Set the **INFORMIXCPPMAP** environment variable to specify the fully qualified pathname of the map file for C++ programs. Information in the map file includes the database server type, the name of the shared library that supports the database object or value object type, the library entry point for the object, and the C++ library for which an object was built.

**setenv****INFORMIXCPPMAP***pathname*

### ***pathname***

The directory path where the C++ map file is stored.

The map file is a text file that can have any filename. You can specify several map files, separated by colons (:) on UNIX™ or semicolons (;) on Windows™.

On UNIX™, the default map file is `$INFORMIXDIR/etc/c++map`. On Windows™, the default map file is `%INFORMIXDIR%\etc\c++map`.

## INFORMIXDIR environment variable

The **INFORMIXDIR** environment variable specifies the directory that contains the subdirectories in which your product files are installed. You must always set **INFORMIXDIR**. Verify that **INFORMIXDIR** is set to the full pathname of the directory in which you installed your database server. If you have multiple versions of a database server, set **INFORMIXDIR** to the appropriate directory name for the version that you want to access. For information about when to set **INFORMIXDIR**, see your *Informix® Installation Guide*.

**setenv****INFORMIXDIR***pathname*

### ***pathname***

is the directory path where the product files are installed.

To set **INFORMIXDIR** to `usr/informix/`, for example, as the installation directory, enter the following command:

```
setenv INFORMIXDIR /usr/informix
```

## INFORMIXSERVER environment variable

The **INFORMIXSERVER** environment variable specifies the default database server to which an explicit or implicit connection is made by an SQL API client, the DB-Access utility, or other HCL Informix® products.

This environment variable must be set before you can use HCL Informix® client products. It has the following syntax.

**setenv****INFORMIXSERVER***dbservername*

### ***dbservername***

is the name of the default database server.

The value of **INFORMIXSERVER** can be a local or remote server, but must correspond to a valid *dbservername* entry in the `$INFORMIXDIR/etc/sqlhosts` file on the computer running the application. The *dbservername* must begin with a lower-case

letter and cannot exceed 128 bytes. It can include any printable characters except uppercase characters, field delimiters (blank space or tab), the newline character, and the hyphen (or minus) symbol.

For example, this command specifies the **coral** database server as the default:

```
setenv INFORMIXSERVER coral
```

**INFORMIXSERVER** specifies the database server to which an application connects if the CONNECT DEFAULT statement is executed. It also defines the database server to which an initial implicit connection is established if the first statement in an application is not a CONNECT statement.

**Important:** You must set **INFORMIXSERVER** even if the application or DB-Access does not use implicit or explicit default connections.

## INFORMIXSHMBASE environment variable (UNIX™)

The **INFORMIXSHMBASE** environment variable affects only client applications connected to HCL Informix® databases that use the interprocess communications (IPC) shared-memory (**ipcshm**) protocol.

**Important:** Resetting **INFORMIXSHMBASE** requires a thorough understanding of how the application uses memory. Normally you do not reset **INFORMIXSHMBASE**.

**INFORMIXSHMBASE** specifies where shared-memory communication segments are attached to the client process so that client applications can avoid collisions with other memory segments that it uses. If you do not set **INFORMIXSHMBASE**, the memory address of the communication segments defaults to an implementation-specific value such as `0x800000`.

**setenv****INFORMIXSHMBASE***value*

**value**

is an integer (in KB) used to calculate the memory address.

The database server calculates the memory address where segments are attached by multiplying the value of **INFORMIXSHMBASE** by `1,024`. For example, on a system that uses the C shell, you can set the memory address to the value `0x800000` by entering the following command:

```
setenv INFORMIXSHMBASE 8192
```

For more information, see your *Informix® Administrator's Guide* and the .

## INFORMIXSQLHOSTS environment variable

The **INFORMIXSQLHOSTS** environment variable specifies where the SQL client or the database server can find connectivity information.

**setenv****INFORMIXSQLHOSTS***pathname*

**pathname**

The full path name of the connectivity information file.

**UNIX:** Default = `$INFORMIXDIR/etc/sqlhosts`

**Windows server:** Default = `%INFORMIXDIR%\etc\sqlhosts.%INFORMIXSERVER%`

For example, the following command overrides the default location and specifies that the `mysqlhosts` file is in the `/work/envt` directory:

```
setenv INFORMIXSQLHOSTS /work/envt/mysqlhosts
```

**Windows™ client:** The `INFORMIXSQLHOSTS` environment variable points to the computer whose registry contains the `SQLHOSTS` subkey. For example, the following command instructs the Windows™ client to look for connectivity information in the registry of a computer named **arizona**:

```
set INFORMIXSQLHOSTS = \\arizona
```

## INFORMIXSTACKSIZE environment variable

The **INFORMIXSTACKSIZE** environment variable specifies the stack size (in KB) that is applied to all client processes. Any value that you set for `INFORMIXSTACKSIZE` in the client environment is ignored by the database server.

**setenv**`INFORMIXSTACKSIZE`*size*

**size**

is an integer, setting the stack size (in KB) for SQL client threads.

For example, to decrease the **INFORMIXSTACKSIZE** to 20 KB, enter the following command:

```
setenv INFORMIXSTACKSIZE 20
```

If **INFORMIXSTACKSIZE** is not set, the stack size is taken from the database server configuration parameter `STACKSIZE` or else defaults to a platform-specific value. The default stack size value for the primary thread of an SQL client is 32 KB for nonrecursive database activity.

**Warning:** For instructions on setting this value, see the . If you incorrectly set the value of **INFORMIXSTACKSIZE**, it can cause the database server to fail.

## INFORMIXTERM environment variable (UNIX™)

The **INFORMIXTERM** environment variable specifies whether DB-Access should use the information in the `terminfