |
|---------------|--|--|---|
| <i>label</i>  | Name of an existing security label       | Must exist as a label for the specified security <i>policy</i> | <a href="#">Identifier on page 1456</a> |
| <i>policy</i> | The security policy of this <i>label</i> | Must already exist in the database                             | <a href="#">Identifier on page 1456</a> |
| <i>user</i>   | User from whom the label is revoked      | Must be the authorization identifier of a user                 | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can issue the REVOKE SECURITY LABEL statement.

A security label is a database object that is always associated with a security policy. That policy defines the set of valid security components that make up the security label. The label stores a set of one or more values for each component of the security policy.

The DBSECADM can associate a security label with the following entities:

- A column of a database table, which a *column security label* can protect
- A row of a database table, which a *row security label* can protect
- A user, whose *user security label* (and any exemptions from rules of the security policy that have been granted to the user) are called the *security credentials* of the user.

When a user who holds a security label for a specific security policy attempts to access a row that is protected by a row security label of the same security policy, the database server compares the sets of values in the user security label and in the row security label in determining whether or not the user should be allowed to access the data. Similarly, LBAC takes into account the user security label and the column security label in determining whether or not the credentials of the user should be allowed to access a protected column.

The GRANT SECURITY LABEL and REVOKE SECURITY LABEL statements enable DBSECADM to control the association of a user with a label. (Data values in a protected table are associated with a row security label or with a column security label by options to the CREATE TABLE or ALTER TABLE statements that only DBSECADM can execute, rather than by the GRANT SECURITY LABEL statement.)

Immediately following the LABEL keyword, the asterisk ( \* ) symbol in the *policy.\** specification instructs the database server to revoke every security label of the *policy*. If instead of an asterisk you specify *policy.label*, that *label* must be the name of a security label of the specified *policy*. In this case, if the statement is successful, only that security label is revoked from the user list.

The USER keyword that can follow the FROM keyword is optional, but any authorization identifier specified in the REVOKE SECURITY LABEL statement must be the identifier of an individual user, rather than the identifier of a role.

---

[CREATE SECURITY POLICY statement on page 322](#)

## Access Specifications

The list of users from whom the security label is revoked can optionally be followed by keywords that specify the type of access to data that the security policy of the label protects

- FOR WRITE ACCESS

These keywords restrict the label to the write access rules of **IDSLBACRULES**, namely **IDLSBACWRITEARRAY**, **IDLSBACWRITESET**, and **IDLSBACWRITETREE**.

- FOR READ ACCESS

These keywords restrict the label to the read access rules of **IDSLBACRULES**, namely **IDLSBACWREADARRAY**, **IDLSBACREADSET**, and **IDLSBACREADTREE**.

- FOR ALL ACCESS

These keywords apply the label to all of the read and write access rules that are listed above. If the REVOKE SECURITY LABEL statement includes no FOR ... ACCESS specification, this option takes effect as the default.

For more information about these **IDSLBACRULES** rules for label-based read and write access, see [Rules Associated with a Security Policy on page 325](#). For information about exemptions to these rules that can be granted for a specific security policy, see [Rules on Which Exemptions Are Revoked on page 749](#).

## Examples of Revoking User Security Labels

The following three statements create three security label components called **level**, **compartments**, and **groups** respectively:

```
CREATE SECURITY LABEL COMPONENT
  level ARRAY ['TS', 'S', 'C', 'U'];
```

```
CREATE SECURITY LABEL COMPONENT
  compartments SET {'A','B','C','D'};

CREATE SECURITY LABEL COMPONENT
  groups TREE ('G1' ROOT,
              'G2' UNDER ROOT,
              'G3' UNDER ROOT);
```

The following statement creates a security policy called **secPolicy** based on the three components above:

```
CREATE SECURITY POLICY secPolicy COMPONENTS
  level, compartments, groups;
```

The following statement creates a security label called **secLabel1**:

```
CREATE SECURITY LABEL secPolicy.secLabel1
  COMPONENT level 'S',
  COMPONENT compartments 'A', 'B',
  COMPONENT groups 'G2';
```

The following statement grants this security label for read access to user **sam**:

```
GRANT SECURITY LABEL secPolicy.secLabel1
  TO sam FOR READ ACCESS;
```

The following statement revokes the security label for read access from user **sam**.

```
REVOKE SECURITY LABEL secPolicy.secLabel1
  FROM sam FOR READ ACCESS;
```

When the REVOKE SECURITY LABEL statement successfully cancels a security label that was held by a user, the database server updates the **sysseclabelauth** table of the system catalog to remove the user from the list of those who hold that security label.

## SETSESSIONAUTH Clause

The REVOKE SETSESSIONAUTH statement revokes the SETSESSIONAUTH privilege from one or more users or roles.

The SETSESSIONAUTH privilege allows users who also hold the DBA privilege to use the SET SESSION AUTHORIZATION statement to set the session authorization to one of a set of specified users.

**Syntax**

SETSESSIONAUTH Clause

**SETSESSIONAUTH ON****PUBLIC**

,

**USER***user**"user"***FROM**

,

**USER***user**"user"***ROLE***role**"role"*

| Element     | Description  | Restrictions                                   | Syntax                                  |
|-------------|--|--|---|
| <i>role</i> | Role from which the privilege is to be revoked   | Must be the authorization identifier of a role | <a href="#">Owner name on page 1488</a> |
| <i>user</i> | After the FROM keyword, a user from whom the privilege is to be revoked. After the ON keyword, a user whose identity the grantee can specify in the SET AUTHORIZATION statement. | Must be the authorization identifier of a user | <a href="#">Owner name on page 1488</a> |

Only a user who holds the DBSECADM role can revoke the SETSESSIONAUTH privilege.

The user or PUBLIC specification that follows the ON keyword specifies whose identity the grantee of the SETSESSIONAUTH privilege is no longer able to assume while using the SET SESSION AUTHORIZATION statement. This can be a user or PUBLIC, but not a role. If PUBLIC is specified, then the grantee of the privilege no longer has the ability to assume the identity of an arbitrary database user.

The USER and ROLE keywords that can follow the FROM keyword are optional. Neither the *user* nor the *role* can be the holder of the DBSECADM role who issues the REVOKE SETSESSIONAUTH statement. The FROM clause cannot specify PUBLIC.

**Examples of the REVOKE SETSESSIONAUTH statement**

Suppose that GRANT SETSESSIONAUTH statements issued by a user who holds the DBSECADM role had made the following assignments of the SETSESSIONAUTH privilege in the current database:

```
GRANT SETSESSIONAUTH ON lynette, manoj TO sam;
GRANT SETSESSIONAUTH ON PUBLIC TO lynette;
```

- The first example above enables user **sam** to set the session authorization to users **lynette** and **manoj**.
- The second example enables user **lynette** to set the session authorization to the PUBLIC group, or to set it to the authorization identifier of any user (but not to any role).

Both the SETSESSIONAUTH privilege and the DBA privilege are required to execute the SET AUTHORIZATION statement. If user **sam** holds the DBA and SETSESSIONAUTH privileges, they could issue the following statement:

```
SET SESSION AUTHORIZATION TO 'lynette';
```

Now **sam** has assumed the identity of user **lynette**, including the discretionary access control (DAC) and label-based access control (LBAC) credentials of user **lynette**. User **sam** can also use this SET SESSION AUTHORIZATION statement in an API that supports Informix® trusted contexts to switch the user ID on a trusted connection. Because a previous example enabled user **lynette** to set the session authorization to any user, that is now a capability of **sam** during this session, where **sam** has assumed the identity of **lynette**.

The following example, however, revokes from user **sam** the ability to set the session authorization to users **lynette** and **manoj**:

```
REVOKE SETSESSIONAUTH ON lynette, manoj FROM sam;
```

Now the previous SET SESSION AUTHORIZATION example would fail, because this REVOKE SETSESSIONAUTH statement excludes **lynette** and **manoj** from the authorization identifiers that user **sam** can assume.

The next example revokes from user **lynette** the ability to set the session authorization to PUBLIC:

```
REVOKE SETSESSIONAUTH ON PUBLIC FROM USER lynette;
```

The PUBLIC scope of the SETSESSIONAUTH privilege that this example revokes had enabled user **lynette** (and user **sam** under the login name of **lynette** in the previous SET SESSION AUTHORIZATION example) to assume the access privileges and security credentials of any user specified by **lynette** in the SET SESSION AUTHORIZATION statement.

### Delimiting user and role identifiers

If you enclose *user* or *role* in double ( " ) or single ( ' ) quotation marks, the identifier is case sensitive, and the database server stores it in the system catalog exactly as you enter it in the REVOKE statement. The following REVOKE statement has the same effect as the previous example for user **lynette** whose authorization identifier includes no uppercase characters:

```
REVOKE SETSESSIONAUTH ON PUBLIC FROM USER "lynette";
```

Suppose that another user also holds the SETSESSIONAUTH privilege on the PUBLIC group, and that their authorization identifier is **Lynette**, with an initial uppercase character. Because their authorization identifier does not match the case sensitive FROM USER "lynette" specification, this example has no effect on their SETSESSIONAUTH privilege on the identifier of any user in the PUBLIC group. The undelimited FROM lynette previous example, however, revokes SETSESSIONAUTH from both **lynette** and **Lynette**.

### REVOKE FRAGMENT statement

Use the REVOKE FRAGMENT statement to revoke from one or more users or roles the Insert, Update, or Delete fragment-level privileges that were granted on individual fragments of a table that has been fragmented by expression. This statement is an extension to the ANSI/ISO standard for SQL.

**Syntax****REVOKE FRAGMENT**Fragment-Level Privileges<sup>351</sup>**ON** *table*(  
, *fragment*  
)**FROM****PUBLIC**, *user* '*user*' *role* '*role*'**AS***revoker* '*revoker*'

| Element         | Description  | Restrictions                                     | Syntax  |
|-----------------|--|--|---|
| <i>fragment</i> | Name of a fragment or the dbspace that stores one fragment. Default is all fragments of <i>table</i> . | Must exist and must store a fragment of table    | <a href="#">Identifier on page 1456</a>           |
| <i>revoker</i>  | User (who is not executing this statement) who was grantor of privileges to be revoked                 | Must be grantor of the fragment-level privileges | <a href="#">Owner name on page 1488</a>           |
| <i>role</i>     | Role from which privileges are to be revoked   | Must exist in the database                       | <a href="#">Owner name on page 1488</a>           |
| <i>table</i>    | Fragmented table whose fragment-level privileges are to be revoked                                     | Must exist and must be fragmented by expression  | <a href="#">Database Object Name on page 1450</a> |
| <i>user</i>     | User from whom privileges are to be revoked  | Must be a valid authorization identifier         | <a href="#">Owner name on page 1488</a>           |

**Usage**

The REVOKE FRAGMENT statement is a special case of the REVOKE statement for assigning privileges on table fragments. Use the REVOKE FRAGMENT statement to revoke the Insert, Update, or Delete privilege on one or more table fragments from one or more users or roles. The DBA can use this statement to revoke privileges on a fragment whose owner is another user.

The REVOKE FRAGMENT statement is valid only for tables that are fragmented by an expression-based distribution scheme. For an explanation of this fragmentation strategy, see [Expression Distribution Scheme on page 35](#).

**Related reference**[GRANT FRAGMENT statement on page 631](#)[GRANT statement on page 592](#)[REVOKE statement on page 727](#)

351. See [Fragment-Level Privileges on page 757](#)

## Specifying Fragments

If you specify no *fragment*, the privileges are revoked for all fragments of *table*. You can specify one fragment or a comma-separated list of fragments enclosed between parentheses that immediately follow the *ON table* specification.

Each *fragment* must be referenced by its name. If you did not declare an explicit identifier when you created the fragment, its name defaults to the name of the dbspace in which it resides.

After a dbspace is renamed successfully by the *onspaces* utility, only the new name is valid. Informix® automatically updates existing fragmentation strategies in the system catalog to substitute the new dbspace name, but you must specify the new name in *REVOKE FRAGMENT* statement to reference a fragment whose default name is the name of a renamed dbspace.

## The FROM Clause

You can specify the *PUBLIC* keyword to revoke the specified fragment-level privileges from *PUBLIC*, thereby revoking the privileges from all users to whom the privileges have not been explicitly granted, or who do not hold a role through which they have received the privileges.

If you enclose *user* or *role* in quotation marks, the name is case sensitive and is stored exactly as you typed it. In an ANSI-compliant database, if you do not use quotation marks around *user* or around *role*, the name is stored in uppercase letters by default, although you can set the *ANSIOWNER* environment variable to preserve lowercase characters in *owner* specifications.

When you include a *role* in the *FROM* clause of *REVOKE FRAGMENT*, the specified fragment privilege is revoked from that role. Users who have that role, however, retain any fragment privileges they hold that were granted to them individually or to *PUBLIC*.

## Fragment-Level Privileges

The keyword or keywords that follow the *FRAGMENT* keyword specify *fragment-level privileges*, which are a logical subset of table-level privileges:

Fragment-Level Privileges

**ALL**

**, INSERT DELETE UPDATE**

You can revoke fragment-level privileges individually or in combination. The following keywords specify the fragment-level privileges that you can revoke.

**Keyword**

**Effect**

**INSERT**

Prevents the user from inserting rows in the fragment

**DELETE**

Prevents the user from deleting rows in the fragment

**UPDATE**

Prevents the user from updating rows in the fragment

**ALL**

Cancels Insert, Delete, and Update privileges on a fragment

If you specify the ALL keyword in a REVOKE FRAGMENT statement, the specified users and roles lose all fragment-level privileges that they currently possess on the specified fragments. For example, assume that a user currently has the Update privilege on one fragment of a table. If you use the ALL keyword to revoke all current privileges on this fragment from this user, the user loses the Update privilege that they had on this fragment.

For the distinction between fragment-level and table-level privileges, see the sections [Definition of Fragment-Level Authorization on page 632](#) and [Effect of Fragment-Level Authorization in Statement Validation on page 633](#).

## The AS Clause

Without the AS clause, the user who executes the REVOKE statement must be a grantor of the privilege that is being revoked. The DBA or the owner of the fragment can use the AS clause to specify another user (who must be the grantor of the privilege) as the revoker of privileges on a fragment.

The AS clause provides the only mechanism by which privileges can be revoked on a fragment whose *owner* is an authorization identifier that is not a valid user account known to the operating system.

## Examples of the REVOKE FRAGMENT Statement

Examples that follow are based on the **customer** table. They all assume that the **customer** table is fragmented by expression into three fragments named **part1**, **part2**, and **part3**.

### Revoking Privileges on One Fragment

#### About this task

The following statement revokes the Update privilege on the fragment of the **customer** table in **part1** from user **ed**:

```
REVOKE FRAGMENT UPDATE ON customer (part1) FROM ed;
```

The following statement revokes the Update and Insert privileges on the fragment of the **customer** table in **part1** from user **susan**:

```
REVOKE FRAGMENT UPDATE, INSERT ON customer (part1) FROM susan;
```

The following statement revokes all privileges currently granted to user **harry** on the fragment of the **customer** table in **part1**:

```
REVOKE FRAGMENT ALL ON customer (part1) FROM harry;
```

## Revoking Privileges on More Than One Fragment

### About this task

The following statement revokes all privileges currently granted to user **millie** on the fragments of the **customer** table in **part1** and **part2**:

```
REVOKE FRAGMENT ALL ON customer (part1, part2) FROM millie;
```

## Revoking Privileges from More Than One User

### About this task

The following statement revokes all privileges currently granted to users **jerome** and **hilda** on the fragment of the **customer** table in **part3**:

```
REVOKE FRAGMENT ALL ON customer (part3) FROM jerome, hilda;
```

## Revoking Privileges Without Specifying Fragments

### About this task

The following statement revokes all current privileges from user **mel** on all fragments for which this user currently has privileges:

```
REVOKE FRAGMENT ALL ON customer FROM mel;
```

### Example

### Related Statements

Related statements: [GRANT FRAGMENT statement on page 631](#) and [REVOKE statement on page 727](#)

For a discussion of fragment-level and table-level privileges, see the section [Fragment-Level Privileges on page 632](#). See also the *Informix® Database Design and Implementation Guide*.

## ROLLBACK WORK statement

Use the ROLLBACK WORK statement to cancel all or part of the current transaction intentionally, undoing any changes that occurred since the beginning of the transaction, or between the ROLLBACK WORK statement and a specified or default savepoint.

### Syntax

#### **ROLLBACKWORK**

**TO SAVEPOINT***savepoint*

| Element          | Description   | Restrictions                           | Syntax                                  |
|------------------|---|--|---|
| <i>savepoint</i> | Name of the savepoint that delimits the scope of the rollback | Must exist in the current transaction. | <a href="#">Identifier on page 1456</a> |

## Usage

The ROLLBACK WORK statement is valid only in databases that support transaction logging. Only logged operations can be rolled back. Use ROLLBACK WORK only at the end of a multistatement operation.

The ROLLBACK WORK statement restores the database to its state that existed before the cancelled portion of the transaction began.

In a database that is not ANSI-compliant, the BEGIN WORK statement starts a transaction. You can end a transaction with the COMMIT WORK statement or cancel all or part of the transaction with the ROLLBACK WORK statement. If you issue the ROLLBACK WORK statement when no transaction is pending in a database that is not ANSI-compliant, Informix® issues an error.

In an ANSI-compliant database, multistatement transactions are implicit. You do not need to mark the beginning of a transaction with the BEGIN WORK statement. You only need to mark the end of each transaction with a COMMIT WORK statement or cancel the transaction with a ROLLBACK WORK statement. If you issue the ROLLBACK WORK statement when no transaction is pending, the statement is accepted but has no effect.

The ROLLBACK WORK statement restores the database to the state that existed before the cancelled portion of the transaction began. Unless you include the TO SAVEPOINT keywords, ROLLBACK WORK cancels the entire transaction.

The ROLLBACK WORK statement releases all row and table locks that the cancelled transaction holds.

In Informix® ESQL/C and SPL, the ROLLBACK WORK statement closes all open cursors except those that are declared as *hold cursors* by including the WITH HOLD keywords. Hold cursors remain open after a transaction is committed or rolled back.

If you use the ROLLBACK WORK statement within an SPL routine that the WHENEVER statement calls, specify WHENEVER SQLERROR CONTINUE and WHENEVER SQLWARNING CONTINUE before the ROLLBACK WORK statement. This step prevents the program from looping if the ROLLBACK WORK statement encounters an error or a warning.

If a program terminates abnormally, the current transaction is implicitly rolled back.

---

### Related reference

[COMMIT WORK statement on page 184](#)

[LOCK TABLE statement on page 659](#)

[BEGIN WORK statement on page 176](#)

[UNLOCK TABLE statement on page 1036](#)

[RELEASE SAVEPOINT statement on page 708](#)

## WORK Keyword

The WORK keyword is optional in a ROLLBACK WORK statement. The following two statements are equivalent:

```
ROLLBACK;
```

```
ROLLBACK WORK;
```

## TO SAVEPOINT Clause

The optional `TO SAVEPOINT` clause specifies a partial rollback. This clause can restrict the scope of the rollback to the operations of the current savepoint level between the `ROLLBACK` statement and the specified or default savepoint. If no *savepoint* is specified after the `SAVEPOINT` keyword, the rollback ends at the most recently set savepoint within the current savepoint level.

When the `ROLLBACK WORK TO SAVEPOINT` statement executes successfully, any effects of DDL and DML statements that preceded the savepoint persist, but changes to the schema of the database or to its data values by statements that follow the savepoint are cancelled. Any locks acquired by these cancelled statements persist, but are released at the end of the transaction. Any savepoints between the specified savepoint and the `ROLLBACK` statement are destroyed, but the savepoint referenced by the `ROLLBACK` statement (and any savepoints that precede the referenced savepoint) continue to exist. Program control passes to the statement that immediately follows the `ROLLBACK` statement.

If the `TO SAVEPOINT` clause is omitted, the `ROLLBACK` statement rolls back the entire transaction, and all savepoints within the transaction are released.

If the specified *savepoint* does not exist in the current transaction, the database server issues an exception.

The `TO SAVEPOINT` clause is not valid in a `ROLLBACK` statement that immediately follows the `TRUNCATE` statement. In this case, the attempted partial rollback fails with an error. To cancel uncommitted changes that the `TRUNCATE` statement has made to a table, issue `ROLLBACK WORK` as the next statement, but with no `TO SAVEPOINT` clause.

The following program fragment rolls back part of the current transaction to a savepoint called **pt109**:

```
BEGIN WORK;
DROP TABLE tab03;
CREATE TABLE tab03 (col1 CHAR(24), col2 DATE);
SAVEPOINT pt108;
...
INSERT INTO tab03 VALUES ('First day of autumn', '09/23/2012');
SAVEPOINT pt109;
...
DELETE FROM tab03 WHERE col2 < '12/09/2009';
SAVEPOINT pt110;
...
ROLLBACK TO SAVEPOINT pt109;
```

The `ROLLBACK` statement in this example has these effects:

- Cancels the DML operation that deleted any rows with **col2** date values earlier than December 9, 2009.
- Releases savepoint **pt110**, and any other savepoints between **pt109** and the `ROLLBACK` statement.
- Cancels any other changes to the database by operations that follow savepoint **pt109** in the lexical order of SQL statements within the current transaction.

Savepoint **pt108**, however, is not released, because it was set earlier than **pt109** in the transaction. Not cancelled by this partial rollback are the effects of any uncommitted DDL or DML operations of the transaction before savepoint **pt109** was set, including the creation of table **tab03** and the `INSERT` operation that added a row to that table. These persist after the

partial rollback, pending the possibility of another partial rollback to a savepoint, and the eventual commitment or rollback of the entire transaction.

## Related Statements

For a discussion of transactions and ROLLBACK WORK, see the *Informix® Guide to SQL: Tutorial*.

## SAVE EXTERNAL DIRECTIVES statement

Use the SAVE EXTERNAL DIRECTIVES statement to create external optimizer directives for a specified query, and save the directives in the database. These directives are applied automatically to subsequent instances of the same query. This statement is an extension to the ANSI/ISO standard for SQL.

### Syntax

#### SAVE EXTERNAL DIRECTIVES

*directive*

#### ACTIVE INACTIVE TEST ONLY

FOR*query*

| Element          | Description                                | Restrictions  | Syntax  |
|------------------|--|---|---|
| <i>directive</i> | Optimizer directive valid for <i>query</i> | Must be valid for the query and delimited by comment indicators | <a href="#">Optimizer Directives on page 1472</a> |
| <i>query</i>     | Text of a valid SELECT statement           | NULL string is not valid  | <a href="#">SELECT statement on page 768</a>      |

### Usage

SAVE EXTERNAL DIRECTIVES associates one or more optimizer directives with a query, and stores a record of this association in the **sysdirectives** system catalog table, for subsequent use with queries that match the specified query string. This statement establishes an association between the list of optimizer directives and the text of a query, but it does not execute the specified query.

If the SAVE EXTERNAL DIRECTIVES statement specifies more than one optimizer directive, use the blank character (ASCII 32) as the separator between consecutive directives, as in the following example:

```
SAVE EXTERNAL DIRECTIVES /** USE_INDEX */ /** ORDERED */ ACTIVE FOR
  SELECT * FROM systables;
```

Unlike in a query, comma ( , ) is not a valid separator in the directives list of SAVE EXTERNAL DIRECTIVES statements.

Only the DBA or user **informix** can execute SAVE EXTERNAL DIRECTIVES. Optimizer directives that it stores in the database are called *external directives*.

**Related reference**

[SET STATEMENT CACHE statement on page 999](#)

[Optimizer Directives on page 1472](#)

## External optimizer directives

External directives that the `SAVE EXTERNAL DIRECTIVES` statement associates with the text of a query can improve performance in some queries for which the default behavior of the query optimizer is not satisfactory.

External optimizer directives are similar to inline optimizer directives that are embedded within a query. However, unlike inline directives, external directives can be applied without revising or recompiling existing applications.

## Enabling or disabling external directives for a session

Informix® ignores external directives if the `EXT_DIRECTIVES` parameter is set to `0` in the configuration file or the `EXTDIRECTIVES` keyword in the `SET ENVIRONMENT` statement is set to `0`, `OFF`, or `off` during a session.

In addition, the client system can disable external directives for its current session when the `IFX_EXTDIRECTIVES` environment variable is set to `0`.

The following table shows whether external directives are disabled (OFF) or enabled (ON) for various combinations of valid `IFX_EXTDIRECTIVES` settings on the client system and valid `EXT_DIRECTIVES` configuration parameter settings on Informix®:

**Table 11. Combinations of IFX\_DIRECTIVES settings and EXT\_DIRECTIVES configuration parameter settings**

| <b>IFX_EXTDIRECTIVES setting on client system</b> | <b>EXT_DIRECTIVES = 0</b> | <b>EXT_DIRECTIVES = 1</b> | <b>EXT_DIRECTIVES = 2</b> |
|---|---------------------------|---------------------------|---------------------------|
| IFX_EXTDIRECTIVES not set                         | OFF                       | OFF                       | ON                        |
| IFX_EXTDIRECTIVES = 1                             | OFF                       | ON                        | ON                        |
| IFX_EXTDIRECTIVES = 0                             | OFF                       | OFF                       | OFF                       |

If `EXT_DIRECTIVES` is set to `1` or `2` when the database server is initialized, then the server is enabled for external directives. Individual sessions can enable or disable external directives by setting `IFX_EXTDIRECTIVES`, as the table shows. Any settings other than `1` or `2` are interpreted as zero, disabling this feature.

When external directives are enabled, the status of individual external directives is specified by the `ACTIVE`, `INACTIVE`, or `TEST ONLY` keywords. (But only queries on which directives are effective can benefit from external directives.)

You can also use the `EXTDIRECTIVES` option of the `SET ENVIRONMENT` statement to enable or disable external directives during a session. What you specify using the `EXTDIRECTIVES` option overwrites the external directive value that is specified in the `EXT_DIRECTIVES` configuration parameter in the `ONCONFIG` file.

To overwrite the value for enabling or disabling the external directive in the ONCONFIG file and:

- To enable the external directives during a session, specify `1`, `on`, or `ON` as the value for SET ENVIRONMENT EXTDIRECTIVES.
- To disable the external directives during a session, specify `0`, `off`, or `OFF` as the value for SET ENVIRONMENT EXTDIRECTIVES.

To enable the default values specified in the EXT\_DIRECTIVES configuration parameter and in the client-side IFX\_EXTDIRECTIVES environment variable during a session, specify DEFAULT as the value for the EXTDIRECTIVES option of the SET ENVIRONMENT statement.

For more information on using the EXTDIRECTIVES option of the SET ENVIRONMENT statement, see [SET ENVIRONMENT statement on page 900](#).

## The directive Specification

Each *directive* specification in the SAVE EXTERNAL DIRECTIVES statement must follow the syntax of the Optimizer Directives segment, as described in [Optimizer Directives on page 1472](#), except that if you specify more than one directive, you must separate them in the directives list by a blank character, rather than by a comma ( , ) symbol, as in the following example:

```
SAVE EXTERNAL DIRECTIVES /*+ AVOID_INDEX (table1 index1)*/ /*+ FULL(table1) */
ACTIVE FOR
SELECT /*+ INDEX( table1 index1 ) */ col1, col2
FROM table1, table2 WHERE table1.col1 = table2.col1;
```

This example associates AVOID\_INDEX and FULL directives with the specified query. The inline INDEX directive is ignored by the query optimizer when the external directives are applied to a query that matches the SELECT statement.

## The ACTIVE, INACTIVE, and TEST ONLY Keywords

You must include one of the ACTIVE, INACTIVE, or TEST ONLY keyword options to enable, disable, or restrict the scope of external directives:

- If external directives are enabled, the ACTIVE keyword applies the list of directives to any subsequent query that matches the *query* string.
- The INACTIVE keyword causes Informix® to ignore the directive. (It is associated with the query in **sysdirectives**, but it is dormant, with no effect.)
- If external directives are enabled, the TEST ONLY keywords apply the directives only to matching queries that the DBA or user **informix** executes. Queries by any other users cannot use TEST ONLY external directives.

An INACTIVE directive has no effect unless the DBA or user **informix** changes the **sysdirectives.active** system catalog column value from zero (INACTIVE) to one (ACTIVE) or two (TEST ONLY) for that directive. External directives do not have SQL identifiers, but the DBA can reference the **sysdirectives.id** column in an UPDATE statement to specify which external directive to update.

Alternatively, the DBA or user **informix** can delete an INACTIVE or TEST ONLY row from **sysdirectives** and use the SET EXTERNAL DIRECTIVES statement to redefine the deleted directive, but now specifying the ACTIVE keyword. This can give other users access to TEST ONLY directives that the DBA has validated.

## The query Specification

The *query* specification that follows the FOR keyword in SAVE EXTERNAL DIRECTIVES must specify the syntax of a valid SELECT statement, as described in [SELECT statement on page 768](#). If the *query* text also includes any inline optimizer directives, the inline directives are ignored when external directives are applied to the query.

When external directives are enabled and the **sysdirectives** system catalog table is not empty, the database server compares every query with the *query* text of every ACTIVE external directive, and for queries executed by the DBA or user **informix**, with every TEST ONLY external directive. If an external directive has been applied to a query, output from the SET EXPLAIN statement indicates EXTERNAL DIRECTIVES IN EFFECT for that query.

The purpose of external directives is to improve the performance of queries that match the *query* string, but the use of such directives can potentially slow other queries, if the query optimizer must compare the *query* strings of a large number of active external directives with the text of every SELECT statement. For this reason, recommends that the DBA not allow the **sysdirectives** table to accumulate more than a few ACTIVE rows. (Another way to avoid unintended performance impact on other queries is to disable this feature.)

If more than one SET EXTERNAL DIRECTIVES statements associate active external directives with the same query, the effect is unpredictable, because the optimizer uses the first sysdirectives row whose *query* string matches the query.

### Related Statements

For information about optimizer directives and their syntax, see the segment Optimizer Directives in [Optimizer Directives on page 1472](#).

For information about the **sysdirectives** table and the **IFX\_EXTDIRECTIVES** environment variable, see the *Informix® Guide to SQL: Reference*.

## SAVEPOINT statement

Use the SAVEPOINT statement to declare the name of a new savepoint within the current SQL transaction, and to set the position of the new savepoint within the lexical order of SQL statements within the transaction. The SAVEPOINT statement is compliant with the ANSI/ISO standard for SQL.

### Syntax

```
SAVEPOINT savepoint
352UNIQUE
```

352. Informix® extension

| Element          | Description                              | Restrictions   | Syntax                                  |
|------------------|--|--|---|
| <i>savepoint</i> | Name declared here for the new savepoint | Cannot be the name of an existing unique savepoint in the same savepoint level | <a href="#">Identifier on page 1456</a> |

## Usage

You can use the SAVEPOINT statement in SQL transactions to support error handling with DB-Access and in SPL, C, and Java™ routines. You can define savepoint to partition a single complex transaction into smaller logical subsets of its component SQL statements. Within that transaction, the subset of statements that follow each savepoint can be rolled back more efficiently than if you had used multiple COMMIT WORK and ROLLBACK WORK statements in multiple transactions.

The SAVEPOINT statement sets the specified savepoint at the current position in the lexical order of statements within the current transaction. After the SAVEPOINT statement executes successfully, subsequent ROLLBACK TO SAVEPOINT statements that reference this savepoint can cancel any uncommitted changes to the database from logged DML or DDL operations in the current transaction that follow the new savepoint but precede the ROLLBACK TO SAVEPOINT statement.

If an existing savepoint in the same transaction has the same name that the SAVEPOINT statement specifies, the existing savepoint is destroyed, unless one of the following conditions is true:

- The existing savepoint was set in a different savepoint level.
- The existing savepoint name was declared with the UNIQUE keyword option. In this case, the SAVEPOINT statement fails with an error, unless the existing UNIQUE savepoint was set in a different savepoint level.

Destroying a savepoint to reuse its name for another savepoint is not the same as releasing the savepoint. Reusing a savepoint name destroys only one savepoint. Releasing a savepoint with the RELEASE SAVEPOINT statement releases the specified savepoint and all savepoints that have been subsequently set.

## The UNIQUE option

This optional keyword specifies that the application does not intend to reuse the name of this savepoint in another SAVEPOINT statement while this savepoint is active within the current savepoint level.

If a savepoint already exists that was set with the same name and with the UNIQUE keyword within the current savepoint level, the SAVEPOINT statement fails with an error, and the existing savepoint is not destroyed.

## Savepoint levels

Informix® supports the construct of nested savepoint levels. A single SQL transaction can have multiple savepoint levels. New savepoint levels are automatically created for the duration of execution of an SPL routine or an external UDR. Recursive calls to the same SPL routine or UDR also increment the savepoint level of the current transaction.

A savepoint level ends when the UDR in which it was created finishes execution. When a savepoint level ends, all savepoints within it are automatically released. Any DDL or DML modifications are inherited by the parent savepoint level (that is, by the savepoint level within which the one that just ended was created), and are subject to any savepoint-related statements that are issued against the parent savepoint level.

The following rules apply to actions within a savepoint level:

- Savepoints can only be referenced within the savepoint level in which they are established. You cannot release, destroy, or roll back to a savepoint established outside of the current savepoint level.
- The uniqueness of savepoint names is only enforced within the current savepoint level. The names of savepoints that are active in other savepoint levels can be reused in the current savepoint level without affecting those savepoints in other savepoint levels.

### Savepoints in distributed SQL transactions

Savepoints are valid in cross-database distributed SQL transactions of a single Informix® instance that supports transactions if all of the participating databases support transaction logging. Savepoints are also supported in cross-server SQL transactions, including operations in high-availability clusters, if all of the participating Informix® instances support savepoints, and all of the databases that are accessed in the transaction use logging.

If any of the participating database servers in a cross-server transaction does not support savepoints, however, and a connection is established between a coordinator that can support savepoints and a subordinate server that cannot, any ROLLBACK TO SAVEPOINT statement within the distributed transaction fails with an error.

### Persistence of savepoints

Savepoints are position markers within SQL transactions, not database objects. An existing savepoint **S** is destroyed by any of the following events within the same transaction:

- A COMMIT WORK or ROLLBACK WORK (without the TO SAVEPOINT clause) statement is executed.
- A RELEASE SAVEPOINT statement is executed that specifies **S** in the same savepoint level.
- A ROLLBACK TO SAVEPOINT or RELEASE SAVEPOINT statement is executed that specifies a savepoint that was established earlier than **S** in the same savepoint level.
- A SAVEPOINT statement specifies the same name as **S** in the same savepoint level, and **S** was not created with the UNIQUE keyword.

### Restrictions on savepoints

Savepoints and savepoint levels are not supported in the following contexts:

- in databases that do not support transaction logging
- in triggered actions
- in XA global transactions
- in applications or UDRs where the AUTOCOMMIT connection attribute is enabled.

In addition, the SAVEPOINT statement (like the RELEASE SAVEPOINT and ROLLBACK WORK TO SAVEPOINT statements) is not valid in UDRs that are invoked within DML statements, as in the following example:

```
SELECT first_1 foo() FROM systables;
```

Here the **foo()** routine cannot set a savepoint.

## SELECT statement

Use the SELECT statement to retrieve values from a database or from an SPL or Informix® ESQL/C collection variable. A SELECT operation is called a *query*.

Rows or values that satisfy the specified search criteria of the query are called *qualifying* rows or values. What the query retrieves to its calling context, after applying any additional logical conditions, is called the *result set* of the query. This result set can be empty.

|---------------|--|---|---|
| <i>column</i> | Name of a column that can be updated after a FETCH | Must be in a FROM clause table, but does not need to be in the select list of the Projection clause | <a href="#">Identifier on page 1456</a> |

## Usage

The SELECT statement can return data from tables in the current database, or in another database of the current database server, or in a database of another database server. Only the SELECT keyword, the Projection clause, and the FROM clause are required specifications.

For hierarchical queries that include the CONNECT BY clause, the FROM clause can specify only a single table that must reside in the local database of the Informix® database server instance to which the current session is connected.

For queries that include the GRID clause, the instances of each table that the FROM clause specifies must have the same schema, the same database locale, and the same code set on every node that the GRID clause specifies.

The SELECT statement can reference no more than one external table that the CREATE EXTERNAL TABLE statement has defined. In complex queries, this external table can be specified only in the outermost query. You cannot reference an external table in a subquery.

You need the Connect access privilege on the database to execute a query, as well as the Select privilege on the table objects from which the query retrieves rows.

The SELECT statement can include various basic clauses, which are identified in the following list.

| Clause  | Effect   |
|---|--|
| <a href="#">Optimizer Directives on page 1472</a>       | Specifies how the query should be implemented          |

| <i>column_alias</i>         | Temporary identifier that you declare here for a <i>column</i>   | Must be unique among <i>columns</i> and <i>column_alias</i> names in this query. Only the GROUP BY clause can reference a <i>column_alias</i> . | <a href="#">Identifier on page 1456</a>           |
| <i>column</i>               | Column from which to retrieve data   | Must exist in a data source that the FROM clause references   | <a href="#">Identifier on page 1456</a>           |
| <i>display_label</i>        | Temporary name declared here for a <i>column</i> or for an expression                                  | See <a href="#">Declaring a Display Label on page 788</a>   | <a href="#">Identifier on page 1456</a>           |
| <i>external</i>             | External table from which to retrieve data   | Must exist  | <a href="#">Database Object Name on page 1450</a> |
| <i>max</i>                  | Integer (> 0) specifying maximum number of rows to return  | If <i>max</i> > number of qualifying rows then all matching rows are returned   | <a href="#">Literal Number on page 1419</a>       |
| <i>max_var</i>              | Host variable or local SPL variable storing the value of <i>max</i>                                    | Same as <i>max</i> ; valid in prepared objects and in SPL routines  | Language dependent                                |
| <i>offset</i>               | Integer (> 0) specifying how many qualifying rows to exclude before the first row of the result set    | Cannot be negative. If <i>offset</i> > (number of qualifying rows), then no rows are returned   | <a href="#">Literal Number on page 1419</a>       |
| <i>off_var</i>              | Host variable or local SPL variable storing the value of <i>offset</i>                                 | Same as <i>offset</i> ; valid in prepared objects and in user-defined routines  | Language dependent                                |
| <i>subquery</i>             | Embedded query   | A subquery within the Projection clause cannot include the SKIP, FIRST, INTO TEMP, or the ORDER BY clause.                                      | <a href="#">SELECT statement on page 768</a>      |
| <i>table, view, synonym</i> | Name of a table, view, or synonym from which to retrieve data  | The synonym and the table or view to which it points must exist   | <a href="#">Database Object Name on page 1450</a> |

The asterisk ( \* ) specifies all columns in the *table* or *view* in their defined order. To retrieve all columns in another order, or a subset of columns, you must specify individual *column* names explicitly. A solitary asterisk ( \* ) can be a valid Projection clause if the FROM clause specifies only a single data source.

To execute a query, the database server constructs a query plan and retrieves all qualifying rows that match the WHERE clause conditions. (Here a *row* refers to one set of values, as specified in the select list, from a single record in the table or joined tables that the FROM clause specifies.) If the query has no ORDER BY clause, the qualifying rows are sequenced in the order of their retrieval, which might vary with each execution; otherwise, their sequence follows the ORDER BY specification.

---

**Related reference**[Expression on page 1193](#)

## Restricting return values with the SKIP, LIMIT, and FIRST options

You can use the SKIP, LIMIT, and FIRST options to restrict the number of return values. The SKIP option excludes the first specified number of return values. The LIMIT and FIRST options set the maximum number of return values.

There is no default value for the *max* or *offset* parameters of the FIRST, LIMIT, or SKIP options. If no integer or integer variable follows the FIRST, LIMIT, or SKIP keyword, the database server interprets that keyword as a column identifier. If no data source in the FROM clause has a column with that name, the query fails with an error.

You can use these features in cross-server distributed queries only if all of the participating database server instances support the SKIP, LIMIT, and FIRST options.

### SKIP option

The SKIP *offset* option specifies the number of qualifying rows to exclude, for *offset* an integer in the SERIAL8 range, counting from the first qualifying row.

The following example retrieves the values from all rows except the first 10 rows:

```
SELECT SKIP 10 a, b FROM tab1;
```

You can also use a host variable to specify how many rows to exclude. In an SPL routine, you can use an input parameter or a local variable to provide this value.

You can also use the SKIP option to restrict the result sets of prepared SELECT statements, of UNION queries, in queries whose result set defines a collection-derived table, and in the events and actions of triggers.

The SKIP option is not valid in the following contexts:

- In the definition of a view
- In nested SELECT statements
- In subqueries, except for table expressions in the FROM clause.

### FIRST option

The FIRST *max* option specifies that the result set includes no more than *max* rows (or exactly *max*, if *max* is not greater than the number of qualifying rows). Any additional rows that satisfy the selection criteria are not returned. If there are fewer than *max* qualifying rows, the sorted and unsorted query results always include the same rows, but typically not in the same order.

The following example retrieves at most 10 rows from table **tab1**:

```
SELECT FIRST 10 a, b FROM tab1;
```

You can use a host variable or the value of an SPL input parameter in a local variable to specify *max*.

The FIRST keyword is also valid in queries that include table expressions in the FROM clause. The following example returns the first 8 qualifying rows, in their order of retrieval from the table expression in the FROM clause of the outer query:

```
SELECT * FROM (SELECT FIRST 8 col1
              FROM tab1 WHERE col1 > 50 );
```

The next example applies the FIRST option to the result of a UNION expression:

```
SELECT FIRST 10 a, b FROM tab1 UNION SELECT a, b FROM tab2;
```

The FIRST option is not valid in any of the following contexts:

- In the definition of a view
- In nested SELECT statements
- In subqueries, except for subqueries that specify table expressions in the FROM clause
- In a singleton SELECT (where *max* = 1) within an SPL routine
- Where embedded SELECT statements are used as expressions

Instead of the FIRST or LIMIT option in the Projection clause, you can instead include the LIMIT clause after the Projection clause and the optional ORDER BY clause. For more information on the LIMIT clause, see [LIMIT Clause on page 849](#).

### LIMIT option

LIMIT is a keyword synonym for the FIRST keyword in the Projection clause. However, you cannot substitute LIMIT for FIRST in other syntactic contexts where FIRST is valid, such as in the FETCH statement.

### Combining the SKIP option and the FIRST or LIMIT option

If a Projection clause with the SKIP *offset* option also includes a *max* limit that the FIRST or LIMIT option specifies, the query result set begins with the row whose ordinal position among qualifying rows is (*offset* + 1), rather than with the first row that satisfies the selection criteria.

If no ORDER BY clause sorts the retrieved rows, the row in position (*offset* + *max*) is the last row in the result set, unless there are fewer than (*offset* + *max*) qualifying rows. The following example ignores the first 50 qualifying rows in table **tab1**, but returns a result set of at most 10 rows, beginning with the fifty-first row:

```
SELECT SKIP 50 FIRST 10 a, b FROM tab1;
```

The SELECT clause in the next example uses the SKIP and FIRST options to insert no more than five rows from table **tab1** into table **tab2**, beginning with the eleventh row:

```
INSERT INTO tab2 SELECT SKIP 10 FIRST 5 * FROM tab1;
```

## Sorting results from SKIP, LIMIT, or FIRST queries

When you combine the ORDER BY clause with the SKIP, LIMIT, or FIRST options in a query, the ORDER BY clause can affect which qualifying rows are in the result set.

Queries that combine the SKIP and the FIRST or LIMIT options with the ORDER BY clause impose a unique order on the qualifying rows. Successive queries that increment the *offset* value by the value of *max* can partition the results into distinct subsets of *max* rows. This capability can support web applications that require a fixed page size, without requiring cursor management.

## Using FIRST or LIMIT with ORDER BY

For a query that includes the FIRST or LIMIT option or the LIMIT clause and an ORDER BY clause, the qualifying rows that are returned in their sort-key order might not be the same result set that the query without ORDER BY returned in the order of retrieval.

With an ORDER BY clause, you can retrieve the first *max* qualifying rows. For example, the following query finds the ten highest-paid employees:

```
SELECT FIRST 10 name, salary FROM emp ORDER BY salary DESC;
```

You can use the FIRST option in a query whose result set defines collection-derived table (CDT) within the FROM clause of another SELECT statement. The following query specifies a CDT that has no more than ten rows:

```
SELECT *
FROM TABLE(MULTISET(SELECT FIRST 10 * FROM employees
ORDER BY employee_id)) vt(x,y), tab2
WHERE tab2.id = vt.x;
```

## Using SKIP and ORDER BY

For a query in which the SKIP option defines an integer *offset* of qualifying rows that are ignored before the first returned row, the order of retrieval determines which rows are omitted from the query result if the ORDER BY clause is absent. However, if the ORDER BY clause is included the *offset* is applied to the sorted rows. Whether sorted in ascending or descending order, these rows that are excluded based on their sort-key value are generally uncorrelated with the qualifying rows that are excluded based on their order of retrieval, unless the query result set is empty.

When you use the SKIP option in a query with an ORDER BY clause, you can exclude the first *offset* rows that have the lowest values according to the ORDER BY criteria. You can also use SKIP to exclude rows with the highest values, if the ORDER BY clause includes the DESC keyword. For example, the following query returns all rows of the **orders** table, except for the fifty oldest orders:

```
SELECT SKIP 50 * FROM orders ORDER BY order_date;
```

Here the result set is empty if there are fewer than 50 rows in the **orders** table. An *offset* of zero ( 0 ) is not invalid, but in that case the SKIP option does nothing.

The following example query contains a collection subquery that performs the following actions:

- retrieves only the eleventh through fifteenth rows from **tab3** as a collection-derived table,
- sorts those five rows by the ascending order of their value in column **a**,
- and stores this result set in a temporary table.

```
SELECT * FROM TABLE (MULTISET (SELECT SKIP 10 FIRST 5 a FROM tab3
ORDER BY a)) INTO TEMP;
```

The following INSERT statement includes a collection subquery whose results define a collection-derived table. The rows are ordered by the value in column **a**, and are inserted into table **tab1**.

```
INSERT INTO tab1 (a) SELECT *
FROM TABLE (MULTISET (SELECT SKIP 10 FIRST 5 a
FROM tab3 ORDER BY a));
```

## Controlling duplicate return values

You can apply the ALL, UNIQUE, or DISTINCT keywords to indicate whether duplicate values are returned, if any exist. If you do not specify any of these keywords in the Projection clause, all qualifying rows are returned by default.

### ALL

Default. Specifies that all qualifying rows are returned, regardless of whether duplicates exist.

### DISTINCT

Excludes duplicates of qualifying rows from the result set

### UNIQUE

Excludes duplicate. UNIQUE is a synonym for DISTINCT, as an extension to the ANSI/ISO standard.

For example, the next query returns all the unique ordered pairs of values from the **stock\_num** and **manu\_code** columns in rows of the **items** table. If several rows have the same pair of values, that pair appears only once in the result set:

```
SELECT DISTINCT stock_num, manu_code FROM items;
```

For information on how the database server identifies duplicate NCHAR and NVARCHAR values in a database that has the NLCASE INSENSITIVE property, see [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

You can specify the DISTINCT or UNIQUE keyword of the SELECT statement no more than once in each level of a query or subquery. The following example uses DISTINCT in both the query and in the subquery:

```
SELECT DISTINCT stock_num, manu_code FROM items
WHERE order_num = (SELECT DISTINCT order_num FROM orders
WHERE customer_num = 120);
```

The example above is valid, because DISTINCT is used no more than once in each of the SELECT statements.

If a query includes the DISTINCT or UNIQUE keyword (rather than the ALL keyword or no keyword) in the Projection clause whose Select list also includes an aggregate function whose argument list begins with the DISTINCT or UNIQUE keyword, the database server issues an error, as in the following example: .

```
SELECT DISTINCT COUNT(DISTINCT ship_weight)
FROM orders;
```

That is, it is not valid in the same query for both the Projection clause and for an aggregate function to restrict the result set to unique values. (In the example above, replacing either of the DISTINCT keyword with UNIQUE would not avoid this error.)

## Queries with multiple aggregate expressions

If the Projection clause does not specify the DISTINCT or UNIQUE keyword of the SELECT statement, the query can include multiple built-in aggregate functions that each includes the DISTINCT or UNIQUE keyword as the first specification in the argument list, as in the following example:

```
SELECT COUNT (DISTINCT customer_num),
COUNT (UNIQUE order_num),
AVG(DISTINCT ship_charge) FROM orders;
```

Support for multiple DISTINCT or UNIQUE aggregate expressions in the same level of a query applies to built-in aggregate functions, but not to user-defined aggregate (UDA) functions that the CREATE AGGREGATE statement defined. The database

server issues an error if the argument lists of more than one UDA expression in the same query begin with the DISTINCT or UNIQUE keywords.

## Duplicate rows in NLSCASE INSENSITIVE databases

In a database that was created with the NLSCASE INSENSITIVE option, columns and expressions of NCHAR or NVARCHAR data types make no distinction between upper case and lower case letters, so that strings of these data types that have the same sequence of characters, but with letter case variants, evaluate as duplicates.

Queries that include the ALL, DISTINCT, or UNIQUE keywords might return results different from what the same query returns from a case-sensitive database into which the same character string values had been loaded. For example, the NVARCHAR strings "aCe", "ACE", and "AcE" evaluate as identical in databases that have the NLSCASE INSENSITIVE property, but the same three strings are processed as distinct values in case-sensitive databases.

Strings of type CHAR, LVARCHAR, and VARCHAR, however, are processed identically in NLSCASE SENSITIVE and in NLSCASE INSENSITIVE databases by queries that use the ALL, DISTINCT, or UNIQUE keywords to include or exclude duplicate rows. For more information about databases with the NLSCASE INSENSITIVE property, see [Specifying NLSCASE case sensitivity on page 206](#) and [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

## Data Types in Distributed Queries

Queries whose only data sources are tables and views in the local database to which the session is connected can return values from columns or expressions of any built-in or user-defined data type that is registered in the local database. Queries that reference tables or views in other databases are called *distributed queries*, and the data types that they can access are a subset of the data types that Informix® supports in local queries.

Among distributed queries, the restrictions on data types depend on the number of participating database servers.

- If all the databases that the query accesses are databases of the same Informix® instance, the query is called a *cross-database* distributed query.
- If the query accesses databases of multiple Informix® instances, the query is called a *cross-server* distributed query.

In both types of distributed queries, all participating databases must have the same ANSI/ISO-compliance status. A cross-server distributed query can use both the SKIP and FIRST options if all participating servers support the SKIP option; otherwise the query fails with an error. More generally, all cross-server operations require that the participating database server instances support the SQL syntax that specifies the operation.

For additional information about distributed queries, see the *Informix® Database Design and Implementation Guide*.

## Data Types in Cross-Database Transactions

A query that accesses tables in more than one database of the local server instance can return only a subset of the SQL data types that a local query can return from tables in the local database. Similarly, a cross-server distributed query on tables in databases of more than one server instance has additional restrictions on returned data types.

Distributed queries (and other distributed DML operations or function calls) that access only databases of the local Informix® instance can access data types of the following categories:

- The *built-in data types* that are not opaque, including these:
  - BIGINT
  - BIGSERIAL
  - BYTE
  - CHAR
  - DATE
  - DATETIME
  - DECIMAL
  - FLOAT
  - INT
  - INTERVAL
  - INT8
  - MONEY
  - NCHAR
  - NVARCHAR
  - SERIAL
  - SERIAL8
  - SMALLFLOAT
  - SMALLINT
  - TEXT
  - VARCHAR
- Most *built-in opaque data types*, including these:
  - BLOB
  - BSON
  - BOOLEAN
  - CLIENTBINVAL
  - CLOB
  - IFX\_LO\_SPEC
  - IFX\_LO\_STAT
  - INDEXKEYARRAY
  - JSON
  - LVARCHAR
  - POINTER
  - RTNPARAMTYPES,
  - SELFUNCARGS
  - STAT
  - XID
- User-defined types (UDTs) that are cast explicitly to any of the built-in types that are listed above
- DISTINCT of any of the built-in types in the preceding list.

Distributed operations across databases of the local Informix® instance can return UDTs and DISTINCT types based on built-in data types only if all the UDTs and DISTINCT types are cast explicitly to built-in data types.

All the opaque UDTs, DISTINCT types, data type hierarchies, and casts must have exactly the same definitions in each database that participates in the distributed query. For queries or other DML operations in cross-database UDRs that use the data types listed above as parameters or as returned data types, the UDR must also have the same definition in each participating database.

A cross-database distributed query (or any other cross-database DML operation) fails with an error if it references a table, view, or synonym in another database of the local Informix® instance that includes a column of any of the following data types:

- LOLIST
- IMPEXP
- IMPEXPBIN
- SENDRECV
- DISTINCT of any of the built-in opaque data types that are listed above.
- Complex types (named or unnamed ROW, COLLECTION, LIST, MULTISSET, or SET)
- DISTINCT of ROW.

## Data Types in Cross-Server Transactions

A distributed query (or any other distributed DML operation or function call) across databases of two or more Informix® instances cannot return complex or large-object data types, nor most user-defined data types (UDTs) or opaque data types.

A distributed query (or any other distributed DML operation or function call) across databases of two or more Informix® instances cannot return complex or large-object data types, nor most user-defined data types (UDTs) or opaque data types. Cross-server distributed queries, DML operations, and function calls can return only the following atomic data types, where *atomic* excludes the complex data types:

- Any non-opaque atomic built-in data type
- BOOLEAN
- BSON
- JSON
- LVARCHAR
- DISTINCT of non-opaque built-in types
- DISTINCT of BOOLEAN
- DISTINCT of BSON
- DISTINCT of JSON
- DISTINCT of LVARCHAR
- DISTINCT of any of the DISTINCT types that appear above in this list.

A cross-server distributed query can support DISTINCT data types only if both of the following conditions are true for every DISTINCT type in the query:

- The DISTINCT data type is explicitly cast to one of the atomic built-in types above,
- The DISTINCT type, its data type hierarchy, and its casts are defined exactly the same way in each database that participates in the distributed query.

For queries or other DML operations in cross-server UDRs (user-defined routines) that use the data types in the preceding list as parameters or as returned data types, the UDR must also have the same definition in every participating database.

### **Cross-server queries of protected tables**

The built-in DISTINCT data type IDSSECURITYLABEL, which stores security label objects, can be accessed in cross-server and cross-database operations on protected data by users who hold sufficient security credentials for the same label-based access control (LBAC) security policy. Like local operations on protected data, distributed queries that access remote tables protected by a security policy can return only the qualifying rows that **IDSLBACRULES** allow, after the database server has compared the security label that secures the data with the security credentials of the user who issues the query.

For additional information about the data types that Informix® supports in cross-server DML operations, see [Data Types in Distributed Queries on page 779](#). For information about the table hierarchies of the DISTINCT data types that are valid in cross-server operations, see [DISTINCT Types in Distributed Operations on page 1184](#).

### **Built-in data types not valid in cross-server queries**

A cross-server query (or any other cross-server DML operation) fails with an error if it references a table, view, or synonym in a database of another Informix® instance that includes a column of any of the following data types:

- BLOB
- BYTE
- CLIENTBINVAL
- CLOB
- IFX\_LO\_SPEC
- IFX\_LO\_STAT
- INDEXKEYARRAY
- POINTER
- RTNPARAMTYPES
- SELFUNCARGS
- STAT
- TEXT
- XID
- User-defined OPAQUE types
- Complex types (named or unnamed ROW, COLLECTION, LIST, MULTISET, or SET)
- DISTINCT of any of the opaque or complex data types that are listed above.

## Requirements for participating database servers and databases

Cross-server operations require that all participating database server instances support the SQL syntax that specifies the operation.

Cross-server queries cannot access the database of another Informix® instance unless both servers define TCP/IP or IPCSTR connections in their DBSERVERNAME or DSERVERALIASES configuration parameters and in the **sqlhosts** information. The requirement that both participating servers support the same type of connection (either TCP/IP or else IPCSTR) applies to any communication between Informix® instances, even if both reside on the same computer.

For the SQL syntax to reference objects in databases of remote server instances that are not part of an Informix® grid, see [Specifying a Database Object in a Cross-Server Query on page 1452](#). For information about grid queries, see [GRID clause on page 809](#).

## Expressions in the Select List

You can use any basic type of expression (column, constant, built-in function, aggregate function, and user-defined routine), or combination thereof, in the select list. The expression types are described in [Expression on page 1193](#). Sections that follow present examples of simple expression in the select list.

You can combine simple numeric expressions by connecting them with arithmetic operators for addition, subtraction, multiplication, and division. If you combine a column expression and an aggregate function, however, you must include the column expression in the GROUP BY clause. (See also [Dependencies between the GROUP BY and Projection clauses on page 834](#).)

In general, you cannot use variables (for example, host variables in an ESQL/C application) in the select list by themselves. A variable is valid in the select list, however, if an arithmetic or concatenation operator connects it to a constant.

In a FOREACH SELECT statement, you cannot use SPL variables in the select list, by themselves or with column names, when the tables in the FROM clause are remote tables. You can use SPL variables by themselves or with a constant in the select list only when the tables in the FROM clause are local tables.

In distributed queries of Informix®, values in expressions (and returned by expressions) are restricted, as [Data Types in Cross-Server Transactions on page 781](#) describes. Any UDRs whose return values are used as expressions in other databases of the same Informix® instance must be defined in each participating database.

The Boolean operator NOT is not valid in the Projection clause.

## Selecting Columns

Column expressions are the most commonly used expressions in a SELECT statement. For a complete description of the syntax and use of column expressions, see [Column Expressions on page 1219](#). The following examples use column expressions in the Projection clause:

```
SELECT orders.order_num, items.price FROM orders, items;
SELECT customer.customer_num cnum, company FROM customer;
SELECT catalog_num, stock_num, cat_advert [1,15] FROM catalog;
SELECT lead_time - 2 UNITS DAY FROM manufact;
```

## Selecting Constants

If you include a constant expression in the projection list, the same value is returned for each row that the query returns (except when the constant expression is **NEXTVAL**). For a complete description of the syntax and use of constant expressions, see [Constant Expressions on page 1235](#). Examples that follow show constant expressions within a select list:

```
SELECT 'The first name is', fname FROM customer;
SELECT TODAY FROM cust_calls;
SELECT SITENAME FROM systables WHERE tabid = ;1
SELECT lead_time - 2 UNITS DAY FROM manufact;
SELECT customer_num + LENGTH('string') from customer;
```

## Selecting Built-In Function Expressions

A built-in function expression uses a function that is evaluated for each row in the query. All built-in function expressions require arguments. This set of expressions contains the time functions and the length function when they are used with a column name as an argument. The following examples show built-in function expressions within the select list of the Projection clause:

```
SELECT EXTEND(res_dtime, YEAR TO SECOND) FROM cust_calls;
SELECT LENGTH(fname) + LENGTH(lname) FROM customer;
SELECT HEX(order_num) FROM orders;
SELECT MONTH(order_date) FROM orders;
```

## Selecting Aggregate Function Expressions

An aggregate function returns one value for a set of queried rows. This value depends on the set of rows that the WHERE clause of the SELECT statement qualifies. In the absence of a WHERE clause, the aggregate functions take on values that depend on all the rows that the FROM clause forms.

Examples that follow show aggregate functions in a projection list:

```
SELECT SUM(total_price) FROM items WHERE order_num = 1013;
SELECT COUNT(*) FROM orders WHERE order_num = 1001;
SELECT MAX(LENGTH(fname) + LENGTH(lname)) FROM customer;
```

If the Projection clause does not specify the DISTINCT or UNIQUE keyword of the SELECT statement, however, the query can include one or more aggregate functions that include the DISTINCT or UNIQUE keyword as the first specification of the argument lists:

```
SELECT SUM(DISTINCT total_price) FROM items WHERE order_num = 1013;
SELECT COUNT(DISTINCT *) FROM orders WHERE order_num = 1001;
SELECT MAX(LENGTH(fname) + LENGTH(UNIQUE lname)) FROM customer;
```

The database server issues an error, however, if both the Projection clause and an aggregate function expression specify the DISTINCT or UNIQUE keyword in the same query.

## Aggregate expressions in grid queries

For grid queries that include aggregate function expressions, you must specify the GRID clause in a subquery, if the value of the aggregate expression that each grid server calculates is a quotient whose denominator varies across the participating grid servers.

## SQL aggregate expressions and OLAP window aggregates

Do not confuse SQL aggregate functions with the On-Line Analytical Processing (OLAP) window aggregation functions, which are a different category of functions.

When an aggregate function expression is immediately followed by the OVER clause, the database server attempts to interpret it as an OLAP aggregation function. Some OLAP aggregation functions have the same names (and support a subset of the same syntax) as SQL aggregate functions, but the two types of functions have different behavior.

An SQL aggregate function can be nested inside an OLAP aggregation function. For example, the following query is valid in a context where **dollars** is a column in the sales **table**:

```
SELECT AVG(SUM(dollars)) OVER() FROM sales;
```

In the example above, the SUM function is an SQL aggregate function and the containing AVG function is an OLAP window function. The order of query processing dictates that OLAP functions are always calculated after grouping and aggregation operations but before the final ORDER BY operation.

---

### Related reference

[OLAP aggregation function expressions on page 1396](#)

### Related information

[Aggregate expressions in grid queries on page 1382](#)

## Selecting OLAP window expressions

You can include OLAP window expressions in the select list of the Projection clause.

The On-Line Analytical Processing (OLAP) functions can return ranking, row numbering, and aggregate function information for the entire result set of a query or subquery, or for partitioned subsets of the qualifying rows that the OLAP window defines. You can use OLAP specifications to define moving windows within a partition of the result set for examining dimensions of the data, and identifying patterns, trends, and exceptions within data sets.

A query that includes OLAP window expressions returns the rows in the result set of the query, and the results of the OLAP window functions, if those functions return anything.

An OLAP window aggregate function expression can be the argument to another OLAP window aggregate function. OLAP window aggregates cannot, however, be arguments to non-analytic aggregate functions.

**Related reference**[OLAP window expressions on page 1383](#)

## Selecting correlated aggregates in subqueries

In a subquery, an aggregate expression with a column operand that was declared in a parent query block is called a *correlated aggregate*. The column operand is called a *correlated column reference*.

SELECT statements and other DML statements can include subqueries with aggregate expressions whose operands reference columns that were declared in a parent query block. When a subquery contains an aggregate with a correlated column reference, the database server evaluates that aggregate in the parent query block where the correlated column reference was declared.

If an aggregate expression in a subquery contains correlated references to columns from more than one parent query block, the correlated aggregate is evaluated in the parent that is nearest to the subquery in the lexical order of query blocks.

### Examples of aggregates with correlated column references

In the following example, the database server evaluates the correlated aggregate `COUNT(n.j)` in the parent query block, which declared the table alias `n` that appears in the correlated column reference of the subquery:

```
CREATE TABLE tab(i INT);
CREATE TABLE tab2(j INT);
. . .
SELECT m.i,
       (SELECT COUNT(n.j)
        FROM tab2 WHERE j=15) AS o
FROM tab m, tab2 n GROUP BY 1;
```

The only exception to the rule illustrated above occurs when the correlated aggregate is an argument to an aggregate in the parent query block. In this scenario, the aggregate is evaluated in the subquery, if the correlated column reference comes from the same query block where the outer aggregate is specified. The next example illustrates nested aggregates:

```
SELECT m.i,
       SUM((SELECT SUM(n.j)
            FROM tab2 WHERE j=15)) AS o
FROM tab m, tab2 n GROUP BY 1;
```

When the database server identifies the aggregate in the subquery above as a nested aggregate, it evaluates the inner `SUM(n.j)` aggregate in the subquery, if the outer aggregate is in the same query block where the table alias in the `n.j` column reference was declared.

A correlated aggregate in a subquery can include multiple correlated references to columns in the parent query block, as in the following example:

```
SELECT A.tabid,
       (SELECT SUM(B.collength * A.rowsize)
        FROM syscolumns B WHERE B.tabid = A.tabid)
FROM systables A WHERE A.tabid = 1;
```

During execution of the statement above, the correlated aggregate

```
SUM(B.collength * A.rowsize)
```

is evaluated in the subquery.

In all other cases, the database server treats an aggregate operating on a column of a table in a parent query block as a correlated aggregate.

**Important:** This behavior for evaluating correlated aggregate expressions was not fully supported in Informix 12.10.xC4 or 11.70.xC8, nor in earlier release versions.

## Selecting User-Defined Function Expressions

User-defined functions extend the range of functions that are available to you and allow you to perform a subquery on each row that you select.

The following example calls the **get\_orders()** user-defined function for each **customer\_num** and displays the returned value under the `n_orders` label:

```
SELECT customer_num, lname, get_orders(customer_num) n_orders
FROM customer;
```

If an SPL routine in a SELECT statement contains certain SQL statements, the database server returns an error. For information on which SQL statements cannot be used in an SPL routine that is called within a query, see [Restrictions on SPL Routines in Data-Manipulation Statements on page 1525](#).

For the complete syntax of user-defined function expressions, see [User-Defined Functions on page 1362](#).

## Selecting Expressions That Use Arithmetic Operators

You can combine numeric expressions with arithmetic operators to make complex expressions. You cannot combine expressions that contain aggregate functions with column expressions. These examples show expressions that use arithmetic operators within a select list in the Projection clause:

```
SELECT stock_num, quantity*total_price FROM customer;
SELECT price*2 doubleprice FROM items;
SELECT count(*)+2 FROM customer;
SELECT count(*)+LENGTH('ab') FROM customer;
```

## Selecting ROW Fields

You can select a specific field of a named or unnamed ROW type column with *row.field* notation, using a period (.) as a separator between the *row* and *field* names. For example, suppose you have the following table structure:

```
CREATE ROW TYPE one (a INTEGER, b FLOAT);
CREATE ROW TYPE two (c one, d CHAR(10));
CREATE ROW TYPE three (e CHAR(10), f two);

CREATE TABLE new_tab OF TYPE two;
CREATE TABLE three_tab OF TYPE three;
```

The following examples show expressions that are valid in the select list:

```
SELECT t.c FROM new_tab t;
SELECT f.c.a FROM three_tab;
SELECT f.d FROM three_tab;
```

You can also enter an asterisk ( `*` ) in place of a field name to signify that all fields of the ROW-type column are to be selected.

For example, if the **my\_tab** table has a ROW-type column named **rowcol** that contains four fields, the following SELECT statement retrieves all four fields of the **rowcol** column:

```
SELECT rowcol.* FROM my_tab;
```

You can also retrieve all fields from a row-type column by specifying only the column name. This example has the same effect as the previous query:

```
SELECT rowcol FROM my_tab;
```

You can use *row.field* notation not only with ROW-type columns but with expressions that evaluate to ROW-type values. For more information, see [Column Expressions on page 1219](#) in the Expression segment.

## Declaring a Display Label

You can declare a display label for any column or column expression in the select list of the Projection clause. This temporary name is in scope only while the SELECT statement is executing.

In DB-Access, a display label appears as the heading for that column in the output of the SELECT statement.

In Informix® ESQL/C, the value of *display\_label* is stored in the **sqlname** field of the **sqlda** structure. For more information on the **sqlda** structure, see the *Informix® ESQL/C Programmer's Manual*.

If your display label is an SQL keyword, use the AS keyword to clarify the syntax. For example, to use UNITS, YEAR, MONTH, DAY, HOUR, MINUTE, SECOND, or FRACTION as display labels, use the AS keyword with the display label. The following statement uses AS with **minute** as a display label:

```
SELECT call_dtime AS minute FROM cust_calls;
```

For the keywords of SQL, see [Keywords of SQL for HCL Informix on page 1527](#).

If you use the INTO Table clause to create a temporary or permanent table to store the query results, you must declare a display label for any database object or expression in the select list that is not a simple column expression. The display label is used as the name of the column in the temporary or permanent table.

If you are using the SELECT statement to define a view, do not use display labels. Specify the desired label names in the CREATE VIEW column list instead.

## Declaring a Column Alias

You can declare an alias for any column in the select list of the Projection clause. The GROUP BY clause can reference the column by its alias. This temporary name is in scope only while the SELECT statement is executing.

If your alias is an SQL keyword of the SELECT statement, use the *AS column\_alias* keyword to clarify the syntax. For example, to use FROM as a table alias, the AS keyword must immediately precede the alias to avoid a syntax error. The following statement uses AS with **from** as an alias:

```
SELECT status AS from FROM stock GROUP BY from;
```

The following equivalent queries declare **pcol** as an alias, and use that alias in the GROUP BY clause:

```
SELECT pseudo_corinthian AS pcol FROM architecture GROUP BY pcol;
SELECTt pseudo_corinthian pcol FROM architecture GROUP BY pcol;
```

## INTO Clause

Use the INTO clause in SPL routines or Informix® ESQL/C programs to specify the program variables or host variables to receive data that the SELECT statement retrieves.

This syntax fragment is part of the [SELECT statement on page 768](#).

INTO Clause

**INTO**

,  
*output\_var*  
378

: *indicator\_var*  
379

\$ *indicator\_var*

**INDICATOR** *indicator\_var*

*data\_structure*

| Element               | Description   | Restrictions  | Syntax            |
|-----------------------|---|---|-------------------|
| <i>data_structure</i> | Structure that was declared as a host variable  | Data types of elements must be able to store the values that are being selected   | Language specific |
| <i>indicator_var</i>  | Program variable to receive a return code if corresponding <i>output_var</i> receives a NULL value            | Optional; use an indicator variable if the possibility exists that the value of the corresponding <i>output_var</i> is NULL | Language specific |
| <i>output_var</i>     | Program or host variable to receive value of the corresponding select list item. Can be a collection variable | Order of receiving variables must match the order of corresponding items in the select list of Projection clause            | Language specific |

The INTO clause specifies one or more variables that receive the values that the query returns. If it returns multiple values, they are assigned to the list of variables in the order in which you specify the variables. If the SELECT statement stands alone (that is, it is not part of a DECLARE statement and does not use the INTO clause), it must be a singleton SELECT

378. ESQL/C only

379. Informix® extension

statement. A *singleton* SELECT statement returns only one row. The following example shows a singleton SELECT statement in Informix® ESQL/C:

```
EXEC SQL SELECT fname, lname, company
  INTO :p_fname, :p_lname, :p_coname
  FROM customer WHERE customer_num = 101;
```

In an SPL routine, if a SELECT returns more than one row, you must use the FOREACH statement to access the rows individually. The INTO clause of the SELECT statement holds the fetched values. For more information, see [FOREACH on page 1107](#).

The number of receiving variables must be equal to the number of items in the select list of the Projection clause. The data type of each receiving variable should be compatible with the data type of the corresponding column or expression in the select list. If the data type of the receiving variable does not match that of the selected item, the data type of the selected item is converted, if possible, to the data type of the variable. If the conversion is impossible, an error occurs, and a negative value is returned in the **status** variable, **sqlca.sqlcode**, or **SQLCODE**. In this case, the value in the program variable is unpredictable. In an ANSI-compliant database, if the number of variables that are listed in the INTO clause differs from the number of items in the select list of the Projection clause, you receive an error.

In Informix® ESQL/C, if the number of variables listed in the INTO clause differs from the number of items in the Projection clause, a warning is returned in the **sqlwarn** structure: **sqlca.sqlwarn.sqlwarn3**. The actual number of variables that are transferred is the lesser of the two numbers. For information about the **sqlwarn** structure, see the *Informix® ESQL/C Programmer's Manual*.

## INTO Clause with Cursors

If the SELECT statement returns more than one row, you must use a cursor in a FETCH statement to fetch the rows individually. You can put the INTO clause in the FETCH statement rather than in the SELECT statement, but you should not put it in both.

The following Informix® ESQL/C code examples show different ways you can use the INTO clause. As both examples show, first you must use the DECLARE statement to declare a cursor.

The following example show how to use the INTO clause in the SELECT statement:

```
EXEC SQL declare q_curs cursor for
  select lname, company
  into :p_lname, :p_company
  from customer;
EXEC SQL open q_curs;
while (SQLCODE == 0)
  EXEC SQL fetch q_curs;
EXEC SQL close q_curs;
```

The following statement shows how to use the INTO clause in a FETCH statement:

```
EXEC SQL declare q_curs cursor for
  select lname, company from customer;
EXEC SQL open q_curs;
while (SQLCODE == 0)
```

```
EXEC SQL fetch q_curs into :p_lname, :p_company;
EXEC SQL close q_curs;
```

## Preparing a SELECT ... INTO Query

In Informix® ESQL/C, you cannot prepare a query that has an INTO clause. You can prepare the query without the INTO clause, declare a cursor for the prepared query, open the cursor, and then use the FETCH statement with an INTO clause to fetch the cursor into the program variable.

Alternatively, you can declare a cursor for the query without first preparing the query and include the INTO clause in the query when you declare the cursor. Then open the cursor and fetch the cursor without using the INTO clause of the FETCH statement.

## Using Array Variables with the INTO Clause

In Informix® ESQL/C, if you use a DECLARE statement with a SELECT statement that contains an INTO clause, and the variable is an array element, you can identify individual elements of the array with integer literals or variables. The value of the variable that is used as a subscript is determined when the cursor is declared; the subscript variable subsequently acts as a constant.

The following Informix® ESQL/C code example declares a cursor for a SELECT ... INTO statement using the variables **i** and **j** as subscripts for the array **a**. After you declare the cursor, the INTO clause of the SELECT statement is equivalent to `INTO a[5], a[2]`.

```
i = 5
j = 2
EXEC SQL declare c cursor for
  select order_num, po_num into :a[i], :a[j] from orders
  where order_num =1005 and po_num =2865;
```

You can also use program variables in the FETCH statement to specify an element of a program array in the INTO clause. The program variables are evaluated at each fetch, rather than when you declare the cursor.

## FROM Clause

The FROM clause of the SELECT statement lists table objects from which to retrieve data.

This syntax fragment is part of the [SELECT statement on page 768](#).

380. Informix® extension

381. Must specify a supertable within a typed table hierarchy

382. See [The ONLY Keyword on page 798](#)

383. See [Lateral derived tables on page 796](#)

384. See [Informix-Extension Outer Joins on page 807](#)

| Element                     | Description  | Restrictions  | Syntax  |
|-----------------------------|--|---|---|
| <i>alias</i>                | Temporary name for a table, view, or derived table in this query | See <a href="#">Aliases for Tables or Views on page 793</a> .   | <a href="#">Identifier on page 1456</a>           |
| <i>derived_column</i>       | Temporary name for a derived column in a table expression        | Unless the underlying collection is a ROW type, you can declare no more than one <i>derived_column</i> name | <a href="#">Identifier on page 1456</a>           |
| <i>external</i>             | External table from which to retrieve data                       | Must exist, but cannot be the outer table in an outer join  | <a href="#">Database Object Name on page 1450</a> |
| <i>subquery</i>             | Nested query whose results are available to the outer query      | See <a href="#">Table expressions on page 794</a>   | <a href="#">SELECT statement on page 768</a>      |
| <i>synonym, table, view</i> | Synonym for a table from which to retrieve data                  | Synonym and table or view to which it points must exist. Must include appropriate qualifiers.               | <a href="#">Database Object Name on page 1450</a> |

Every SELECT statement requires the FROM clause, whether or not any data source is required. If your query uses the database server to evaluate an expression that requires no data source, the FROM clause can reference any existing table in the current database on which you hold sufficient access privileges, as in the following example:

```
SELECT ATANH(SQRT(POW(4,2) + POW(5,2))) FROM systables;
```

## Aliases for Tables or Views

You can declare an alias for a table or view in the FROM clause. If you do so, you must use the alias to refer to the table or view in other clauses of the SELECT statement. You can also use aliases to make the query shorter.

The following examples show typical uses of the FROM clause. The first query selects all the columns and rows from the **customer** table. The second query uses a join between the **customer** and **orders** table to select all the customers who have placed orders.

```
SELECT * FROM customer;
SELECT fname, lname, order_num FROM customer, orders
WHERE customer.customer_num = orders.customer_num;
```

The next example is equivalent to the second query in the preceding example, but it declares aliases in the FROM clause and uses them in the WHERE clause:

- 385. See [Iterator Functions on page 801](#)
- 386. See [Collection-Derived Table on page 1436](#)
- 387. See [Collection Subquery on page 1141](#)
- 388. Informix® extension
- 389. See [ANSI Joins on page 802](#)
- 390. See [Aliases for Tables or Views on page 793](#)

```
SELECT fname, lname, order_num FROM customer c, orders o
WHERE c.customer_num = o.customer_num;
```

Aliases (sometimes called *correlation names*) are especially useful with a self-join. For more information about self-joins, see [Specifying a Join in the WHERE Clause on page 818](#). In a self-join, you must list the table name twice in the FROM clause and declare a different alias for each of the two instances of the table name.

If you use a potentially ambiguous word as an alias (or as a display label), you must begin its declaration with the keyword AS. This keyword is required if you use any of the keywords ORDER, FOR, AT, GROUP, HAVING, INTO, NOT, UNION, WHERE, WITH, CREATE, or GRANT as an alias for a table or view.

The database server would issue an error if the next example did not include the AS keyword to indicate that **not** is a display label, rather than an operator:

```
CREATE TABLE t1(a INT);
SELECT a AS not FROM t1;
```

If you do not declare an alias for a collection-derived table, the database server assigns an implementation-dependent name to it.

## Table expressions

A *table expression* (sometimes called a *derived table*) is the name of a table or view, or a specification that evaluates to a set of rows. These rows are typically the result of a query that is embedded in a nested SELECT statement, or in some other SQL statement.

Table expressions can have the following syntax. These options are a subset of the table options in the ANSI Table Reference and the Other Table Reference in the [FROM Clause on page 791](#).

Figure 8. Table expression

393. See [Collection Subquery on page 1141](#)

394. See [Lateral derived tables on page 796](#)

395. See [Iterator Functions on page 801](#)

| Element             | Description   | Restrictions  | Syntax   |
|---------------------|---|---|--|
| <i>table_object</i> | Name, synonym, or alias of a table, view, or EXTERNAL table | Must exist, or must reference a derived table that the SELECT statement creates | <a href="#">Identifier on page 1456</a> or <a href="#">Database Object Name on page 1450</a> |

## Usage

Table expressions can be simple or complex:

- Simple table expressions

A *simple* table expression is one whose underlying query can be folded into the main query while preserving the correctness of the query result.

- Complex table expressions

A *complex* table expression is one whose underlying query cannot be folded into the main query while preserving the correctness of the query result. The database server materializes such table expressions into a temporary table that is used in the main query. Subqueries in the FROM clause that specify aggregates, set operators, or the ORDER BY clause are implemented as complex table expressions, which typically require more resources of the database server than simple table expressions.

In either case, the table expression is evaluated as a general SQL query and its results can be thought of as a logical table. This logical table and its columns can be used just like an ordinary base table, but it is not persistent. It exists only during the execution of the query that references it.

## Restrictions on table expressions

Table expressions have the same syntax as general SELECT statements, but with most of the restrictions that apply to subqueries in other contexts. A table expression cannot include the SELECT INTO clause that explicitly creates a result table.

Informix® does not support Generalized Key indexes. It supports table expressions in the triggered actions of CREATE TRIGGER statements, and as the triggering event of a Select trigger. Informix® also supports the ORDER BY clause in table expressions.

Informix® supports iterator functions as FROM clause table expressions. The CALL statement of SPL, however, cannot invoke an iterator TABLE function within a subquery in the FROM clause.

Apart from these restrictions, any valid SQL query can be a table expression. A table expression can be nested within another table expression and can include tables and views in its definition. You can use table expressions in CREATE VIEW statements to define views.

## Correlated subqueries and derived tables

A *correlated subquery* is a subquery that refers to a column of a table that is not listed in its FROM clause. Conversely, any subquery that references only columns in tables that are listed in its FROM clause is an *uncorrelated subquery*.

In the following example, the uncorrelated subquery that defines a derived table in its FROM clause contains a correlated subquery in its WHERE clause:

```
SELECT * FROM (SELECT * FROM t1
WHERE a IN (SELECT b FROM t2 WHERE t1.a = t2.b));
```

Here the subquery in the first WHERE clause is a correlated subquery, because it references column **a** of table **t1**, but its FROM clause specifies only table **t2**.

In FROM clause table expressions, HCL Informix® also supports the ORDER BY clause, which is not valid in subqueries outside the FROM clause. Columns or expressions that are specified by the ORDER BY clause in a table expression need not be included in the Projection clause.

## Lateral derived tables

The LATERAL keyword must immediately precede any query in the FROM clause that defines a derived table, if that query references any other table or column that appears earlier in the same FROM clause than the query that defines the derived table.

Lateral derived tables, and the scope of reference of the table and column aliases that can be declared in their syntax, are part of the ISO/ANSI standard for the SQL language. This syntax fragment is part of the [FROM Clause on page 791](#).

LATERAL derived table

**LATERAL** (*subquery*) **AS***alias*

(  
, *column\_alias*  
)

| Element             | Description   | Restrictions  | Syntax                                       |
|---------------------|---|---|--|
| <i>alias</i>        | Temporary name declared here for the derived table of <i>subquery</i> results | See <a href="#">Aliases for Tables or Views on page 793</a> . | <a href="#">Identifier on page 1456</a>      |
| <i>column_alias</i> | Temporary name declared here for a column in the derived table                |   | <a href="#">Identifier on page 1456</a>      |
| <i>subquery</i>     | Specifies rows to be retrieved  | Can be uncorrelated or correlated                             | <a href="#">SELECT statement on page 768</a> |

## Usage

The LATERAL keyword is required if the *subquery* whose result set is the derived table references any table or column that appears earlier in the same FROM clause. Here *earlier* means "to the left of the derived-table" in the left-to-right order of syntax tokens in the FROM clause. A derived table defined with the LATERAL keyword is called a *lateral derived table*.

This support for references to columns in other tables in the FROM clause, rather than only to columns in subsequent derived tables, can improve performance in SELECT statements that join one or more derived tables. Lateral table and column references are also valid in derived tables within DELETE, UPDATE, and CREATE VIEW statements.

The LATERAL keyword is not required in the FROM clause for derived tables in which all uncorrelated table and column references have already been resolved.

### Restrictions on lateral correlated references

The following restrictions apply to lateral derived table and column references:

- They cannot be used in ANSI FULL OUTER JOIN queries.
- They cannot be used in ANSI RIGHT OUTER JOIN queries.
- They cannot be used in Informix®-extension OUTER JOIN queries.

### Examples of lateral derived tables

The following query includes a lateral derived table in the FROM clause, where t1\_a is a lateral correlation reference:

```
SELECT * FROM t1 ,
        LATERAL (SELECT t2.a AS t2_a
                FROM t2 WHERE t2.a = t1.a);
```

In the next example, d.deptno is a lateral correlation reference:

```
SELECT d.deptno, d.deptname,
       empinfo.avgsal, empinfo.empcount
FROM department d,
     LATERAL (SELECT AVG(e.salary) AS avgsal,
                  COUNT(*) AS empcount
              FROM employee e
              WHERE e.workdept=d.deptno) AS empinfo;
```

Here the avgsal and empcount aliases for column expressions and the empinfo lateral table reference appear in the projection list of the outer query, which joins qualifying rows from the **department** table and the derived table, using the correlation deptno.

### Usability and Performance Considerations

Although equivalent functionality is available through views, subqueries as table expressions simplify the formulation of queries, make the syntax more flexible and intuitive, and support the ANSI/ISO standard for SQL.

The query optimizer does not materialize simple table expressions that the FROM clause specifies. The performance of a query that uses the ANSI/ISO syntax for a table expression in the FROM clause is at least as good as a that of a query that uses the Informix®-extension TABLE (MULTISET ( SELECT ... )) syntax to specify an equivalent derived table in the FROM clause. Subqueries in the FROM clause that include aggregate functions, set operators like the UNION, INTERSECT, or MINUS operators, or ORDER BY specifications are implemented as complex table expressions that can impose greater costs than simple table expressions. Use the SET EXPLAIN statement to examine the query plan and the estimated cost of a table expression.

The following are examples of valid table expressions:

```
SELECT * FROM (SELECT * FROM t);

SELECT * FROM (SELECT * FROM t) AS s;

SELECT * FROM (SELECT * FROM t) AS s WHERE t.a = s.b;
```

```

SELECT * FROM (SELECT * FROM t) AS s, (SELECT * FROM u) AS v WHERE s.a = v.b;

SELECT * FROM (SELECT SKIP 2 col1 FROM tab1 WHERE col1 > 50 ORDER BY col1 DESC);

SELECT * FROM (SELECT col1,col3 FROM tab1
  WHERE col1 < 50 GROUP BY col1,col3 ORDER BY col3 ) vtab(vcol0,vcol1);

SELECT * FROM (SELECT * FROM t WHERE t.a = 1) AS s,
OUTER
(SELECT * FROM u WHERE u.b = 2 GROUP BY 1) AS v WHERE s.a = v.b;

SELECT * FROM (SELECT a AS colA FROM t WHERE t.a = 1) AS s,
OUTER
(SELECT b AS colB FROM u WHERE u.b = 2 GROUP BY 1) AS v
  WHERE s.colA = v.colB;

CREATE VIEW vu AS SELECT * FROM (SELECT * FROM t);

SELECT * FROM ((SELECT * FROM t) AS r) AS s;

```

## Restrictions on External Tables in Joins and Subqueries

When you use external tables in joins or subqueries, the following restrictions apply:

- No more than one external table is valid in a query.
- The external table cannot be the outer table in an outer join.
- For subqueries that cannot be converted to joins, you can use an external table in the main query, but not in the subquery.
- You cannot do a self-join on an external table.

For more information on subqueries, see your *Informix® Performance Guide*.

## The ONLY Keyword

If the FROM clause includes a permanent table that is a supertable within a typed table hierarchy, the query returns the qualifying rows from both the supertable and from its subtables by default, unless you specify the ONLY keyword.

For the SELECT statement to return rows from the supertable only, you must include the ONLY keyword immediately before the supertable name in the FROM clause, and you must enclose the identifier or synonym of the supertable within parentheses, as in this example:

```
SELECT * FROM ONLY(super_tab);
```

The data sources for this query do not include the subtables of **super\_tab**.

## Selecting from a Collection Variable

The SELECT statement in conjunction with the Collection-Derived Table segment allows you to select elements from a collection variable.

### About this task

The Collection-Derived Table segment identifies the collection variable from which to select the elements. (See [Collection-Derived Table on page 1436](#).)

To modify the contents of a column of a collection data type, you can use the SELECT statement with a collection variable in various ways:

- You can select the contents (if any) of a collection column into a collection variable.

You can assign the data type of the column to a collection variable of type COLLECTION (that is, an untyped collection variable).

- You can select the contents from a collection variable to determine the data that you might want to update.
- You can select the contents from a collection variable INTO another variable in order to update certain collection elements.

The INTO clause identifies the variable for the element value that is selected from the collection variable. The data type of the host variable in the INTO clause must be compatible with that of the corresponding collection element.

- You can use a Collection cursor to select one or more elements from the Informix® ESQL/C collection variable.

For more information, including restrictions on the SELECT statement, see [Associating a Cursor with a Prepared Statement on page 480](#).

- You can use a Collection cursor to select one or more elements from an SPL collection variable.

For more information, including restrictions on the SELECT statement, see [Using a SELECT ... INTO Statement on page 1109](#).

When one of the tables to be joined is a collection, the FROM clause cannot specify a join. This restriction applies when the collection variable holds your collection-derived table. See also [Collection-Derived Table on page 1436](#), and the INSERT, UPDATE, and DELETE statement descriptions in this chapter.

## Selecting from a Row Variable (ESQL/C)

The SELECT statement can include the Collection-Derived Table segment to select one or more fields from a **row** variable.

### About this task

The Collection-Derived Table segment identifies the **row** variable from which to select the fields. For more information, see [Collection-Derived Table on page 1436](#).

To select fields:

1. Create a **row** variable in your Informix® ESQL/C program.
2. Optionally, fill the **row** variable with field values.  
You can select a ROW-type column into the **row** variable with the SELECT statement (without the Collection-Derived Table segment). Alternatively, you can insert field values into the **row** variable with the UPDATE statement and the Collection-Derived Table segment.
3. Select row fields from the **row** variable with the SELECT statement and the Collection-Derived Table segment.
4. Once the **row** variable contains the correct field values, you can use the INSERT or UPDATE statement on a table or view name to save the contents of the **row** variable in a named or unnamed row column.

## Results

The INTO clause can specify a host variable to hold a field value selected from the **row** variable.

The type of the host variable must be compatible with that of the field. For example, this code fragment puts the **width** field value into the **rect\_width** host variable.

```
EXEC SQL BEGIN DECLARE SECTION;
  ROW (x INT, y INT, length FLOAT, width FLOAT) myrect;
  double rect_width;
EXEC SQL END DECLARE SECTION;
...
EXEC SQL SELECT rect INTO :myrect FROM rectangles
  WHERE area = 200;
EXEC SQL SELECT width INTO :rect_width FROM table(:myrect);
```

The SELECT statement on a **row** variable has the following restrictions:

- No expressions are allowed in the select list of the Projection clause.
- ROW columns cannot be in a WHERE clause comparison condition.
- The Projection clause must be an asterisk ( **\*** ) if the row-type contains fields of opaque, distinct, or built-in data types.
- Columns listed in the Projection clause can have only unqualified names. They cannot use the syntax *database@server:table.column*.
- The following clauses are not allowed: GROUP BY, HAVING, INTO TEMP, ORDER BY, and WHERE.
- The FROM clause has no provisions to do a join.

You can modify the **row** variable with the Collection-Derived Table segment of the UPDATE statements. (The INSERT and DELETE statements do not support a **row** variable in the Collection-Derived Table segment.)

The **row** variable stores the fields of the row. It has no intrinsic connection, however, with a database column. Once the **row** variable contains the correct field values, you must then save the variable into the ROW column with one of the following SQL statements:

- To update the ROW column in the table with the **row** variable, use an UPDATE statement on a table or view name and specify the **row** variable in the SET clause. For more information, see [Updating ROW-Type Columns on page 1046](#).
- To insert a row into a ROW column, use the INSERT statement on a table or view and specify the **row** variable in the VALUES clause. See [Inserting Values into ROW-Type Columns on page 647](#).

For examples of how to use SPL row variables, see the *Informix® Guide to SQL: Tutorial*. For information on using Informix® ESQL/C **row** variables, see the discussion of complex data types in the *Informix® ESQL/C Programmer's Manual*.

## Iterator Functions

The FROM clause can include a call to an iterator function to specify the source for a query. An *iterator function* is a user-defined function that returns to its calling SQL statement multiple times, each time returning at least one value.

You can query the returned result set of an iterator UDR using a virtual table interface. This syntax fragment is part of the [FROM Clause on page 791](#).

Iterator

**TABLE** (

396

### FUNCTION PROCEDURE

*iterator* (

Routine Parameter List <sup>397</sup>

))

**AS**

*table*

(

, *column*

)

| Element         | Description   | Restrictions  | Syntax                                  |
|-----------------|---|---|---|
| <i>column</i>   | Name declared here for a virtual column in <i>table</i>                     | Must be unique among <i>column</i> names in <i>table</i> , and cannot include qualifiers. | <a href="#">Identifier on page 1456</a> |
| <i>iterator</i> | Name of the iterator function   | Must be registered in the database  | <a href="#">Identifier on page 1456</a> |
| <i>table</i>    | Name declared here for virtual table holding the <i>iterator</i> result set | Cannot include qualifiers   | <a href="#">Identifier on page 1456</a> |

The keyword FUNCTION (or PROCEDURE) was required in releases earlier than Informix® 10.5. These keyword extensions to the ANSI/ISO standard for SQL are optional in this release, and have no effect. The following two query specifications, which specify **fibGen()** as an iterator function, are equivalent:

```
SELECT * FROM TABLE FUNCTION ( fibGen(10));
SELECT * FROM TABLE ( fibGen(10));
```

The *table* can only be referenced within the context of this query. After the SELECT statement terminates, the virtual table no longer exists.

396. Informix® extension

397. See [Routine Parameter List on page 1514](#)

The number of columns must match the number of values returned by the iterator. An external function can return no more than one value (but that can be of a collection data type). An SPL routine can return multiple values.

The database server issues error -595, however, if any argument to the iterator *table* function is an aggregate expression.

To reference the virtual *table* columns in other parts of the SELECT statement, for example, in the WHERE clause or HAVING clause, you must declare its name and the virtual column names in the FROM clause. You do not need to declare the *table* name or *column* names in the FROM clause if you use the asterisk notation in the Select list of the Projection clause:

```
SELECT * FROM ...
```

For more information and examples of using iterator functions in queries, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

## ANSI Joins

If the FROM clause specifies more than one table reference, the query can join rows from several tables or views. A *join condition* specifies a relationship between at least one column from each table to be joined. Because the columns in a join condition are being compared, they must have compatible data types.

This syntax fragment is part of the [FROM Clause on page 791](#).

| Element                     | Description   | Restrictions  | Syntax  |
|-----------------------------|---|---|---|
|                             | FROM clause for a table or view                             |   |   |
| <i>column</i>               | Column of a table or view to be joined                      | Must exist in the table or view   | <a href="#">Identifier on page 1456</a>           |
| <i>synonym, table, view</i> | Name of a synonym, table, or view to be joined in the query | Synonym and the table or view to which it points must exist. Must include appropriate qualifiers. | <a href="#">Database Object Name on page 1450</a> |
| <i>subquery</i>             | Embedded query  | Cannot contain the FIRST or the ORDER BY clause   | <a href="#">SELECT statement on page 768</a>      |

You must use the same form of join syntax (either Informix® extension or ANSI-compliant) for all of the outer joins in the same query block. When you use the ANSI-compliant join syntax, you must also specify the join condition in the ON clause.

Rows from the tables or views are *joined* when there is a match between the values of specified columns. When the columns to be joined have the same name, you must qualify each column name with its data source. If you join a table to itself, you must list the table name twice in the FROM clause and assign it two different table aliases. Then use the aliases to qualify the column names.

By default, the order in which the database server joins tables and views is independent of the order in which they are referenced in the FROM clause. To force the order in which table objects are joined to match the FROM clause order, you can specify the ORDERED optimizer directive after the SELECT keyword. For more information, see the section [Join-Order Directive on page 1480](#).

Join-method optimizer directives that you specify for an ANSI-compliant joined query are ignored, but are listed under *Directives Not Followed* in the explain output file.

### Multiple join specifications require parentheses around the original table and join segment

The ANSI-Joined Table segment must be enclosed between parentheses if it is immediately followed by another join specification. For example, the first of the following two queries returns an error; the second query is valid:

```
SELECT * FROM (T1 LEFT JOIN T2) CROSS JOIN T3 ON (T1.c1 = T2.c5)
WHERE (T1.c1 < 100);    -- Ambiguous order of operations;

SELECT * FROM (T1 LEFT JOIN T2 ON (T1.c1 = T2.c5)) CROSS JOIN T3
WHERE (T1.c1 < 100);    -- Unambiguous order of operations;
```

The following valid query specifies nested LEFT OUTER joins of table expressions within the FROM clause of the outer SELECT statement:

```
SELECT * FROM
( (SELECT C1,C2 FROM T3) AS VT3(V31,V32)
LEFT OUTER JOIN
( (SELECT C1,C2 FROM T1) AS VT1(VC1,VC2)
LEFT OUTER JOIN
(SELECT C1,C2 FROM T2) AS VT2(VC3,VC4)
ON VT1.VC1 = VT2.VC3)
ON VT3.V31 = VT2.VC3);
```

## Join keyword definitions

In an ANSI-compliant join that specifies the LEFT, RIGHT, or FULL keywords in the FROM clause, the OUTER keyword is optional.

**Table 12. Join keywords**

| FROM Clause Keywords | Corresponding Result Set   |
|----------------------|--|
| CROSS JOIN           | The Cartesian product, which is all possible paired combinations that include one row from each of the joined tables.  |
| INNER JOIN           | All the rows in a table that have one or more matching rows in the other table (or tables). The unmatched rows are discarded.  |
| LEFT OUTER JOIN      | <p>All the rows of the first table reference and the qualifying rows from the second table reference</p> <p>The LEFT keyword specifies a join that treats the first table reference as the dominant table in the join. In a left outer join, the subordinate part of the outer join appears to the right of the keyword that begins the outer join specification. The result set includes all the rows that an INNER join returns, plus all rows that would otherwise have been discarded from the dominant table.</p>   |
| RIGHT OUTER JOIN     | <p>The qualifying rows from the first table reference and all the rows of the second table reference</p> <p>The RIGHT keyword specifies a join that treats the second table reference as the dominant table in the join. In a right outer join, the subordinate part of the outer join appears to the left of the keyword that begins the outer join specification. The result set includes all the rows that an INNER join returns, plus all rows that would otherwise have been discarded from the dominant table.</p> |
| FULL OUTER JOIN      | The union of all rows from an INNER join of the two tables, and of all rows of each table that have no match in the other table (using NULL values in the selected columns of the other table)   |

## Using the ON Clause

Use the ON clause to specify the join condition and any expressions as optional join filters.

The following example from the **stores\_demo** database illustrates how the join condition in the ON clause combines the **customer** and **orders** tables:

```
SELECT c.customer_num, c.company, c.phone, o.order_date
FROM customer c LEFT JOIN orders o
ON c.customer_num = o.customer_num;
```

The following table shows part of the joined **customer** and **orders** tables.

| customer_num | company             | phone        | order_date |
|--------------|---------------------|--------------|------------|
| 101          | All Sports Supplies | 408-789-8075 | 05/21/2008 |
| 102          | Sports Spot         | 415-822-1289 | NULL       |
| 103          | Phil's Sports       | 415-328-4543 | NULL       |
| 104          | Play Ball!          | 415-368-1100 | 05/20/2008 |
| —            | —                   | —            | —          |

In an outer join, the join filters (expressions) that you specify in the ON clause determine which rows of the subordinate table join to the dominant (or outer) table. The dominant table, by definition, returns all its rows in the joined table. That is, a join filter in the ON clause has no effect on the dominant table.

If the ON clause specifies a join filter on the dominant table, the database server joins only those dominant table rows that meet the criterion of the join filter to rows in the subordinate table. The joined result contains all rows from the dominant table. Rows in the dominant table that do not meet the criterion of the join filter are extended with NULL values for the subordinate columns.

The following example from the **stores\_demo** database illustrates the effect of a join filter in the ON clause:

```
SELECT c.customer_num, c.company, c.phone, o.order_date
FROM customer c LEFT JOIN orders o
ON c.customer_num = o.customer_num
AND c.company <> "All Sports Supplies";
```

The row that contains All Sports Supplies remains in the joined result.

| customer_num | company             | phone        | order_date |
|--------------|---------------------|--------------|------------|
| 101          | All Sports Supplies | 408-789-8075 | NULL       |
| 102          | Sports Spot         | 415-822-1289 | NULL       |
| 103          | Phil's Sports       | 415-328-4543 | NULL       |
| 104          | Play Ball!          | 415-368-1100 | 05/20/2008 |
| —            | —                   | —            | —          |

Even though the order date for customer number 101 is 05/21/2008 in the **orders** table, the effect of placing the join filter (`c.company <> "All Sports Supplies"`) prevents this row in the dominant **customer** table from being joined to the subordinate **orders** table. Instead, a NULL value for **order\_date** is extended to the row of All Sports Supplies.

Applying a join filter to a base table in the subordinate part of an outer join can improve performance. For more information, see your *Informix® Performance Guide*.

## Specifying a Post-Join Filter

When you use the ON clause to specify the join, you can use the WHERE clause as a post-join filter. The database server applies the post-join filter of the WHERE clause to the results of the outer join.

The following example illustrates the use of a post-join filter. This query returns data from the **stores\_demo** database. Suppose you want to determine which items in the catalog are not being ordered. The next query creates an outer join of the data from the **catalog** and **items** tables and then determines which catalog items from a specific manufacturer (HRO) have not sold:

```
SELECT c.catalog_num, c.stock_num, c.manu_code, i.quantity
FROM catalog c LEFT JOIN items i
ON c.stock_num = i.stock_num AND c.manu_code = i.manu_code
WHERE i.quantity IS NULL AND c.manu_code = "HRO";
```

The WHERE clause contains the post-join filter that locates the rows of HRO items in the catalog for which nothing has been sold.

When you apply a post-join filter to a base table in the dominant or subordinate part of an outer join, you might improve performance. For more information, see your *Informix® Performance Guide*.

## Using a Join as the Dominant or Subordinate Part of an Outer Join

With the ANSI join syntax, you can nest joins. You can use a join as the dominant or subordinate part of an outer or inner join.

Suppose you want to modify the previous query (the post-join filter example) to get more information that will help you determine whether to continue carrying each unsold item in the catalog. You can modify the query to include information from the **stock** table so that you can see a short description of each unsold item with its cost:

```
SELECT c.catalog_num, c.stock_num, s.description, s.unit_price,
       s.unit_descr, c.manu_code, i.quantity
FROM (catalog c INNER JOIN stock s
ON c.stock_num = s.stock_num
AND c.manu_code = s.manu_code)
LEFT JOIN items i
ON c.stock_num = i.stock_num
AND c.manu_code = i.manu_code
WHERE i.quantity IS NULL
AND c.manu_code = "HRO";
```

In this example, an inner join between the **catalog** and **stock** tables forms the dominant part of an outer join with the **items** table.

For additional examples of outer joins, see the *Informix® Guide to SQL: Tutorial*.

## Informix®-Extension Outer Joins

The Informix®-extension syntax for outer joins begins with an implicit left outer join. That is, you begin the Informix®-extension outer join with the OUTER keyword.

This syntax fragment is part of the [FROM Clause on page 791](#).

Informix® OUTER Clause

**OUTER**

ANSI Tables <sup>405</sup>

Other Tables <sup>405</sup>

```
(
,
,
ANSI Tables 405
Other Tables 405
,
406 Informix® OUTER Clause
406 Informix® OUTER Clause
,
,
ANSI Tables 405
Other Tables 405
)
```

The following example uses the OUTER keyword to create an outer join that lists all customers and their orders, regardless of whether they have placed orders:

```
SELECT c.customer_num, c.lname, o.order_num FROM customer c,
       OUTER orders o WHERE c.customer_num = o.customer_num;
```

This example returns all the rows from the **customer** table with the rows that match in the **orders** table. If no record for a customer appears in the **orders** table, the returned **order\_num** column for that customer has a NULL value.

If you have a complex outer join, that is, the query has more than one outer join, you must either embed the additional outer join or joins in parentheses, as the syntax diagram shows, or establish join conditions, or relationships, between the dominant table and each subordinate table in the WHERE clause.

When an expression or a condition in the WHERE clause relates two subordinate tables, you must use parentheses around the joined tables in the FROM clause to enforce dominant-subordinate relationships, as in this example:

```
SELECT c.company, o.order_date, i.total_price, m.manu_name
       FROM customer c,
            OUTER (orders o, OUTER (items i, OUTER manufact m))
       WHERE c.customer_num = o.customer_num
            AND o.order_num = i.order_num
            AND i.manu_code = m.manu_code;
```

When you omit parentheses around the subordinate tables in the FROM clause, you must establish join conditions between the dominant table and each subordinate table in the WHERE clause. If a join condition is between two subordinate tables, the query fails.

The following example, however, successfully returns a result

405. See [FROM Clause on page 791](#)

406. Informix® extension

- that joins the dominant **customer** table with the subordinate **orders** table,
- and joins the dominant **customer** table with the subordinate **cust\_calls** table:

```
SELECT c.company, o.order_date, c2.call_descr
FROM customer c, OUTER orders o, OUTER cust_calls c2
WHERE c.customer_num = o.customer_num
AND c.customer_num = c2.customer_num;
```

The *Informix® Guide to SQL: Tutorial* has examples of complex outer joins.

### Restrictions on Informix®-extension outer joins

If you use this Informix®-extension syntax for an outer join, all of the following restrictions apply to the same SELECT statement:

- You must use Informix®-extension syntax for all outer joins in a single query block.
- You must include the join condition in the WHERE clause.
- You cannot begin another outer join with the LEFT JOIN or the LEFT OUTER JOIN keywords.
- You cannot define a lateral table reference or include the LATERAL keyword.
- Within the Informix®-extension outer join, the Table Reference syntax segment cannot include a lateral table reference that is declared in the same SELECT statement.

## GRID clause

Use the GRID clause to specify the scope of a cross-server query whose data sources are tables of database servers that are nodes of a grid.

The GRID clause is not valid unless the session is connected to a database within an existing grid. A grid can be created by using appropriate cdr commands and ifx\_grid routines of the Enterprise Replication facility.

This syntax is an extension to the ANSI/ISO standard for the SQL language.

This syntax fragment is part of the [SELECT statement on page 768](#).

GRID clause

**GRID ALL** '

*grid region*

,

| Element       | Description  | Restrictions  | Syntax                                  |
|---------------|--|---|---|
| <i>grid</i>   | Name of the grid that is in scope for this query   | Must exist and must be defined by the cdr define grid command   | <a href="#">Identifier on page 1456</a> |
| <i>region</i> | Name of the region that is in scope for this query | Must exist and must be defined by the cdr define region command | <a href="#">Identifier on page 1456</a> |

## Usage

Any SELECT statement that explicitly or implicitly includes the GRID clause is called a *grid query*. The result of a grid query are qualifying rows from a logical UNION or UNION ALL of each table in the FROM clause across tables with the same names and the same schema in every grid server. This union can include tables across all nodes in the grid, or across a subset of those grid nodes, called a *region*.

**Note:** The tables that the FROM clause of a grid query specifies must all have the same schema and must meet other requirements that this topic identifies. Because of these restrictions, not all Informix® grids can support grid queries.

## The optional ALL keyword

If the optional ALL keyword immediately follows the GRID keyword, the result of the grid query is a logical UNION ALL, meaning that the result set of the grid query can include duplicate rows. Otherwise, if you omit the ALL keyword, only distinct values are returned from the logical UNION of the results from each participating grid server.

## SET ENVIRONMENT statement options for grid queries

Two options to the SET ENVIRONMENT statement can define a default GRID clause, so that any subsequent SELECT statements with no GRID clause is interpreted as grid query that includes the default GRID clause:

### SET ENVIRONMENT SELECT\_GRID

This statement can specify a grid or region as the default scope of subsequent grid queries that return the union of unique qualifying rows. The GRID clause can omit the grid or region name for grid queries that return UNION results for the specified default nodes.

### SET ENVIRONMENT SELECT\_GRID\_ALL

This statement can specify a grid or region as the default scope of subsequent grid queries that return the union of all qualifying rows, including duplicates. The GRID clause can omit the grid or region name for grid queries that return UNION ALL results for the specified default nodes.

While either of these options to the SET ENVIRONMENT statement is enabled, the SQL parser applies the current default GRID clause to every SELECT statement in the session that does not include an explicit GRID clause. No more than one default GRID clause can be in effect during the same session at the same point in time. When either option is in effect, using the SET ENVIRONMENT statement to set the other keyword option, or to reset the same keyword option for a different grid or region disables the previously set default.

You can also disable the default GRID clause by issuing either of these SQL statements:

```
SET ENVIRONMENT SELECT_GRID DEFAULT;_
SET ENVIRONMENT SELECT_GRID_ALL DEFAULT;
```

Each of the statements above prevents the database server from interpreting every subsequent query in the current session as a grid query. Unless you define a new default GRID clause in the same session, any subsequent SELECT statement must include an explicit GRID clause to run as a grid query.

While either the SELECT\_GRID session environment option for UNION queries or the SELECT\_GRID\_ALL session environment option for UNION ALL queries has specified a default grid or region as the scope of grid queries in the current session, you

can omit the GRID clause in grid queries on the nodes of that grid or region, as in the following example, where **tab1** and **tab2** are tables that have the same schema, locale, and code set on every grid server within the **region\_03** subset of a grid:

```
SET ENVIRONMENT SELECT_GRID 'region_03'
SELECT * FROM tab1;
SELECT * FROM tab2;
```

The two queries above are executed as if you had explicitly specified this GRID clause:

```
SELECT * FROM tab1 GRID 'region_03';
SELECT * FROM tab2 GRID 'region_03';
```

No more than one of the SELECT\_GRID and SELECT\_GRID\_ALL session environment options to the SET ENVIRONMENT statement can be enabled for the current user session at the same point in time. When either option is in effect, using the SET ENVIRONMENT statement to set the other keyword option, or to reset the same keyword option for a different grid or region disables the previously set default.

The following SQL statements replace the previous default GRID clause by defining a different default GRID clause that combines the UNION ALL results from participating grid servers in a different region, the **region\_04** subset of a grid:

```
SET ENVIRONMENT SELECT_GRID_ALL 'region_04'
SELECT * FROM tab1;
SELECT * FROM tab2;
```

Those two queries will be executed as if you had specified this GRID clause:

```
SELECT * FROM tab1 GRID ALL 'region_04';
SELECT * FROM tab2 GRID ALL 'region_04';
```

By default, a grid query fails if the database server that issues the grid query cannot connect to one or more of the nodes within the grid or region that the explicit or default GRID clause specifies. Another session environment variable that the SET ENVIRONMENT statement can enable can return partial results from a grid query, even if some grid servers in the specified grid or region are unavailable:

#### **SET ENVIRONMENT GRID\_NODE\_SKIP**

This statement can enable processing of a grid query to continue when one or more of the grid servers is unavailable.

If you issue the SQL statement

```
SET ENVIRONMENT GRID_NODE_SKIP ON;
```

the database server ignores any node which is not available, and returns qualifying rows from the participating grid servers. You can identify any skipped nodes by invoking the `ifx_gridquery_skipped_nodes()` function.

Another function, `ifx_gridquery_skipped_node_count()`, can be used to detect how many nodes were skipped. For more information about these functions, see the .

#### **Tables in the FROM clause of grid queries**

Only permanent database tables are valid in the FROM clause of a grid query. They must be defined as grid tables by running the `cdr change gridtable` command.

The following table objects are not supported:

- Synonyms or views on tables, except for tables in the **sysmaster** database
- Table objects that the CREATE EXTERNAL TABLE statement defined
- Tables that are qualified by the name of a database server or grid server
- Tables on which a concurrent ALTER TABLE, ALTER FRAGMENT, or ALTER INDEX operation is being performed
- Tables that have a different schema from other tables of the same name in databases of participating grid servers
- Tables in databases that were not created with the same database locale and code set
- Tables in databases whose settings for the SQL\_LOGICAL\_CHAR configuration parameter or the **DELIMIDENT** or **GL\_USEGLU** environment variables are not the same across all databases participating in the grid query.

In addition, the projection list of a grid query cannot include any column or expression whose data type is not supported in cross-server queries. The unsupported data types include all complex or large-object types, and some user-defined types (UDTs) and opaque types.

The same restrictions that apply to DISTINCT data types in distributed DML operations across databases of the same Informix® instance also apply to DISTINCT data types in grid queries. For a discussion of the data types that are valid in distributed queries, see the topics [Data Types in Cross-Server Transactions on page 781](#) and [DISTINCT Types in Distributed Operations on page 1184](#).

### **Additional restrictions on grid queries**

The user executing the grid query must be a valid user on all nodes within the grid or region.

A grid query cannot be a subquery that contains references to its outer query.

The grid query cannot reference any of the following among its specifications:

- A subquery (but the grid query itself can be a subquery of an outer query that it does not reference)
- A join operation across grid servers
- Connection requests that result in cross-server joins
- A procedure or function that does not exist on all participating grid servers.

Neither the UNION nor UNION ALL set operators, nor the INTERSECT, MINUS, or EXCEPT set operators, are valid in a grid query block.

The GRID clause should not be included in SELECT statements outside a grid context. For more information about grids, see the [SET ENVIRONMENT statement on page 900](#) and the .

## WHERE clause of SELECT

The WHERE clause can specify join conditions for Informix®-extension joins, post-join filters for ANSI-compliant joins, and for search criteria on data values.

This syntax fragment is part of the [SELECT statement on page 768](#).

WHERE Clause

### WHERE

Logical\_Operator

Condition <sup>407</sup>

Join <sup>408</sup>

Function Expression <sup>409</sup>

( *subquery* )

(

Collection Subquery <sup>410</sup>

)

Statement Local Variable Expressions <sup>411</sup>

| Element                 | Description             | Restrictions  | Syntax   |
|-------------------------|-------------------------|---|--|
| <i>Logical_Operator</i> | Combines two conditions | Valid options are <i>logical union</i> (= OR or OR NOT) or <i>logical intersection</i> (= AND or AND NOT) | <a href="#">Conditions with AND or OR on page 1162</a> |
| <i>subquery</i>         | Embedded query          | Cannot include the FIRST or ORDER BY keywords   | <a href="#">SELECT statement on page 768</a>           |

## Using a Condition in the WHERE Clause

You can use these simple conditions or comparisons in the WHERE clause:

- Relational-operator condition
- IN or BETWEEN . . . AND
- IS NULL or IS NOT NULL
- LIKE or MATCHES

You also can use a SELECT statement within the WHERE clause; this is called a *subquery*. The following WHERE clause operators are valid in a subquery:

407. See [Condition on page 1144](#)

408. See [Specifying a Join in the WHERE Clause on page 818](#)

409. See [Function Expressions on page 1252](#)

410. See [Collection Subquery on page 1141](#)

411. See [Statement-Local Variable Expressions on page 1365](#)

The following examples show the IN condition:

```
SELECT lname, fname, company FROM customer
   WHERE state IN ('CA','WA', 'NJ');
SELECT * FROM cust_calls
   WHERE user_id NOT IN (USER );
```

For more information, see the [IN Subquery on page 1159](#).

## BETWEEN Condition

The BETWEEN condition is satisfied when the value to the left of BETWEEN is in the inclusive range of the two values on the right of BETWEEN. The first two queries in the following example use literal values after the BETWEEN keyword. The third query uses the built-in CURRENT function and a literal interval to search for dates between the current day and seven days earlier.

```
SELECT stock_num, manu_code FROM stock
   WHERE unit_price BETWEEN 125.00 AND 200.00;
SELECT DISTINCT customer_num, stock_num, manu_code
   FROM orders, items
   WHERE order_date BETWEEN '6/1/07' AND '9/1/07';
SELECT * FROM cust_calls WHERE call_dtime
   BETWEEN (CURRENT - INTERVAL(7) DAY TO DAY) AND CURRENT;
```

For more information, see the [BETWEEN Condition on page 1149](#).

## Using IS NULL and IS NOT NULL Conditions

The IS NULL condition is satisfied if the specified *column* contains a NULL value, or if the specified *expression* evaluates to NULL.

If you use the IS NOT NULL predicate, the condition is satisfied when the *column* contains a value that is not NULL, or when the *expression* does not evaluate to NULL. The following example selects the order numbers and customer numbers for which the order has not been paid:

```
SELECT order_num, customer_num FROM orders
   WHERE paid_date IS NULL;
```

For a complete description of the IS NULL and IS NOT NULL operators, see the [IS NULL and IS NOT NULL Conditions on page 1152](#).

## LIKE or MATCHES Condition

The LIKE or MATCHES condition is satisfied if either of the following is true:

- The value of the column that precedes the LIKE or MATCHES keyword matches the pattern that the quoted string specifies. You can use wildcard characters in the string.
- The value of the column that precedes the LIKE or MATCHES keyword matches the pattern that is specified by the column that follows the LIKE or MATCHES keyword. The value of the column on the right serves as the matching pattern in the condition.

The following examples use a backslash ( \ ) as the default escape character. The default escape character is set by the DEFAULTESCCHAR configuration parameter or the **DEFAULTESCCHAR** session environment option.

The following SELECT statement returns all rows in the **customer** table in which the **lname** column begins with the literal string 'Baxter'. Because the string is a literal string, the condition is case sensitive.

```
SELECT * FROM customer WHERE lname LIKE 'Baxter%' ;
```

The next SELECT statement returns all rows in the **customer** table in which the value of the **lname** column matches the value of the **fname** column:

```
SELECT * FROM customer WHERE lname LIKE fname;
```

The following examples use the LIKE condition with a wildcard. The first SELECT statement finds all stock items that are some kind of ball. The second SELECT statement finds all company names that contain a percent ( % ) sign. Backslash ( \ ) is used as the default escape character for the percent ( % ) sign wildcard. The third SELECT statement uses the ESCAPE option with the LIKE condition to retrieve rows from the **customer** table in which the **company** column includes a percent ( % ) sign. The **z** is used as an escape character for the percent ( % ) sign:

```
SELECT stock_num, manu_code FROM stock
  WHERE description LIKE '%ball';
SELECT * FROM customer WHERE company LIKE '%\%%';
SELECT * FROM customer WHERE company LIKE '%z%%' ESCAPE 'z';
```

The following examples use MATCHES with a wildcard in SELECT statements. The first SELECT statement finds all stock items that are some kind of ball. The second SELECT statement finds all company names that contain an asterisk ( \* ). The backslash ( \ ) is used as the default escape character for a literal asterisk ( \* ) character. The third statement uses the ESCAPE option with the MATCHES condition to retrieve rows from the **customer** table where the **company** column includes an asterisk ( \* ). The **z** character is specified as an escape character for the asterisk ( \* ) character:

```
SELECT stock_num, manu_code FROM stock
  WHERE description MATCHES '*ball';

SELECT * FROM customer WHERE company MATCHES '*\**';

SELECT * FROM customer WHERE company MATCHES '*z**' ESCAPE 'z';
```

For information about the supported data types of operands in LIKE or MATCHES expressions, see the topic [LIKE and MATCHES Condition on page 1154](#).

## IN Subquery

With the IN subquery, more than one row that satisfies the IN or NOT IN condition can be returned, but only one column can be returned.

This example shows the use of a NOT IN subquery in a SELECT statement:

```
SELECT DISTINCT customer_num FROM orders
WHERE order_num NOT IN
  (SELECT order_num FROM items
   WHERE stock_num = 1);
```

For additional information, see the [IN Condition on page 1151](#).

## EXISTS Subquery

From the EXISTS subquery, rows that satisfy EXISTS conditions in one or more columns can be returned. (Similarly, the NOT EXISTS subquery can return rows that satisfy NOT EXISTS conditions in one or more columns.)

The following example of a SELECT statement with a NOT EXISTS subquery returns the stock number and manufacturer code for every item that has never been ordered (and is therefore not listed in the **items** table).

It is appropriate to use a NOT EXISTS subquery in this SELECT statement because you need the correlated subquery to test both **stock\_num** and **manu\_code** in the **items** table.

```
SELECT stock_num, manu_code FROM stock
WHERE NOT EXISTS
  (SELECT stock_num, manu_code FROM items
   WHERE stock.stock_num = items.stock_num AND
         stock.manu_code = items.manu_code);
```

The preceding example would work equally well if you use a SELECT \* in the subquery in place of the column names, because you are testing for the existence of a row or rows.

For additional information, see the [EXISTS Subquery condition on page 1160](#).

## ALL, ANY, SOME Subqueries

The following examples return the order number of all orders that contain an item whose total price is greater than the total price of every item in order number 1023. The first SELECT uses the ALL subquery, and the second SELECT produces the same result by using the MAX aggregate function.

```
SELECT DISTINCT order_num FROM items
WHERE total_price > ALL (SELECT total_price FROM items
                        WHERE order_num = 1023);

SELECT DISTINCT order_num FROM items
WHERE total_price > SELECT MAX(total_price) FROM items
                    WHERE order_num = 1023);
```

The following SELECT statements return the order number of all orders that contain an item whose total price is greater than the total price of at least one of the items in order number 1023. The first SELECT statement uses the ANY keyword, and the second SELECT statement uses the MIN aggregate function:

```
SELECT DISTINCT order_num FROM items
WHERE total_price > ANY (SELECT total_price FROM items
                        WHERE order_num = 1023);
```

```
SELECT DISTINCT order_num FROM items
WHERE total_price > (SELECT MIN(total_price) FROM items
WHERE order_num = 1023);
```

You can omit the keywords ANY, ALL, or SOME in a subquery if the subquery returns exactly one value. If you omit ANY, ALL, or SOME, and the subquery returns more than one value, you receive an error. The subquery in the next example returns only one row, because it uses an aggregate function:

```
SELECT order_num FROM items
WHERE stock_num = 9 AND quantity =
(SELECT MAX(quantity) FROM items WHERE stock_num = 9);
```

See also [ALL, ANY, and SOME Subqueries on page 1161](#).

## Specifying a Join in the WHERE Clause

You join two tables by creating a relationship in the WHERE clause between at least one column from one table and at least one column from another. The join creates a temporary composite table where each pair of rows (one from each table) that satisfies the join condition is linked to form a single row.

This syntax fragment is part of the [WHERE clause of SELECT on page 813](#).

Join

Data Source

*column*

Relational Operator<sup>412</sup>

Data Source

*column*

Data Source

*alias . external . table . view . synonym .*

| Element                     | Description  | Restrictions  | Syntax  |
|-----------------------------|--|---|---|
| <i>alias</i>                | Temporary alternative name declared in the FROM clause for a table or view | See the Self joins section; <a href="#">FROM Clause on page 791</a>                               | <a href="#">Identifier on page 1456</a>           |
| <i>column</i>               | Column of a table or view to be joined                                     | Must exist in the table or view   | <a href="#">Identifier on page 1456</a>           |
| <i>external</i>             | External table from which to retrieve data                                 | External table must exist. Must include appropriate qualifiers.                                   | <a href="#">Database Object Name on page 1450</a> |
| <i>synonym, table, view</i> | Name of a synonym, table, or view to be joined in the query                | Synonym and the table or view to which it points must exist. Must include appropriate qualifiers. | <a href="#">Database Object Name on page 1450</a> |

412. See [Relational Operator on page 1429](#)

Rows from the tables or views are *joined* when there is a match between the values of specified columns. When the columns to be joined have the same name, you must qualify each column name with its data source. You can create two-table joins, multiple-table joins, self-joins, and outer joins (Informix®-extension syntax).

## Two-table joins

The following example shows a two-table join:

```
SELECT order_num, lname, fname FROM customer, orders
WHERE customer.customer_num = orders.customer_num;
```

## Multi-table joins

A multiple-table join is a join of more than two tables. Its structure is similar to the structure of a two-table join, except that you have a join condition for more than one pair of tables in the WHERE clause. When columns from different tables have the same name, you must qualify the column name with its associated table or table alias, as in *table.column*.

The following multiple-table join yields the company name of the customer who ordered an item as well as its stock number and manufacturer code:

```
SELECT DISTINCT company, stock_num, manu_code
FROM customer c, orders o, items i
WHERE c.customer_num = o.customer_num
AND o.order_num = i.order_num;
```

## Self joins

You can join a table to itself. To do so, you must list the table name twice in the FROM clause and assign it two different table aliases. Use the aliases to refer to each of the *two* tables in the WHERE clause. The next example is a self-join on the **stock** table. It finds pairs of stock items whose unit prices differ by a factor greater than 2.5. The letters **x** and **y** are each aliases for the **stock** table.

```
SELECT x.stock_num, x.manu_code, y.stock_num, y.manu_code
FROM stock x, stock y WHERE x.unit_price > 2.5 * y.unit_price;
```

## Informix®-extension outer joins

The next outer join lists the company name of the customer and all associated order numbers, if the customer has placed an order. If not, the company name is still listed, and a NULL value is returned for the order number.

```
SELECT company, order_num FROM customer c, OUTER orders o
WHERE c.customer_num = o.customer_num;
```

For the syntax of outer joins, see [Informix-Extension Outer Joins on page 807](#).

## Hierarchical Clause

The Hierarchical clause sets the conditions for recursive queries on a table object in which a hierarchy of parent-child dependencies exists among the rows. SELECT statements that include this clause are called *hierarchical queries*.

The table object on which the hierarchical query operates must be specified in the FROM clause of the SELECT statement. The table object is typically a self-referencing table in which one or more columns acts as a foreign key constraint for another column (or for a subset of the columns) in the same table.

A hierarchical query operates on rows in which one or more column values correspond to nodes within a logical structure of parent-child relationships. If parent rows have multiple children, sibling relationships exist among child rows of the same parent. These relationships might reflect, for example, the reporting structure among employees and managers within the divisions and management levels of an organization.

The syntax that this clause supports is an extension to the ANSI/ISO standard for SQL. This syntax fragment is part of the [SELECT statement on page 768](#).

Hierarchical Clause

START WITH Clause <sup>413</sup>

CONNECT BY Clause <sup>414</sup>

The table object on which the hierarchical query operates must be specified in the FROM clause of the SELECT statement. The table object can be any of the following table objects:

- A table or updateable view
- A temporary table
- A table in another database of the same Informix® instance to which the session is connected
- A derived table that is the result of a query
- A table that is protected by a label-based access control (LBAC) security policy
- A table with column level encryption or row level encryption
- A synonym for any of the other table objects.

The following table objects are not supported in the FROM clause of a hierarchical query:

- A join of two or more tables
- A view that is not updatable
- A table in a database of a remote Informix® instance
- An external table that the CREATE EXTERNAL TABLE statement defined
- A sequence object.

Informix® supports sequence objects in the projection list of hierarchical queries, in the WHERE clause, and in other contexts where an expression is valid in SELECT statements, but not in the hierarchical query clause.

The hierarchical clause is valid in correlated subqueries and in uncorrelated subqueries.

Hierarchical queries can include all types of optimizer directives, with these exceptions:

- Join-order directives
- Join-method directives

Hierarchical queries do not support the Parallel Database Query (PDQ) feature of Informix®.

413. See [START WITH Clause on page 824](#)

414. See [CONNECT BY Clause on page 824](#)

The Hierarchical clause can specify recursive queries on a table whose rows describe a hierarchy of parent-child relationships.

- The hierarchy can be a simple hierarchy, such as the reporting structure of an organization in which every node that is not the root reports to a single node at higher level within the hierarchy. (In the LBAC security feature of Informix®, a security label component of type TREE has the logical structure of a simple hierarchy.)
- The Hierarchical clause can query data hierarchies of more complex topologies, in which nodes have many-to-many relationships, and in which a child node can be the ancestor of its parent. For information about using the Hierarchical clause to query a table that has cycles within the data hierarchy, see [CONNECT BY Clause on page 824](#).

**Important:** Hierarchical queries are most efficient for data sets in which parent-child dependencies in the table have the logical topology of a simple graph. If the self-referencing table includes more than one independent hierarchy for the same set of columns, or if any child row is also an ancestor of its parent, see [Dependency patterns that are not a simple graph on page 832](#).

**Note:** The Hierarchical clause is unrelated to table hierarchies, in which a hierarchy of parent-child relationships exist among the schemas of a set of typed tables. Similarly, the hierarchy of a set of DISTINCT data types that all derive from a common base type resembles a data hierarchy, but is unrelated to the Hierarchical clause, where the hierarchy exists in parent-child dependencies between data entities, rather than relationships among data types.

### SQL Syntax Specific to Hierarchical Queries

Besides the START WITH, CONNECT BY, and CONNECT NOCYCLE BY keywords that specify the conditions for recursive queries of a table that contains hierarchical data, hierarchical queries also support syntax tokens that are valid only in hierarchical queries, and that cannot be used in SELECT statements that have no CONNECT BY clause. Syntax tokens specific to hierarchical queries include two operators, three pseudocolumns, and a built-in function:

- CONNECT\_BY\_ROOT operator  
This operator can return an expression for the root ancestor of its operand.
- PRIOR operator  
This operator can reference a returned value from the previous recursive step (where "step" refers to an iteration of the recursive query).
- LEVEL pseudocolumn  
This pseudocolumn returns an integer, indicating which step of the recursive query returned a row within the hierarchy.
- CONNECT\_BY\_ISCYCLE pseudocolumn  
This pseudocolumn can indicate whether a row has a child row that is also its ancestor.
- CONNECT\_BY\_ISLEAF pseudocolumn  
This pseudocolumn can indicate whether a row has any children among the rows that the query returns.
- SYS\_CONNECT\_BY\_PATH function

This function can construct and return a string that represents the path from a specified row to the root of the hierarchy

- SIBLINGS keyword in the ORDER BY clause

The ORDER SIBLINGS BY clause can sort returned rows for siblings of the same parent at every level.

A *pseudocolumn* is a built-in identifier that the SQL parser can recognize in specific contexts, and that shares the same namespace as columns and variables. These pseudocolumns and the SYS\_CONNECT\_BY\_PATH function are typically specified in the Projection clause of the SELECT statement, but the LEVEL pseudocolumn and the PRIOR operator can be specified in the Hierarchical clause.

For details of the syntax and semantics of these tokens that support only hierarchical queries, see [Conditions in the CONNECT BY Clause on page 826](#) and [ORDER SIBLINGS BY Clause on page 846](#).

### Overview of Hierarchical Queries

The clauses of a SELECT statement that includes the Hierarchical clause are processed in the following sequence:

1. FROM clause (for only a single table object in the current database)
2. Hierarchical clause
3. WHERE clause (without join predicates)
4. GROUP BY clause
5. HAVING clause
6. Projection clause
7. ORDER BY clause

The ORDER BY SIBLING option of the ORDER BY clause can order the set of rows that are children of the same parent.

A subquery that includes the Hierarchical clause returns the intermediate result set in a partial order, where the rows produced in iteration (n+1) for a specific hierarchy immediately follow the row in iteration (n) that produced them. However, specifying an ORDER BY clause, a GROUP BY or HAVING clause, or the DISTINCT or UNIQUE keyword in the Projection clause destroys that partial order.

The Hierarchical clause follows the WHERE clause in the lexical sequence of SELECT statement clauses, but the WHERE clause predicates are processed on the result of the Hierarchical clause. The WHERE clause cannot specify join predicates if the SELECT statement includes the Hierarchical clause, but the table object that is specified in the FROM clause can be the result set of a query that joins one or more tables.

Any SELECT statement that includes a hierarchical-query-clause is called a hierarchical query, which performs a recursive series of queries on the table that the FROM clause specifies:

1. The optional START WITH clause can specify a condition. Any rows that satisfy this condition are returned as the first intermediate result set of the hierarchical query.
2. The next step applies the condition that is specified in the CONNECT BY clause to the table. Any rows that satisfy that condition are returned as the second intermediate result set.
3. The next step applies the CONNECT BY condition to the table. Any rows that are returned comprise the third intermediate result set.

4. The CONNECT BY clause runs queries recursively to produce successive intermediate result sets, until an iteration yields an empty result set.
5. The hierarchical SELECT statement then combines all of the intermediate result sets of the preceding recursive steps, producing the final result set of the Hierarchical clause.
6. The predicates of the WHERE clause are then applied to this set of rows that the Hierarchical clause retrieved, and the remaining clauses of the SELECT statement are then applied in the order listed.

After the START WITH and CONNECT BY clauses return all of the intermediate result sets, you can use the ORDER SIBLINGS BY clause to sort the sibling rows that have the same parent for every level within the hierarchy. For more information, see [ORDER SIBLINGS BY Clause on page 846](#).

You can use output from the SET EXPLAIN statement to view the execution path of a hierarchical query.

The Hierarchical clause provides an efficient alternative to using the Node database extension to retrieve information from hierarchical data sets

### Example of a Hierarchical Data Set

In several topics that follow, SQL code examples that illustrate hierarchical queries are based on hierarchic data in the following **employee** table, whose rows contains information about employees within an organizational hierarchy. The **mgrid** column shows the employee identifier (**empid**) of the manager to whom the employee reports:

```
CREATE TABLE employee(
    empid INTEGER NOT NULL PRIMARY KEY,
    name  VARCHAR(10),
    salary DECIMAL(9, 2),
    mgrid INTEGER
);
```

Data values for the 17 rows in the **employee** table are these.

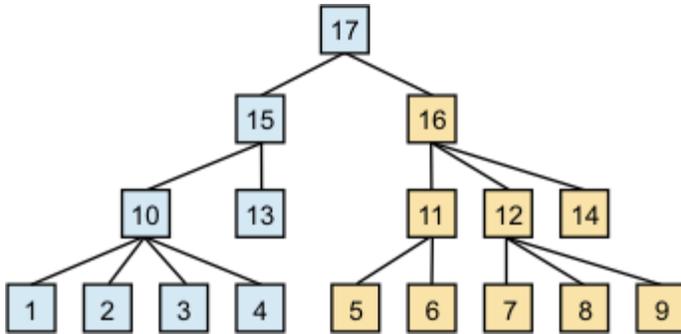

```
INSERT INTO employee VALUES ( 1, 'Jones', 30000, 10);
INSERT INTO employee VALUES ( 2, 'Hall', 35000, 10);
INSERT INTO employee VALUES ( 3, 'Kim', 40000, 10);
INSERT INTO employee VALUES ( 4, 'Lindsay', 38000, 10);
INSERT INTO employee VALUES ( 5, 'McKeough', 42000, 11);
INSERT INTO employee VALUES ( 6, 'Barnes', 41000, 11);
INSERT INTO employee VALUES ( 7, 'O'Neil', 36000, 12);
INSERT INTO employee VALUES ( 8, 'Smith', 34000, 12);
INSERT INTO employee VALUES ( 9, 'Shoeman', 33000, 12);
INSERT INTO employee VALUES (10, 'Monroe', 50000, 15);
INSERT INTO employee VALUES (11, 'Zander', 52000, 16);
INSERT INTO employee VALUES (12, 'Henry', 51000, 16);
INSERT INTO employee VALUES (13, 'Aaron', 54000, 15);
INSERT INTO employee VALUES (14, 'Scott', 53000, 16);
INSERT INTO employee VALUES (15, 'Mills', 70000, 17);
INSERT INTO employee VALUES (16, 'Goyal', 80000, 17);
INSERT INTO employee VALUES (17, 'Urbassek', 95000, NULL);
```

Each pair of **empid** and **mgrid** values express referential relationships that the recursive iterations of a query with an appropriate CONNECT BY condition can correctly assemble into a hierarchy.

Here the NULL value in the **mgrid** column in the last row shows that employee **Urbassek**, whose **empid** value is 17 is the root node of this reporting hierarchy.

The following diagram illustrates the four levels of the reporting hierarchy (with nodes that show the **empid** values) for the **employee** table data:

Figure 9. Relationships of Elements in a Reporting Hierarchy

## START WITH Clause

The optional **START WITH** clause specifies a condition. The row that satisfies this condition becomes the root for beginning the recursive operations of the **CONNECT BY** clause in hierarchical queries.

The **START WITH** clause is an extension to the ANSI/ISO standard for SQL. This syntax fragment is part of the [Hierarchical Clause on page 819](#).

**START WITH** Clause

**START WITH** Condition <sup>415</sup>

### Usage

The **START WITH** clause specifies a search condition that the **CONNECT BY** clause uses for the first iteration of its recursive actions. If you omit the **START WITH** clause, the **CONNECT BY** clause treats every row as the root of the hierarchy for the initial set of intermediate results.

## CONNECT BY Clause

The **CONNECT BY** clause specifies conditions for performing recursive operations in hierarchical queries.

The **CONNECT BY** clause is an extension to the ANSI/ISO standard for SQL. This syntax fragment is part of the [Hierarchical Clause on page 819](#).

**CONNECT BY** Clause

**CONNECT BY NOCYCLE** Condition <sup>416</sup>

415. See [Condition on page 1144](#)

416. See [Condition on page 1144](#)

## Usage

If you include the `START WITH` clause, the search condition that it specifies is applied in producing the first intermediate result set for the hierarchical query. This consists of the rows of the table specified in the `FROM` clause for which the `START WITH` condition is true.

If the `START WITH` clause is omitted, no `START WITH` condition is available as a filter, and the first intermediate result set is the entire set of rows in the table that the `FROM` clause specifies.

The `CONNECT BY` clause produces successive intermediate result sets by applying the `CONNECT BY` search condition until this recursive process terminates when an iteration yields an empty result set.

## The NOCYCLE Keyword

Rows returned by recursive queries of the `CONNECT BY` clause must be part of a simple hierarchy. `SELECT` statements that include the `Hierarchical` clause fail with an error if the query returns a row that is both the ancestor and the descendant of another node. This topology is called a cycle.

You can include the `NOCYCLE` keyword between the `CONNECT BY` keywords and the condition specification of the `CONNECT BY` clause to filter out any rows that would otherwise cause the hierarchical query to fail with error -26079 because of a cycle in an intermediate result set.

For example, for the hierarchical data set of the `employee` table that is described in the topic [Hierarchical Clause on page 819](#), the following `UPDATE` statement introduces a cycle for the employees whose `empid` values are 5 and 17:

```
UPDATE employee SET mgrid = 5 WHERE name = 'Urbassek';
```

After the hierarchical data set has been modified by the `UPDATE` statement above, the following query (which omits the `NOCYCLE` keyword) fails:

```
SELECT empid, name, mgrid , CONNECT_BY_ISLEAF leaf
FROM employee
START WITH name = 'Goyal'
CONNECT BY PRIOR empid = mgrid;
```

Error -26079 is issued when the last `CONNECT BY` step detects that employee **McKeough** is part of a loop:

| empid | name     | mgrid | leaf |
|-------|----------|-------|------|
| 16    | Goyal    | 17    | 0    |
| 14    | Scott    | 16    | 1    |
| 12    | Henry    | 16    | 0    |
| 9     | Shoeman  | 12    | 1    |
| 8     | Smith    | 12    | 1    |
| 7     | O'Neil   | 12    | 1    |
| 11    | Zander   | 16    | 0    |
| 6     | Barnes   | 11    | 1    |
| 5     | McKeough | 11    | 0    |

```
26079: CONNECT BY query resulted in a loop/cycle.
Error in line 8
Near character position 28
```

You can include the `NOCYCLE` keyword between the `CONNECT BY` keywords and the *condition* specification of the `CONNECT BY` clause to filter out any rows that would otherwise cause the hierarchical query to fail with error -26079 because of a cycle

in an intermediate result set. The following query differs from the query that failed by including the `CONNECT_BY_ISCYCLE` pseudocolumn in the Projection clause, and by including the `NOCYCLE` keyword in the `CONNECT BY` clause.

```
SELECT empid, name, mgrid, CONNECT_BY_ISLEAF leaf, CONNECT_BY_ISCYCLE cycle
FROM employee
START WITH name = 'Goyal'
CONNECT BY NOCYCLE PRIOR empid = mgrid;
```

| empid | name     | mgrid | leaf | cycle |
|-------|----------|-------|------|-------|
| 16    | Goyal    | 17    | 0    | 0     |
| 14    | Scott    | 16    | 1    | 0     |
| 12    | Henry    | 16    | 0    | 0     |
| 9     | Shoeman  | 12    | 1    | 0     |
| 8     | Smith    | 12    | 1    | 0     |
| 7     | O'Neil   | 12    | 1    | 0     |
| 11    | Zander   | 16    | 0    | 0     |
| 6     | Barnes   | 11    | 1    | 0     |
| 5     | McKeough | 11    | 0    | 0     |
| 17    | Urbassek | 5     | 0    | 1     |
| 15    | Mills    | 17    | 0    | 0     |
| 13    | Aaron    | 15    | 1    | 0     |
| 10    | Monroe   | 15    | 0    | 0     |
| 4     | Lindsay  | 10    | 1    | 0     |
| 3     | Kim      | 10    | 1    | 0     |
| 2     | Hall     | 10    | 1    | 0     |
| 1     | Jones    | 10    | 1    | 0     |

17 row(s) retrieved.

Because the `NOCYCLE` keyword enabled the `CONNECT BY` clause to continue processing after the cycle was detected, **Urbassek** was returned from the `CONNECT BY` step that had failed in the previous example, and processing continued until all of the rows in the data set had been returned. In the output display above, **leaf** is an alias for the `CONNECT_BY_ISLEAF` pseudocolumn, and **cycle** is an alias for the `CONNECT_BY_ISCYCLE` pseudocolumn, with both aliases declared in the Projection clause. In these results, **Urbassek** is marked in the **cycle** column as the cause of the loop.

The result set above implies that the cycle can be removed from the **employee** table by changing the **mgrid** value in the row that had identified **McKeough** as the manager of **Urbassek**:

```
UPDATE employee SET mgrid = NULL WHERE empid = 17;
```

## Conditions in the CONNECT BY Clause

Besides expressions and operators that are valid in Boolean conditions and in general SQL expressions, the *condition* that is specified in `CONNECT BY` clause supports two more syntax constructs, the `PRIOR` operator and the `LEVEL` pseudocolumn that are valid only in `SELECT` statements that include the Hierarchical clause.

### The PRIOR Operator

The `PRIOR` unary operator can be included in the `CONNECT BY` clause with a column name as its operand. `PRIOR` can be used to distinguish column references to the result of the most recent previous recursive step of the `CONNECT BY` clause

from column references to the current result set. The column name immediately follows this right-associative operator, as in the following syntax fragment:

```
CONNECT BY mgrid = PRIOR empid
```

Here the CONNECT BY condition is satisfied by those rows in which the manager specified in the **mgrid**, column matches the employee value was in the **empid** column in the previous iteration.

The PRIOR operator can be applied to expressions more complex than column names. The following condition uses an arithmetic expression as the operand of PRIOR:

```
CONNECT BY PRIOR (salary - 10000) = salary
```

The PRIOR operator can be included more than once in the same CONNECT BY condition. See also the topic [Hierarchical Clause on page 819](#), which provides an example of a hierarchical query that uses the PRIOR operator in a condition of the CONNECT BY clause.

### The LEVEL Pseudocolumn

A *pseudocolumn* is a keyword of SQL that shares the same namespace as column names, and that is valid in some contexts where a column expression is valid.

LEVEL is a pseudocolumn that returns the ordinal number of the recursive step in the Hierarchic clause that returned the row. For all the rows returned by the START WITH clause, LEVEL return the value 1. Rows that are returned by applying the first iteration of the CONNECT BY clause return 2. Rows that are returned by successive iterations of the CONNECT BY have LEVEL values incremented by 1, so that LEVEL = (N + 1) indicates a row that the Nth CONNECT BY iteration returned. The data type of the LEVEL column is INTEGER.

The following example of a hierarchical query specifies LEVEL in the select list of the Projection clause:

```
SELECT name, LEVEL FROM employee START WITH name = 'Goyal'
CONNECT BY PRIOR empid = mgrid;
```

The query returns these results:

| name     | level |
|----------|-------|
| Goyal    | 1     |
| Zander   | 2     |
| McKeough | 3     |
| Barnes   | 3     |
| Henry    | 2     |
| O'Neil   | 3     |
| Smith    | 3     |
| Shoeman  | 3     |
| Scott    | 2     |

9 row(s) retrieved.

LEVEL can be included in the Projection clause of SELECT statements that include the Hierarchical clause, and in the *condition* of the CONNECT BY clause.

The LEVEL pseudocolumn is not valid, however, in the following contexts:

- A SELECT statement that has no CONNECT BY clause
- The START WITH *condition* of the Hierarchical clause
- An operand of the CONNECT\_BY\_ROOT operator
- An argument to the SYS\_CONNECT\_BY\_PATH function.

### Additional Syntax Valid Only in Hierarchical Queries

The following syntax tokens support hierarchical queries, and are valid only in hierarchical queries. Unlike the PRIOR operator and the LEVEL pseudocolumn, however, they are not valid in the Hierarchical clause:

- The CONNECT\_BY\_ISCYCLE pseudocolumn
- The CONNECT\_BY\_ISLEAF pseudocolumn
- The CONNECT\_BY\_ROOT unary operator
- The SYS\_CONNECT\_BY\_PATH() function of SQL.

### The CONNECT\_BY\_ISCYCLE Pseudocolumn

CONNECT\_BY\_ISCYCLE is a pseudocolumn that returns a `1` if the row would cycle at the next level in the hierarchy. That is, the row has an immediate child that is also an ancestor given the search-condition that is specified in the CONNECT BY clause. If the row does not directly cause a cycle, the column returns `0`. A value other than `0` is only possible when NOCYCLE is specified in the CONNECT BY clause. The data type of this column is INTEGER.

The following UPDATE statement creates a loop in the data hierarchy of the **employee** table:

```
UPDATE employee SET mgrid = 5 WHERE empid = 17;
```

The following hierarchical query includes the CONNECT\_BY\_ISCYCLE pseudocolumn in the Projection clause, but the CONNECT BY clause throws an error in the step where it encounters the loop that the UPDATE statement created.

```
SELECT empid,
       name,
       mgrid,
       CONNECT_BY_ISLEAF leaf,
       CONNECT_BY_ISCYCLE cycle
FROM   employee
START WITH name = 'Goyal'
CONNECT BY PRIOR empid = mgrid;

665: Internal error on semantics -
CONNECT_BY_ISCYCLE is used without NOCYCLE parameter..
Error in line 1
Near character position 72
```

This query avoids the -655 error by specifying the NOCYCLE in the CONNECT BY clause that throws an error in the step where it encounters the loop that the UPDATE statement created.

```
SELECT empid, name, mgrid,
       CONNECT_BY_ISLEAF leaf, CONNECT_BY_ISCYCLE cycle
FROM   employee
START WITH name = 'Goyal'
CONNECT BY NOCYCLE PRIOR empid = mgrid;
```

For the results of this query, see the example in the description of the NOCYCLE keyword in the topic [CONNECT BY Clause on page 824](#).

The CONNECT\_BY\_ISCYCLE pseudocolumn is not valid in the following contexts:

- A SELECT statement that has no CONNECT BY clause
- The START WITH or CONNECT BY clause
- An operand of the CONNECT\_BY\_ROOT operator
- An argument to the SYS\_CONNECT\_BY\_PATH function

### The CONNECT\_BY\_ISLEAF Pseudocolumn

CONNECT\_BY\_ISLEAF is a pseudocolumn that returns a `1` if the row is a leaf in the hierarchy as defined by the CONNECT BY clause. A node is a *leaf node* if it has no children in the query result hierarchy (not in the actual data hierarchy). If the row is not a leaf the column returns `0`. The data type of the column is INTEGER.

The following hierarchical query specifies the CONNECT\_BY\_ISLEAF pseudocolumn in the Projection clause, and declares **leaf** as an alias for that column, which shows in the DB-Access display of the result set:

```
SELECT empid, name, mgrid, CONNECT_BY_ISLEAF leaf
FROM employee
START WITH name = 'Goyal'
CONNECT BY PRIOR empid = mgrid;
```

| empid | name     | mgrid | leaf |
|-------|----------|-------|------|
| 16    | Goyal    | 17    | 0    |
| 14    | Scott    | 16    | 1    |
| 12    | Henry    | 16    | 0    |
| 9     | Shoeman  | 12    | 1    |
| 8     | Smith    | 12    | 1    |
| 7     | O'Neil   | 12    | 1    |
| 11    | Zander   | 16    | 0    |
| 6     | Barnes   | 11    | 1    |
| 5     | McKeough | 11    | 1    |

9 row(s) retrieved.

### The CONNECT\_BY\_ROOT Operator

For every row in the hierarchy, the CONNECT\_BY\_ROOT unary operator accepts as its operand an expression that evaluates to a row that is a node of the hierarchy. CONNECT\_BY\_ROOT returns the expression for the root ancestor of its operand. This syntax fragment is part of the [Hierarchical Clause on page 819](#).

CONNECT\_BY\_ROOT Operator

**CONNECT\_BY\_ROOT** *expression*

The *expression* operand can be any SQL expression, but it must not contain any hierarchical query token, including the following tokens:

- The CONNECT\_BY\_ROOT or PRIOR unary operators
- The CONNECT\_BY\_ISCYCLE, CONNECT\_BY\_ISLEAF, or LEVEL pseudocolumns
- The SYS\_CONNECT\_BY\_PATH function.

The return data type of this right-associative operator is the data type of the specified expression.

The hierarchical query in the following example returns rows from the **employee** table that include both the identifying number of the manager to whom the employee reports directly, and also the name of the manager at the root of the hierarchy for this query.

```
SELECT empid, name, mgrid, CONNECT_BY_ROOT name AS topboss
FROM employee
START WITH name = 'Goyal'
CONNECT BY PRIOR empid = mgrid;
```

| empid | name     | mgrid | topboss |
|-------|----------|-------|---------|
| 16    | Goyal    | 17    | Goyal   |
| 14    | Scott    | 16    | Goyal   |
| 12    | Henry    | 16    | Goyal   |
| 9     | Shoeman  | 12    | Goyal   |
| 8     | Smith    | 12    | Goyal   |
| 7     | O'Neil   | 12    | Goyal   |
| 11    | Zander   | 16    | Goyal   |
| 6     | Barnes   | 11    | Goyal   |
| 5     | McKeough | 11    | Goyal   |

9 row(s) retrieved.

The CONNECT\_BY\_ROOT operator is not valid in the following contexts:

- A SELECT statement that has no CONNECT BY clause
- The START WITH or CONNECT BY clause
- An argument to the SYS\_CONNECT\_BY\_PATH function

### The SYS\_CONNECT\_BY\_PATH Function

Calls to SYS\_CONNECT\_BY\_PATH ( ) function are valid in SELECT statements that include the Hierarchical clause, but this function cannot be called from the Hierarchical clause. Informix® returns an error if you attempt to run this function within the *condition* of the START WITH or CONNECT BY clauses.

The SYS\_CONNECT\_BY\_PATH function can be used in hierarchical queries to build a string that represents a path from the row corresponding to the root node to the current row.

This is the calling syntax for SYS\_CONNECT\_BY\_PATH to return a string for a specified row at LEVEL *N*. This syntax fragment is part of the [Hierarchical Clause on page 819](#).

SYS\_CONNECT\_BY\_PATH Function

```
SYS_CONNECT_BY_PATH (
, string_expression , ' format_string '
)
```

| Element              | Description  | Restrictions | Syntax                                     |
|----------------------|--|--------------|--|
| <i>format_string</i> | Typically a constant string that serves as a separator | None         | <a href="#">Quoted String on page 1424</a> |

| Element                  | Description                          | Restrictions                             | Syntax                                  |
|--------------------------|--------------------------------------|--|---|
| <i>string_expression</i> | An expression that identifies a row. | Cannot include hierarchical query tokens | <a href="#">Expression on page 1193</a> |

SYS\_CONNECT\_BY\_PATH builds the string representation of the path from the root to a specified row at LEVEL N of the hierarchy by recursively concatenating the successive returned values:

- *path1* := *string\_expression1* || *format\_string* represents the path to the root row from the first intermediate result set,
- *path2* := *path1* || *string\_expression2* || *format\_string* evaluates to the path from the root to a row in the second intermediate result set,
- ...
- *pathN* := *path(N-1)* || *string\_expressionN* || *format\_string* evaluates to the path from the root to the Nth intermediate result set.

The expressions in arguments to SYS\_CONNECT\_BY\_PATH must not include any hierarchical query construct, including the following constructs:

- The CONNECT\_BY\_ROOT or PRIOR unary operators
- The CONNECT\_BY\_ISCYCLE, CONNECT\_BY\_ISLEAF, or LEVEL pseudocolumns
- The SYS\_CONNECT\_BY\_PATH function.

Also not valid in the argument list are aggregate expressions.

The return value from SYS\_CONNECT\_BY\_PATH ( ) is of type LVARCHAR(4000).

The hierarchical query in the following example calls the SYS\_CONNECT\_BY\_PATH function in the Projection list with the **employee.name** column and the slash (/) character as its arguments.

```
SELECT empid, name, mgrid, SYS_CONNECT_BY_PATH( name, '/') as hierarchy
FROM employee
START WITH name = 'Henry'
CONNECT BY PRIOR empid = mgrid;
```

The query returns the rows within the subset of the data hierarchy in which **Henry** is specified as the root in the START WITH clause, showing the name and **empid** number of each employee and of the employee's manager, and the path within the hierarchy to **Henry**. The CONNECT BY clause uses the equality predicate `PRIOR empid = mgrid` to return the employees who report to the managers (in this case, only **Henry**) whose **empid** was returned by the previous step. The result set of the query is:

```
empid      12
name       Henry
mgrid      16
hierarchy  /Henry

empid      9
name       Shoeman
mgrid      12
hierarchy  /Henry/Shoeman
```

```

empid      8
name       Smith
mgrid      12
hierarchy  /Henry/Smith

empid      7
name       O'Neil
mgrid      12
hierarchy  /Henry/O'Neil

4 row(s) retrieved.

```

These rows are listed in the order in which they were retrieved:

- The START WITH clause returned the **Henry** row at the root of this hierarchy.
- The first step of the CONNECT BY clause returned three rows, corresponding to the three employees who report to **Henry**.
- The next CONNECT BY step returned no rows, because the **Shoeman, Smith,** and **O'Neil** rows that returned by the previous step are all leaf nodes within this hierarchy, for which the `PRIOR empid = mgrid` condition evaluates to false.

Query execution ended, returning the four rows that are shown, where **hierarchy** is an alias for the path to **Henry** that `SYS_CONNECT_BY_PATH(name, '/')` returned for each row. (In the first returned row, the string `/Henry` shows the root status of **Henry**.)

## Dependency patterns that are not a simple graph

You can run a recursive hierarchical query on a data set that includes complex dependencies, such as multiple root nodes, or multiple parent nodes for child nodes. However, cycling might occur and more records might be returned, based on hierarchical data tree structures.

The CONNECT BY clause cannot analyze data sets that include cycles where some child nodes are identified as ancestors of their parent node. If your data set includes cycles, the cycles might be artifacts of rows that contain invalid data.

If the data set that the self-referential table describes includes more than one hierarchy, include the START WITH clause with a condition that is only true for the root of the hierarchy that you want the recursive query to return. Run a separate query on the table for each hierarchy, using a different START WITH clause to specify the root in each query.

## GROUP BY Clause

Use the GROUP BY clause to produce a single row of results for each group. A *group* is a set of rows that have the same values for each column (or column expression) that is referenced in this clause.

This syntax fragment is part of the [SELECT statement on page 768](#).

## GROUP BY Clause

**GROUP BY**

,  
*table\_object* .

*column*

417

*col\_alias select\_number*

| Element              | Description   | Restrictions   | Syntax   |
|----------------------|---|--|--|
| <i>col_alias</i>     | Alias for a column name   | Must have been declared in the Projection clause   | <a href="#">Identifier on page 1456</a>  |
| <i>column</i>        | Group rows by the value of this column (or of this expression)  | See <a href="#">Dependencies between the GROUP BY and Projection clauses on page 834</a> . | <a href="#">Identifier on page 1456</a> ,<br><a href="#">Expression on page 1193</a> |
| <i>select_number</i> | Integer specifying the ordinal position of a column or expression in the select list of the Projection clause | See the Select numbers section.  | <a href="#">Literal Number on page 1419</a>  |
| <i>table_object</i>  | Name, synonym, or alias of the table or view containing <i>column</i>   | Must exist and must be specified in the FROM clause  | <a href="#">Identifier on page 1456</a>  |

The SELECT statement with a GROUP BY clause returns a single row of results for each group of rows that have the same value in *column*, or that have the same value in the column that *col\_alias* references, or that have the same value in the column or expression that the *select\_number* specifies.

In an NLSCASE INSENSITIVE database, collation and string comparisons on NCHAR and NVARCHAR data disregard lettercase differences, so that the database server treats case variants among strings composed of same sequence letters as duplicates. For queries that group data on NCHAR or NVARCHAR columns, if some of the qualifying rows differ only in letter case, the number of groups will be smaller than from the same query on the same data set in a case-sensitive database. For more information on data processing in databases that were created with the NLSCASE INSENSITIVE property, see [Duplicate rows in NLSCASE INSENSITIVE databases on page 779](#) and [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

In a column listed in a GROUP BY clause, each row that contains a NULL value belongs to a single group. That is, all NULL values are grouped together.

**Select numbers**

You can use one or more integers in the GROUP BY clause to stand for column expressions. In the next example, the first SELECT statement uses select numbers for **order\_date** and **paid\_date - order\_date** in the GROUP BY clause. You can group only by a combined expression using the select numbers.

417. Informix® extension

In the second SELECT statement, you cannot replace the 2 with the arithmetic expression **paid\_date - order\_date**:

```
SELECT order_date, COUNT(*), paid_date - order_date
FROM orders GROUP BY 1, 3;
SELECT order_date, paid_date - order_date
FROM orders GROUP BY order_date, 2;
```

## Dependencies between the GROUP BY and Projection clauses

The GROUP BY clause restricts what the Projection clause can specify. If you include a GROUP BY clause, each *column* in the select list of the Projection clause must also be referenced in the GROUP BY clause. Some column data types and column expressions that are valid in the Projection clause, however, cannot be referenced in the GROUP BY clause.

If a column expression in the select list is only the column name or alias, you must use its name or its alias in the GROUP BY clause, if none of the restrictions below apply to the column. If a column is combined with another column by an arithmetic operator, you can choose to group the query result set in either of two ways:

- By the names or aliases of the individual columns,
- or else by the combined expression using the *select number*, a literal integer that specifies the ordinal position of that expression within the select list of the Projection clause.

The following restrictions, however, prevent some columns and expressions from being included in the GROUP BY clause, or can prevent the query from including the GROUP BY clause.

- Constant expressions are not valid in the GROUP BY clause.
- You cannot include a ROWID in a GROUP BY clause.
- If the Projection clause includes a BYTE or TEXT column or a BYTE or TEXT column expression, the query cannot include the GROUP BY clause.
- If the Projection clause includes a column of a user-defined data type, the column cannot be used in a GROUP BY clause unless the UDT can use the built-in bit-hashing function. Any UDT that cannot use the built-in bit-hashing function must be created with the CANNOTHASH modifier, which tells the database server that the UDT cannot be used in a GROUP BY clause.

The following section identifies restrictions on the GROUP BY clause when the Projection clause includes aggregate expressions or time expressions.

### Columns in aggregate expressions and time expressions

If you specify an aggregate function and one or more column expressions in the select list of a query that includes the GROUP BY clause, the GROUP BY clause must list the name or the alias of each column in the select list that is not used as part of an aggregate or of a time expression. The query fails with error -321, however, if the GROUP BY clause includes a select number corresponding to the ordinal position of an aggregate expression within the select list.

If an OLAP window function is specified in the Projection clause of a query that includes the GROUP BY clause, all column references within the OLAP window function must also be included in the GROUP BY clause. The database server issues an

error, however, if any of the columns referenced in the GROUP BY clause are operands of an aggregate expression or of a time expression.

The GROUP BY clause in the following example specifies one column that is not in an aggregate expression. Here the **total\_price** column must not be in the GROUP BY list, because it appears in the Projection clause as the argument to an aggregate function.

```
SELECT order_num, COUNT(*), SUM(total_price)
FROM items GROUP BY order_num;
```

During execution of this query, the COUNT and SUM aggregates are applied to each **order\_num** group, rather than calculating the number of orders and the sum of their **total\_price** values across the set of all rows in the **items** table.

## HAVING Clause

Use the HAVING clause to apply one or more qualifying conditions to groups or to the entire result set.

This syntax fragment is part of the [SELECT statement on page 768](#).

HAVING Clause

### HAVING

Condition <sup>418</sup>

In the following examples, each condition compares one calculated property of the group with another calculated property of the group or with a constant. The first SELECT statement uses a HAVING clause that compares the calculated expression `COUNT(*)` with the constant `2`. The query returns the average total price per item on all orders that have more than two items.

The second SELECT statement lists customers and the call months for customers who have made two or more calls in the same month:

```
SELECT order_num, AVG(total_price) FROM items
GROUP BY order_num HAVING COUNT(*) > 2;
SELECT customer_num, EXTEND (call_dtime, MONTH TO MONTH)
FROM cust_calls GROUP BY 1, 2 HAVING COUNT(*) > 1;
```

You can use the HAVING clause to place conditions on the GROUP BY column values as well as on calculated values.

This example returns **cust\_code** and **customer\_num**, **call\_dtime**, and groups them by **call\_code** for all calls that have been received from customers with **customer\_num** less than 120:

```
SELECT customer_num, EXTEND (call_dtime), call_code
FROM cust_calls GROUP BY call_code, 2, 1
HAVING customer_num < 120;
```

The HAVING clause generally complements a GROUP BY clause. If you omit the GROUP BY clause, the HAVING clause applies to all rows that satisfy the query, and all rows in the table make up a single group. The following example returns the average price of all the values in the table, as long as more than ten rows are in the table:

```
SELECT AVG(total_price) FROM items HAVING COUNT(*) > 10;
```

418. See [Condition on page 1144](#)

Because conditions in the WHERE clause cannot include aggregate expressions, you can use the HAVING clause to apply conditions with aggregates to the entire result set of a query, as in the example above.

The condition in the HAVING clause cannot include a DISTINCT or UNIQUE aggregate expression. For example, the following query fails with a syntax error:

```
SELECT order_num, COUNT(*) number, AVG (total_price) average
FROM items
GROUP BY order_num
HAVING COUNT(DISTINCT *) > 2;
```

No error is issued, however, if the DISTINCT keyword is omitted from the example above.

## Set operators in combined queries

The set operators UNION, UNION ALL, INTERSECT, and MINUS can manipulate the result sets of two queries that specify the same number of columns in the Projection clause, and that have compatible data types in the corresponding columns of both queries.

(The MINUS set operator has EXCEPT as its keyword synonym. Results that the MINUS and EXCEPT operators return from the same operands are always identical.)

These operators perform basic set operations of *union*, *intersection*, and *difference* on the result sets of two queries that are the left and right operands of the set operators:

- The UNION set operator combines the qualifying rows from two queries into a single result set that consists of the distinct rows that either or both of the queries returned. (If you also include the ALL keyword, the UNION ALL result set can include duplicate rows.)
- The INTERSECT set operator compares the result sets from two queries, but returns only the distinct rows that are in the result sets of both queries.
- The MINUS set operator compares the result sets from two queries, but returns only the distinct rows in the result set of the left query that are absent from the result set of the right query.

The set operators are useful in business analytic contexts. They can also be used in SELECT statements to check the integrity of your database after you have performed a DML operation like UPDATE, INSERT, DELETE, or MERGE. The set operators can similarly be used when you transfer data to a history table, for example, when you need to verify that the correct data is in the history table before you delete rows from the original table.

All of the set operators have the same precedence. In complex queries that include more than one set operator, the precedence of operators is from left to right. Use parentheses to group set operators and their operands, if you need to override the default left-to-right precedence of set operators.

Only the UNION set operator supports the ALL keyword. The ALL keyword is not valid with the INTERSECT, MINUS, or EXCEPT set operators, from which only distinct rows are returned.

When comparing rows to calculate a set intersection or difference, two NULL values are considered equal in INTERSECT and MINUS operations.

## Restrictions on a Combined SELECT

Several restrictions apply to queries that you can combine with the UNION, INTERSECT, MINUS, or EXCEPT set operators.

- The number of items in the Projection clause of each query must be the same, and the corresponding items in each Projection clause must have compatible data types.
- The Projection clause of each query cannot specify BYTE or TEXT objects. (This restriction does not apply to UNION ALL operations.)
- If a combined query includes the ORDER BY clause of the SELECT statement, it must follow the last Projection clause, and you must specify each ordered item by its integer *select\_number*, not by its SQL identifier. Sorting takes place after the set operation is complete.
- You can store the combined results of any set operator in a temporary table, but the INTO TEMP clause can appear only in the final SELECT statement.
- In Informix® ESQL/C, you cannot use an INTO clause in a compound query unless exactly one row is returned, and you are not using a cursor. In this case, the INTO clause must be in the first SELECT statement that the set operator combines.

A *UNION subquery* is a query that includes the UNION or UNION ALL operator within a subquery. The following additional restrictions affect UNION subqueries, but they do not apply to combined queries that include the INTERSECT, MINUS, or EXCEPT set operators:

- The CREATE VIEW statement cannot specify a UNION subquery to define the view.
- Only columns in the local database are valid in a UNION subquery. You cannot reference a remote table or view in a UNION subquery.

Unlike UNION, the INTERSECT, MINUS, and EXCEPT set operators are valid in the following contexts:

- In combined queries that reference columns of tables in other databases of the local Informix® server instance, and in tables of other Informix® server instances.
- In view definitions. (You cannot, however, specify WITH CHECK OPTION in a CREATE VIEW statement that also includes a set operator.)

The following restrictions, however, affect all combined queries, including UNION and UNION ALL subqueries and queries that include the INTERSECT, MINUS, or EXCEPT set operators:

- Combined queries cannot be triggering events. If a valid combined query specifies a column on which a Select trigger has been defined, the query succeeds, but the trigger (or the INSTEAD OF trigger on a view) is ignored.
- General expressions that include host variables are not valid on the left of the ALL, ANY, IN, NOT IN and SOME operators in a query that includes a UNION subquery or any other set operator. An expression that consists solely of a single host variable, however, is valid in this context.

For example, the following query is valid under the above restriction:

```
SELECT col1 FROM tab1 WHERE ? <= ALL
(SELECT col2 FROM tab2 UNION SELECT col3 FROM tab3);
```

In this example, the expression to the left of ALL is a single host variable (?), which is the only expression involving host variables that is supported before the ALL, ANY, IN, NOT IN, or SOME operators in a query that also includes a set operator.

In contrast, the following example shows an invalid query:

```
SELECT col1 FROM tab1 WHERE (? + 8) <= ALL
(SELECT col2 FROM tab2 UNION SELECT col3 FROM tab3);
```

This query fails because an operand of the <= relational operator to the left of the ALL operator is (? + 8). An arithmetic expression that includes a host variable is not valid syntax in a UNION subquery, nor in queries that are combined by any other set operator.

Expressions that do not contain host variables are not subject to this restriction. Thus, the following query (that includes the same UNION subquery) is valid:

```
SELECT col1 FROM tab1 WHERE (col1 + 8) <= ALL
(SELECT col2 FROM tab2 UNION SELECT col3 FROM tab3);
```

## UNION Operator

Place the UNION operator between two SELECT statements to combine the queries into a single query.

You can string several SELECT statements together using the UNION operator. Corresponding items do not need to have the same name. Omitting the ALL keyword excludes duplicate rows.

### UNION ALL operator

If you use the UNION ALL operator, all the qualifying rows from both queries are returned, without excluding any duplicate rows. (If you combine two queries by using the UNION operator without the ALL keyword, any duplicate rows are removed from the combined set of qualifying rows. That is, if multiple rows contain identical values in the corresponding columns or expressions that the Projection clauses of both queries specify, only one row from each set of duplicates is retained in the result set.)

The next example uses UNION ALL to combine the results of two SELECT statements without removing duplicates. The query returns a list of all the calls that were received during the first quarter of 2007 and the first quarter of 2008.

```
SELECT customer_num, call_code FROM cust_calls
WHERE call_dtime BETWEEN
    DATETIME (2007-1-1) YEAR TO DAY
    AND DATETIME (2007-3-31) YEAR TO DAY
UNION ALL
SELECT customer_num, call_code FROM cust_calls
WHERE call_dtime BETWEEN
    DATETIME (2008-1-1)YEAR TO DAY
    AND DATETIME (2008-3-31) YEAR TO DAY;
```

If you want to remove duplicates from the result set, use UNION without the keyword ALL as the set operator between the queries. In the preceding example, if the combination 101 B were returned by both SELECT statements, the UNION operator would cause the combination to be listed only once. (If you want to remove duplicates within each SELECT statement, use

the DISTINCT or UNIQUE keyword immediately before the Select list of the Projection clause, as described in [Controlling duplicate return values on page 777.](#))

The ALL keyword is valid for specifying set operations only with the UNION operator. The database server issues an error if ALL immediately follows the INTERSECT, MINUS, or EXCEPT set operators, which exclude duplicates.

For information on how the database server identifies duplicate NCHAR and NVARCHAR values in databases that have the NLCASE INSENSITIVE property, see the topic [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174.](#)

## UNION in subqueries

You can use the UNION and UNION ALL operators in subqueries of SELECT statements within the WHERE clause, the FROM clause, and in collection subqueries. In this release of Informix®, however, subqueries that include UNION or UNION ALL are not supported in the following contexts:

- In the definition of a view
- In the event or in the Action clause of a trigger
- With the FOR UPDATE clause or with an Update cursor
- In a distributed query (accessing tables outside the local database)

For more information about collection subqueries, see [Collection Subquery on page 1141.](#) For more information about the FOR UPDATE clause, see [FOR UPDATE Clause on page 851.](#)

In a combined subquery, the database server can resolve a column name only within the scope of its qualifying table reference. The following query, for example, returns an error:

```
SELECT * FROM t1 WHERE EXISTS
  (SELECT a FROM t2
   UNION
   SELECT b FROM t3 WHERE t3.c IN
    (SELECT t4.x FROM t4 WHERE t4.4 = t2.z));
```

Here **t2.z** in the innermost subquery cannot be resolved, because **z** occurs outside the scope of reference of the table reference **t2**. Only column references that belong to **t4**, **t3**, or **t1** can be resolved in the innermost subquery. The scope of a table reference extends downwards through subqueries, but not across the UNION operator to sibling SELECT statements.

## INTERSECT Operator

When two queries are combined by this set operator, INTERSECT calculates the set intersection of the rows returned by the two queries that are its operands.

The rows that INTERSECT returns are present in the results sets of both the left and the right SELECT statements. The INTERSECT results are always distinct or unique rows, because INTERSECT eliminates any duplicate rows.

Consider the following example, where the table **t1** has following rows:

```
create table t1 (col1 int);
insert into t1 values (1);
insert into t1 values (2);
```

```

insert into t1 values (2);
insert into t1 values (2);
insert into t1 values (3);
insert into t1 values (4);
insert into t1 values (4);
insert into t1 values (NULL);
insert into t1 values (NULL);
insert into t1 values (NULL);

```

In the same example, table **t2** has these rows:

```

create table t2 (col1 int);
insert into t2 values (1);
insert into t2 values (3);
insert into t2 values (4);
insert into t2 values (4);
insert into t2 values (NULL);

```

The following query returns the distinct rows from both the query on the left and right sides of the INTERSECT operand. The important thing to be noted here is the result has a NULL value. Because the NULL value in table **t2** is considered to be equal when table **t2** is compared to table **t1**, so a NULL value from the set intersection is returned in the combined result set:

```

SELECT col1 FROM t1 INTERSECT SELECT col1 FROM t2;

   col1
-----
      1
      3
      4
4 row(s) retrieved.

```

The INTERSECT operator has some (but not all) of the same restrictions as the UNION operator, but INTERSECT does not support the ALL keyword that enables UNION to return duplicate values. See also the topic [Restrictions on a Combined SELECT on page 837](#).

## MINUS operator

When two queries are combined by this set operator, the MINUS operator calculates the set difference between the rows returned by the SELECT statement on the left side and the rows returned by the SELECT statement on the right side.

The MINUS operator returns only the rows that are present in first result set but that are not in the second set. The MINUS results are always distinct or unique rows, because MINUS eliminates any duplicate rows.

For the same data set that is listed in the [INTERSECT Operator on page 839](#) topic, the following query returns all the distinct rows from result set of the query to the left of the MINUS operator that are not in the result set of the query on the right:

```

SELECT col1 FROM t1 MINUS SELECT col1 FROM t2;

   col1
-----
      2

```

```
1 row(s) retrieved.
```

The MINUS operator has some (but not all) of the same restrictions as the UNION operator, but MINUS does not support the ALL keyword that enables UNION to return duplicate values. See also the topic [Restrictions on a Combined SELECT on page 837](#).

## ORDER BY Clause

The ORDER BY clause sorts query results by specified columns or expressions.

This syntax fragment is part of the [SELECT statement on page 768](#).

ORDER BY Clause

**ORDER**

| Element              | Description  | Restrictions  | Syntax                                      |
|----------------------|--|---|---|
| <i>column</i>        | Sort rows by value in this column  | None  | <a href="#">Identifier on page 1456</a>     |
| <i>display_label</i> | Temporary name for a column or for a column expression                   | Must be unique among labels declared in the Projection clause | <a href="#">Identifier on page 1456</a>     |
| <i>first, last</i>   | First and last byte in column substring to sort the result set           | Integers; for BYTE, TEXT, and character data types only       | <a href="#">Literal Number on page 1419</a> |
| <i>select_number</i> | Ordinal position of a column in the select list of the Projection clause | See <a href="#">GROUP BY Clause on page 832</a> .             | <a href="#">Literal Number on page 1419</a> |
| <i>table</i>         | Name, synonym, or alias of the table or view containing <i>column</i>    | Must exist and must be specified in the FROM clause           | <a href="#">Identifier on page 1456</a>     |

The ORDER BY clause implies that the query returns more than one row. In SPL, the database server issues an error if you specify the ORDER BY clause without a FOREACH loop to process the returned rows individually within the SPL routine.

The following query specifies a derived table in the FROM clause whose rows are ordered by the **col1** value, and declares **vtab** as the name of the derived table, and **vcol** as the name of its only column:

```
SELECT vcol FROM
(SELECT FIRST 5 col1 FROM tab1 ORDER BY col1) vtab(vcol);
```

### ORDER BY in NLSCASE INSENSITIVE databases

In databases created with the NLSCASE INSENSITIVE property, operations on columns and expressions of NCHAR or NVARCHAR data types make no distinction between upper case and lower case letters. For this reason, queries that include the ORDER BY clause might return rows in a sequence that disregard variants in letter case, if the column or expression are of NLS data types, and the data includes values that differ only in letter case.

If the data set includes letter case variants of the same string, these will be processed as duplicates, with case variants listed in their order of retrieval. For example, a set of NCHAR or NVARCHAR strings that were processed as duplicates might appear in this order:

```
gAMma
GAMma
GaMMa
gamma
GAMMA
```

For more information, see [Duplicate rows in NLSCASE INSENSITIVE databases on page 779](#) and [NCHAR and NVARCHAR expressions in case-insensitive databases on page 1174](#).

### Ordering by a Column or by an Expression

To order query results by an expression, you must also declare a display label for the expression in the Projection clause, as in the following example, which declares the display label **span** for the difference between two columns:

```
SELECT paid_date - ship_date span, customer_num FROM orders
ORDER BY span;
```

Informix® supports columns and expressions in the ORDER BY clause that do not appear in the select list of the Projection clause. You can omit a display label for the derived column in the select list and specify the derived column by means of a select number in the ORDER BY clause.

The select list of the Projection clause must include any column or expression that the ORDER BY clause specifies, however, if any of the following is true:

- The query includes the DISTINCT, UNIQUE, or UNION operator.
- The query includes the INTO TEMP *table* clause.
- The distributed query accesses a remote database whose server requires every column or expression in the ORDER BY clause to also appear in the select list of the Projection clause.
- An expression in the ORDER BY clause includes a display label for a column substring. (See the next section, [Ordering by a Substring on page 843.](#))

The next query selects one column from the **orders** table and sorts the results by the value of another column. By default, the rows are listed in ascending order.

```
SELECT ship_date FROM orders ORDER BY order_date;
```

You can order by an aggregate expression only if the query also has a GROUP BY clause. This query declares the display label **maxwgt** for an aggregate in the ORDER BY clause:

```
SELECT ship_charge, MAX(ship_weight) maxwgt
FROM orders GROUP BY ship_charge ORDER BY maxwgt;
```

If the current processing locale defines a localized collation, then NCHAR and NVARCHAR column values are sorted in that localized order.

In Informix®, no *column* in the ORDER BY clause can be a collection type, but a query whose result set defines a collection-derived table can include the ORDER BY clause. For an example, see [Collection-Derived Table on page 1436.](#)

You might improve the performance of some non-PDQ queries that use the ORDER BY clause to sort a large set of rows if you increase the setting of the DS\_NONPDQ\_QUERY\_MEM configuration parameter.

## Ordering by a Substring

You can order by a substring instead of by the entire length of a character, BYTE, or TEXT column, or of an expression returning a character string. The database server uses the substring to sort the result set. Define the substring by specifying integer subscripts (the *first* and *last* parameters), representing the starting and ending byte positions of the substring within the column value.

The following SELECT statement queries the **customer** table and specifies a column substring in the ORDER BY column. This instructs the database server to sort the query results by the portion of the **lname** column contained in the sixth through ninth bytes of the column value.

```
SELECT * from customer ORDER BY lname[6,9];
```

Assume that the value of **lname** in one row of the **customer** table is `Greenburg`. Because of the column substring in the ORDER BY clause, the database server determines the sort position of this row by using the value `burg`, rather than the complete column value `Greenburg`.

When ordering by an expression, you can specify substrings only for expressions that return a character data type. If you specify a column substring in the ORDER BY clause, the column must have one of the following data types: BYTE, CHAR, NCHAR, NVARCHAR, TEXT, or VARCHAR.

Informix® can also support LVARCHAR column substrings in the ORDER BY clause, if the column is in a database of the local database server.

For information on the GLS aspects of using column substrings in the ORDER BY clause, see the *Informix® GLS User's Guide*.

## Ordering by a CASE expression

The ORDER BY clause can include CASE expressions to specify a sorting key.

In the following example, column `a_col` of table `tab_case` is of type INT. The query on table `tab_case` includes both column `a_col` and the aggregate expression `SUM(a_col)` in the Projection list, and groups the results by the value of `a_col`. The ORDER BY clause specifies two sorting keys:

- A CASE expression that immediately follows the ORDER BY keywords
- The `AVG(a_col)` aggregate expression:

```
CREATE TABLE tab_case(a_col INT, b_col VARCHAR(32));

SELECT a_col, SUM(a_col)
FROM tab_case
GROUP BY a_col
ORDER BY CASE
    WHEN a_col IS NULL
    THEN 1
    ELSE 0 END ASC,
    AVG(a_col);
```

Here the ASC keyword explicitly identifies the result of the CASE expression as an ascending sort key. By default, the `AVG(a_col)` sorting key also specifies an ascending order.

In the following similar example, based on a query on the same `tab_case` table, a second CASE expression returns either 1 or 0 as the sorting key value for the returned `AVG(a_col)` aggregate values.

```
SELECT a_col, SUM(a_col)
FROM tab_case GROUP BY a_col
ORDER BY CASE
    WHEN a_col IS NULL
    THEN 1
    ELSE 0 END ASC,
    AVG(a_col),
    CASE
    WHEN AVG(a_col) IS NULL
```

```
THEN 1
ELSE 0 END;
```

## Ascending and Descending Orders

You can use the ASC and DESC keywords to specify ascending (smallest value first) or descending (largest value first) order.

The default order is ascending. For DATE and DATETIME data types, *smallest* means earliest in time and *largest* means latest in time. For character data types in the default locale, the order is the ASCII collating sequence, as listed in [Collating Order for U.S. English Data on page 1431](#).

For NCHAR or NVARCHAR data types, the localized collating order of the current session is used, if that is different from the code set order. For more information about collation, see [SET COLLATION statement on page 862](#).

If you specify the ORDER BY clause, NULL values by default are ordered as less than values that are not NULL. Using the ASC order, a NULL value comes before any non-NULL value; using DESC order, the NULL comes last.

### Specifying the order of NULL values

The ORDER BY clause can include the NULLS FIRST keywords or the NULLS LAST keywords to show explicitly (or else to override) the default sort order of NULL values:

- The NULLS FIRST keywords instruct the database server to put NULL values first in the sorted query results. In an ascending sort, the ASC NULLS FIRST keywords request the default order. In a descending sort, DESC NULLS FIRST specifies that rows with a NULL value in the sort key column precede non-NULL rows in the sorted result set.
- The NULLS LAST keywords instruct the database server to put NULL values last in the sorted query results. In a descending sort, the DESC NULLS LAST keywords request the default order. In an ascending sort, ASC NULLS LAST specifies that rows with a NULL value in the sort key column follow non-NULL rows in the sorted result set.

## Nested Ordering

If you list more than one column in the ORDER BY clause, your query is ordered by a nested sort. The first level of sort is based on the first column; the second column determines the second level of sort. The following example of a nested sort selects all the rows in the **cust\_calls** table and orders them by **call\_code** and by **call\_dtime** within **call\_code**:

```
SELECT * FROM cust_calls ORDER BY call_code, call_dtime;
```

## Using Select Numbers

In place of column names, you can enter in the ORDER BY clause one or more integers that refer to the position of items listed in the select list of the Projection clause. You can also use a select number to sort by an expression.

The following example orders by the expression **paid\_date - order\_date** and **customer\_num**, using select numbers in a nested sort:

```
SELECT order_num, customer_num, paid_date - order_date
FROM orders
ORDER BY 3, 2;
```

Select numbers are required in the ORDER BY clause when SELECT statements are joined by the UNION or UNION ALL keywords, or when compatible columns in the same position have different names.

## Ordering by Rowids

You can specify the ROWID keyword in the ORDER BY clause. This specifies the **rowid** column, a hidden column in nonfragmented tables and in fragmented tables that were created with the WITH ROWIDS clause. The **rowid** column contains a unique internal record number that is associated with a row in a table. (It is recommended, however, that you utilize primary keys as your access method, rather than exploiting the **rowid** column.)

The ORDER BY clause cannot specify the **rowid** column if the table from which you are selecting is a fragmented table that has no **rowid** column.

You do not need to include the ROWID keyword in the Projection clause when you specify ROWID in the ORDER BY clause.

For further information about **rowid** values and how to use the **rowid** column in column expressions, see [WITH ROWIDS Option on page 41](#) and [Using Rowids on page 1226](#).

## ORDER BY Clause with DECLARE

In Informix® ESQL/C, you cannot use a DECLARE statement with a FOR UPDATE clause to associate a cursor with a SELECT statement that has an ORDER BY clause.

## Placing Indexes on ORDER BY Columns

When you include an ORDER BY clause in a SELECT statement, you can improve the performance of the query by creating an index on the column or columns that the ORDER BY clause specifies. The database server uses the index that you placed on the ORDER BY columns to sort the query results in the most efficient manner. For more information on how to create indexes that correspond to the columns of an ORDER BY clause, see [Using the ASC and DESC Sort-Order Options on page 263](#).

## ORDER SIBLINGS BY Clause

The ORDER SIBLINGS BY clause is valid only in a hierarchical query. The optional SIBLINGS keyword specifies an order that first sorts the parent rows, and then sorts the child rows of each parent for every level within the hierarchy.

Rows that have duplicate lists of values in the columns specified after the SIBLINGS BY keywords are arbitrarily ordered among the rows with the same list of values and the same parent. If a hierarchical query includes the ORDER BY clause without the SIBLINGS keyword, rows are ordered according to the sort specifications that follow the ORDER BY keywords.

Neither the ORDER BY clause nor the ORDER SIBLINGS BY option to the ORDER BY clause is required in hierarchical queries.

The hierarchical query in the following example returns the subset of rows in the hierarchical data set whose root is **Goyal**, as listed in the topic [Hierarchical Clause on page 819](#). This query includes the ORDER SIBLINGS BY clause to sort by **name** the employees who report to the same manager:

```
SELECT empid, name, mgrid, LEVEL
FROM employee
  START WITH name = 'Goyal'
  CONNECT BY PRIOR empid = mgrid
 ORDER SIBLINGS BY name;
```

The rows returned by this query are sorted in the following order:

| empid | name     | mgrid | level |
|-------|----------|-------|-------|
| 16    | Goyal    | 17    | 1     |
| 12    | Henry    | 16    | 2     |
| 7     | O'Neil   | 12    | 3     |
| 9     | Shoeman  | 12    | 3     |
| 8     | Smith    | 12    | 3     |
| 14    | Scott    | 16    | 2     |
| 11    | Zander   | 16    | 2     |
| 6     | Barnes   | 11    | 3     |
| 5     | McKeough | 11    | 3     |

9 row(s) retrieved.

Here the START WITH clause returned the **Goyal** row at the root of this hierarchy. Two subsequent CONNECT BY steps (marked as 2 and 3 in the **level** pseudocolumn) returned three sets of sibling rows:

- **Henry**, **Scott**, and **Zander** are siblings whose parent is **Goyal**;
- **O'Neil**, **Shoeman**, and **Smith** are siblings whose parent is **Henry**;
- **Barnes** and **McKeough** are siblings whose parent is **Zander**.

The next CONNECT BY step returned no rows, because the rows for which **level** = 3 are leaf nodes within this hierarchy. At this point in the execution of the query, the ORDER SIBLINGS BY clause was applied to the result set, sorting the rows in the order shown above.

Because the sort key, **name**, is a VARCHAR column, the returned rows within each set of siblings are in the ASCII order of their **employee.name** values. Only the sets of siblings that are leaf nodes in the hierarchy of returned rows appear consecutively in the sorted result set, because the managers are immediately followed by the employees who report to them, rather than by their siblings. An exception in this example is **Scott**, whose child nodes form an empty set.

The SIBLINGS keyword in the ORDER BY clause is an extension to the ISO standard syntax for the SQL language. The SELECT statement fails with an error if you include the SIBLINGS keyword in the ORDER BY clause of a query or subquery that does not include a valid CONNECT BY clause.

For more information about hierarchical queries and the CONNECT BY clause, see [Hierarchical Clause on page 819](#).

## OLAP window functions in the ORDER BY clause of SELECT statements

You can include OLAP window functions in the final ORDER BY clause of SELECT statements that do not include the CONNECT BY clause.

If an OLAP function clause is present in the ORDER BY clause, then the OLAP function is evaluated first, before the ORDER BY evaluation.

More generally, for simple SELECT statements that includes one or more OLAP window functions, the database server follows this sequence of processing:

- Apply any joins, filters, GROUP BY, or HAVING specifications to obtain the set of qualifying rows to return as the query result.
- Create window partitions of qualifying rows and apply the specified OLAP functions to each row in each partition (or to the entire query result set, if no partitions are defined).
- Apply the ORDER BY clause of the SELECT statement to the final query result.

For nested queries, each subquery follows the order above, but OLAP window partitions and their OLAP functions are applied to the result set of the innermost subquery in which the OLAP window is defined.

If the OLAP window includes a window ORDER clause, that clause, rather than the ORDER BY clause of the SELECT statement, defines the row numbers that the window ROW\_NUMBER function assigns to the rows in partitions of the same OLAP window. The window ORDER clause does not, however, define the ordering of the query result set, which the ORDER BY clause of SELECT statement defines.

If the OLAP window does not include a window ORDER clause, the row numbers that the window ROW\_NUMBER function assigns to the rows are in arbitrary order, as returned by the query or subquery, rather than according to any ORDER BY clause of the SELECT statement.

---

[OLAP window expressions on page 1383](#)

## Ordering STANDARD or RAW result tables

When the SELECT INTO Table clause defines a permanent table to store the result of a query, any non-trivial column expression in that clause must also declare an alias for the corresponding column in the newly-created result table. To specify that column as a sorting key for the result table, the ORDER BY clause must also reference the same alias, rather than specifying the non-trivial column expression.

For example, in the following nested query, **tab56** is the identifier of a result table, and **tab56\_col0** is an alias for the non-trivial column expression that a subquery in the Projection clause defines. The ORDER BY clause specifies the same subquery as a sorting key, rather than referencing that non-trivial column expression by its alias:

```
SELECT ( SELECT tab54.tab54_col7 tab56_col0
        FROM tab54
        WHERE (tab54.tab54_col7 = -1423023 )
        ) tab56_col0,
      "" tab56_col1
FROM tab57
WHERE tab57.tab57_col1 == -6296233
ORDER BY (
```

```

SELECT tab54.tab54_col7 tab56_col0
FROM tab54
WHERE (tab54.tab54_col7 = -1423023 )
) NULLS FIRST,2 NULLS FIRST
INTO tab56;

```

Specifying the non-trivial column expression in the ORDER BY clause is acceptable in a normal SELECT statement, but not in an ORDER BY clause that sorts a result table that the SELECT INTO Table clause created. In the example above, the database server returns SQL error -19828.

To avoid this error, the example above must be modified to remove the non-trivial column expression from the ORDER BY clause, replacing that expression with its alias:

```

SELECT ( SELECT tab54.tab54_col7 tab56_col0
        FROM tab54
        WHERE (tab54.tab54_col7 = -1423023 )
        ) tab56_col0,
      "" tab56_col1
FROM tab57
WHERE tab57.tab57_col1 == -6296233
ORDER BY
      tab56_col0      -- Substituted alias for column expression in result table)
NULLS FIRST,2 NULLS FIRST
INTO tab56;

```

## LIMIT Clause

The LIMIT clause can restrict the result set of the query to some maximum number of rows. If this clause specifies a value smaller than the number of qualifying rows, the query returns only a subset of the rows that satisfy the selection criteria.

The LIMIT clause is an extension to the ISO/ANSI standard for the SQL language. This syntax fragment is part of the [SELECT statement on page 768](#).

LIMIT clause

<sup>427</sup>**LIMIT**

*max max\_var*

| Element        | Description   | Restrictions  | Syntax                                      |
|----------------|---|---|---|
| <i>max</i>     | Integer (> 0) specifying maximum number of rows to return           | If <i>max</i> > number of qualifying rows then all matching rows are returned | <a href="#">Literal Number on page 1419</a> |
| <i>max_var</i> | Host variable or local SPL variable storing the value of <i>max</i> | Same as <i>max</i> ; valid in prepared objects and in SPL routines            | Language dependent                          |

### Usage

The LIMIT clause specifies that the result set includes no more than *max* rows (or exactly *max* rows, if *max* is less than the number of qualifying rows). Any additional rows that satisfy the query selection criteria are not returned.

427. Informix® extension

The following example sets *max* with a literal integer to retrieve at most 10 rows from table **tab1**:

```
SELECT a, b FROM tab1 LIMIT 10;
```

You can also use a host variable, or the value of an SPL input parameter in a local variable, to assign the value of *max*.

If the LIMIT clause follows the ORDER BY clause, the returned rows are sorted according to the ORDER BY specifications. Because query results are generally not retrieved in any particular sequence, using ORDER BY to constrain the order of rows can be useful in queries whose LIMIT clause returns only a subset of the qualifying rows.

For example, the following query returns data about the ten highest-paid employees:

```
SELECT name, salary FROM emp
ORDER BY salary DESC LIMIT 10;
```

You can use the LIMIT clause in a query whose result set defines a collection-derived table (CDT) within the FROM clause of another SELECT statement. The following query specifies a CDT that has no more than ten rows:

```
SELECT *
FROM TABLE(MULTISET(SELECT * FROM employees
ORDER BY employee_id LIMIT 10 )) vt(x,y), tab2
WHERE tab2.id = vt.x;
```

The next example applies the LIMIT clause to the result of a UNION query:

```
SELECT a, b FROM tab1 LIMIT 10 UNION SELECT a, b FROM tab2;
```

## Restrictions on the LIMIT clause

The LIMIT clause is not valid in any of the following contexts:

- In the definition of a view
- In nested SELECT statements
- In subqueries, except for subqueries that specify table expressions in the FROM clause
- In a singleton SELECT (where *max* = 1) within an SPL routine
- Where embedded SELECT statements are used as expressions.

## Dependencies between the LIMIT clause and Projection clause

Syntax of the LIMIT clause that can follow the ORDER BY clause resembles the syntax of the FIRST option in the Projection clause, where LIMIT is valid as a keyword synonym for FIRST. The following examples are both valid, and both queries return the same results:

```
SELECT FIRST 5 c1, c2 FROM tab ORDER BY c3;
SELECT c1, c2 FROM tab ORDER BY c3 LIMIT 5;
```

Whether or not a query that uses the LIMIT clause also specifies ORDER BY can affect which qualifying rows are in the result sent if the Projection clause includes the SKIP options. The SKIP option, which specifies an offset for the *max* qualifying rows that FIRST or LIMIT restricts, is valid only in the Projection clause, but its specification can affect which of the sorted rows the LIMIT clause includes in the query result.

The following query retrieves two column values from each row of table *tab*, but the SKIP option excludes the first twenty rows. After ORDER BY sorts the rows by their value in a third column, the LIMIT clause restricts the query result to only the ten rows with the smallest values in column *c3*:

```
SELECT SKIP 20 c1, c2 FROM tab ORDER BY c3 LIMIT 10;
```

Combining the SKIP option and the LIMIT clause is also valid in queries that include table expressions in the FROM clause, as in this example:

```
SELECT * FROM (SELECT SKIP 2 col1 FROM tab1
               WHERE col1 > 50 LIMIT 8);
```

But because you cannot use FIRST as a synonym for LIMIT outside the Projection clause, the following query fails with a syntax error:

```
SELECT SKIP 20 c1, c2 FROM tab ORDER BY c3 FIRST 10;
```

The database server also issues an error if the FIRST or LIMIT *max* value in the Projection clause differs from the *max* value in the LIMIT clause, if both *max* specifications are in the same query block and apply to the same query result set, as in these bad examples:

```
SELECT FIRST 20 c1, c2 FROM tab ORDER BY c3 LIMIT 10;
SELECT LIMIT 10 c1, c2 FROM tab ORDER BY c3 LIMIT 20;
```

No error is issued, however, if both the FIRST or LIMIT option in the Projection clause and the LIMIT clause specify the same *max* value. The following examples are equivalent and valid:

```
SELECT LIMIT 20 c1, c2 FROM tab ORDER BY c4;
SELECT c1, c2 FROM tab ORDER BY c4 LIMIT 20;
```

Besides the SKIP, FIRST, and LIMIT options, the DISTINCT and UNIQUE specifications of the Projection clause can also restrict query results to a subset of the qualifying rows, as their Projection clause topics explain.

## FOR UPDATE Clause

Use the FOR UPDATE clause in ESQL/C applications and in DB-Access when you intend to update the values returned by a prepared SELECT statement when the values are fetched.

Preparing a SELECT statement that contains a FOR UPDATE clause is equivalent to preparing the SELECT statement without the FOR UPDATE clause and then declaring a FOR UPDATE cursor for the prepared statement. This syntax fragment is part of the [SELECT statement on page 768](#).

FOR UPDATE Clause

<sup>428</sup> **FOR UPDATE**

**OF**

, *column*

| Element       | Description  | Restrictions  | Syntax                                  |
|---------------|--|---|---|
| <i>column</i> | Name of a column that can be updated after a FETCH | Must be in the FROM clause <i>table</i> , but it need not be in the Projection list. All columns must be from the same table. | <a href="#">Identifier on page 1456</a> |

428. Informix® ESQL/C and DB-Access only

The FOR UPDATE keywords notify the database server that updating is possible, causing it to use more stringent locking than it would with a Select cursor. You cannot modify data through a cursor without this clause. You can specify which columns can be updated.

After you declare a cursor for a SELECT . . . FOR UPDATE statement, you can update or delete the currently selected row using an UPDATE or DELETE statement with the WHERE CURRENT OF clause. The keywords CURRENT OF refer to the row that was most recently fetched; they replace the usual conditional expressions in the WHERE clause. To update rows with a specific value, your program might contain statements such as those in the following example:

```
EXEC SQL BEGIN DECLARE SECTION;
    char fname[ 16];
    char lname[ 16];
EXEC SQL END DECLARE SECTION;
. . .

EXEC SQL connect to 'stores_demo';
/* select statement being prepared contains a for update clause */
EXEC SQL prepare x from 'select fname, lname from customer for update';
EXEC SQL declare xc cursor for x;

for (;;)
{
EXEC SQL fetch xc into $fname, $lname;
if (strncmp(SQLSTATE, '00', 2) != 0) break;
printf("%d %s %s\n",cnum, fname, lname );
if (cnum == 999)          --update rows with 999 customer_num
    EXEC SQL update customer set fname = 'rosey' where current of xc;
}

EXEC SQL close xc;
EXEC SQL disconnect current;
```

A SELECT . . . FOR UPDATE statement, like an Update cursor, allows you to perform updates that are not possible with the UPDATE statement alone, because both the decision to update and the values of the new data items can be based on the original contents of the row. The UPDATE statement cannot query the table that is being updated.

**Note:** A normal update inside the FETCH loop of a cursor cannot guarantee that the updated rows are not fetched again after the UPDATE. The WHERE CURRENT OF specification relates the UPDATE to the Update cursor, and guarantees that each row is updated no more than once, by internally keeping a list of the rows that have already been updated. These rows will not be fetched again by the Update cursor.

## Restrictions

A SELECT statement that includes the FOR UPDATE clause must conform to the following restrictions:

- The statement can select data from only one table.
- The statement cannot include any aggregate functions.
- The statement cannot include any of the following clauses or keywords: DISTINCT, EXCEPT, FOR READ ONLY, GROUP BY, INTO TEMP, INTERSECT, INTO EXTERNAL, MINUS, ORDER BY, UNION, UNIQUE.

- DECLARE statements that associate a cursor with the statement cannot also include the FOR UPDATE keywords.
- The statement is valid only in ESQL/C routines and (within transactions) in the DB-Access utility. It cannot, for example, be issued within an SPL routine.

For information on how to declare an update cursor for a SELECT statement that does not include a FOR UPDATE clause, see [Using the FOR UPDATE Option on page 473](#).

### Update cursors in SPL routines

You cannot include the FOR UPDATE keywords in the SELECT . . . INTO segment of the FOREACH statement of SPL. An SPL routine, however, can provide the functionality of a FOR UPDATE cursor

- by declaring a *cursor* name in the FOREACH statement,
- and then using the WHERE CURRENT OF *cursor* clause in UPDATE or DELETE statements that operate on the current row of that *cursor* within the same FOREACH loop.

### FOR READ ONLY Clause

Use the FOR READ ONLY keywords to specify that the Select cursor declared for the SELECT statement is a read-only cursor. A read-only cursor is a cursor that cannot modify data.

Normally, you do not need to include the FOR READ ONLY clause in a SELECT statement. SELECT is a read-only operation by definition, so the FOR READ ONLY clause is usually unnecessary. In certain circumstances, however, you must include the FOR READ ONLY keywords in a SELECT statement.

If you attempt to include both the FOR READ ONLY clause and the FOR UPDATE clause in the same SELECT statement, the SELECT statement fails. For information on declaring a read-only cursor for a SELECT statement that does not include a FOR READ ONLY clause, see [DECLARE statement on page 467](#).

In an ANSI-compliant database, Select cursors are update cursors by default. An update cursor is a cursor that can be used to modify data. These update cursors are incompatible with the read-only mode of the database. For example, this SELECT statement against the **customer\_ansi** table fails:

```
EXEC SQL declare ansi_curs cursor for
select * from customer_ansi;
```

The solution is to include the FOR READ ONLY clause in your Select cursors. The read-only cursor that this clause specifies is compatible with the read-only mode of the database. For example, the following SELECT FOR READ ONLY statement against the **customer\_ansi** table succeeds:

```
EXEC SQL declare ansi_read cursor for
select * from customer_ansi for read only;
```

DB-Access executes all SELECT statements with Select cursors, so you must specify FOR READ ONLY in all queries that access data in a read-only ANSI-compliant database. The FOR READ ONLY clause causes DB-Access to declare the cursor for the SELECT statement as a read-only cursor.

For more information on level-0 backups, see your *Informix® Backup and Restore Guide*. For more information on Select cursors, read-only cursors, and update cursors, see [DECLARE statement on page 467](#).

## INTO table clauses

Use the INTO Table clauses to create a new temporary, permanent, or external table to receive the data that the SELECT statement retrieves.

This syntax fragment is part of the [SELECT statement on page 768](#).

INTO table clauses

**INTO TEMP** *table*

**WITH NO LOG**

432

INTO EXTERNAL clause <sup>429</sup>

**INTO**

**STANDARD RAW**

*owner* .

*table* <sup>433</sup>

Storage <sup>430</sup>

Lock Mode <sup>431</sup>

| Element      | Description  | Restrictions   | Syntax                                  |
|--------------|--|--|---|
| <i>owner</i> | Authorization identifier of the owner of the result table  | Without this, the user issuing the query is owner by default   | <a href="#">Owner name on page 1488</a> |
| <i>table</i> | Name declared here of a table to receive the query results | Must be unique among names of tables, views, synonyms, and sequence objects that you own in the current database | <a href="#">Identifier on page 1456</a> |

You must have the Connect privilege on the database to create a temporary, permanent, or external table. The name of a temporary table need not be unique among the identifiers of temporary tables in other user sessions.

Column names in the permanent, temporary, or external table must be specified in the Projection clause, where you must supply a display label for all expressions that are not simple column expressions. The display label becomes the column name in the permanent, temporary, or external table. If you do not declare a display label for a simple column expression, the resulting new table uses the column name from the select list of the Projection clause.

429. See [INTO EXTERNAL clause on page 857](#)

430. See [Storage options on page 376](#)

431. See [LOCK MODE Options on page 392](#)

432. See [INTO TEMP clause on page 855](#)

433. See [INTO STANDARD and INTO RAW Clauses on page 856](#)

The following INTO TEMP example creates the **pushdate** table with two columns, **customer\_num** and **slowdate**:

```
SELECT customer_num, call_dtime + 5 UNITS DAY slowdate
FROM cust_calls INTO TEMP pushdate;
```

The following INTO STANDARD example creates the **stab1** table with two columns, **fc01** and **col2**:

```
SELECT col1::FLOAT fc01, col2
FROM tab1 INTO STANDARD stab1;
```

Here **col1** is an INTEGER column in the **tab1** table from which the query retrieves data, but the **fc01** values are cast to FLOAT in the resulting **stab1** table. A query that omits the STANDARD keyword would create the same result table, because STANDARD is the default table type.

### Results when no rows are returned

When you use an INTO Table clause combined with the WHERE clause, and no rows are returned, the SQLNOTFOUND value is 100 in ANSI-compliant databases and 0 in databases that are not ANSI compliant. If the SELECT INTO TEMPWHERE statement is a part of a multistatement PREPARE and no rows are returned, the SQLNOTFOUND value is 100 for both ANSI-compliant databases and databases that are not ANSI-compliant.

This release of Informix® continues to process the remaining statements of a multistatement prepared object after encountering the SQLNOTFOUND value of 100. You can maintain the legacy behavior, however, of not executing the remaining prepared statements by setting the **IFX\_MULTIPREPSTMT** environment variable to 1.

### Restrictions with INTO table clauses in ESQL/C

In Informix® ESQL/C, do not use both the INTO *table* clause and the INTO *variable* clause in the same query. If you do, no results are returned to the program variables and the **SQLCODE** variable is set to a negative value. For more information about the INTO *variable* clause, see [INTO Clause on page 789](#).

## INTO TEMP clause

The INTO TEMP clause creates a temporary table to hold the query results.

The default initial extent and next extent for a temporary table that the INTO TEMP clause creates are each eight pages. The temporary table must be accessible by the built-in RSAM access method of the database server; you cannot specify another access method.

If you use the same query results more than once, using a temporary table saves time. In addition, using an INTO TEMP clause often gives you clearer and more understandable SELECT statements.

Data values in a temporary table are static; they are not updated as changes are made to the tables that were used to build the temporary table. You can use the CREATE INDEX statement to create indexes on a temporary table.

A logged temporary table exists until one of the following events occurs:

- The application disconnects from the database.
- A DROP TABLE statement is issued on the temporary table.
- The database is closed.

A nonlogging temporary table exists until one of the following events occurs:

- The application disconnects from the database.
- A DROP TABLE statement is issued on the temporary table.

If your Informix® database does not have transaction logging, the temporary table behaves in the same way as a table created with the WITH NO LOG option.

If you specify more than one temporary dbspace in the **DBSPACETEMP** environment variable (or if this is not set, in the DBSPACETEMP configuration parameter), the INTO TEMP clause loads the rows of the results set of the query into each of these dbspaces in round-robin fashion. For more information about the storage location of temporary tables that queries with the INTO TEMP clause create, see [Where temporary tables are stored on page 403](#).

Because operations on nonlogging temporary tables are not logged, using the WITH NO LOG option reduces the overhead of transaction logging.

Because nonlogging temporary tables do not disappear when the database is closed, you can use a nonlogging temporary table to transfer data from one database to another while the application remains connected. The behavior of a temporary table that you create with the WITH NO LOG option of the INTO TEMP clause resembles that of a RAW table.

For more information about temporary tables, see [CREATE TEMP TABLE statement on page 397](#).

## INTO STANDARD and INTO RAW Clauses

You can use the INTO STANDARD and INTO RAW clauses to create a new permanent table that stores the result set of the SELECT statement. This syntax provides a single mechanism to specify a query, to receive the qualifying records, and to insert those query results into a permanent database table.

When using SELECT INTO to create a new permanent table, you can specify its type as STANDARD or RAW. The default type is STANDARD. You can optionally specify the storage location, extent size, and lock mode options for the new table.

The column names of the new permanent table are the names specified in the select list of the Projection clause. If an asterisk ( \*) appears as the select list of the Projection clause, the asterisk is expanded to all the column names the corresponding tables or views in the FROM clause of the SELECT statement. Any shadow columns are not expanded by the asterisk specification.

The following example creates a new raw table called **ptabl** to store the results of a join query:

```
SELECT t1col1, t1col2, t2col1
FROM tab1, tab2
WHERE t1col1 < 100 and t2col1 > 5
INTO RAW ptabl;
```

In the example above, the new **ptabl** table would contain the columns **t1col1**, **t1col2** and **t2col1**.

All expressions other than simple column expressions must have a display label defined in the Projection clause. This display label is used as the name of the column in the new table. If a simple (or trivial) column expression has no display label, the table uses the column name. If there are duplicate display labels or column names in the select list, an error is returned.

The next example fails with error -249, because it declares no display label for the **col1+5** expression:

```
SELECT col1+5, col2
FROM tab1
INTO ptab1;
```

The following revised query avoids the -249 error in the previous example:

```
SELECT col1+5 pcol1, col2
FROM tab1
INTO ptab1;
```

The corrected example above creates the standard **ptab1** table to store the query results in its columns **pcol1** and **col2**.

### Restrictions on result tables

As with most DDL statements, attempts to create the new result table in another database using the fully qualified table name fail with a syntax error.

It is similarly an error to create a result table with the same name as an existing table in the same database.

The SELECT INTO . . . TABLE statement cannot be used as a part of a subquery.

You can, however, use a column that is not part of the projection list of the SELECT clause as a sort key in the ORDER BY clause. The following query is valid, where the result of the join is ordered by column **ptab2**, which is not included in the projection list:

```
SELECT t1col1, t1col2, t2col1
FROM tab1, tab2
WHERE t1col1 < 100 and t2col1 > 5
ORDER BY t2col2 DESC
INTO RAW ptab2;
```

For a description of CREATE TABLE statement syntax that can similarly create a query result table and populate that table by inserting the qualifying rows, see [AS SELECT clause on page 341](#).

### INTO EXTERNAL clause

The INTO EXTERNAL clause unloads query results into an external table, creating a default external table description that you can use when you later reload the files.

This syntax fragment is part of the [INTO table clauses on page 854](#).
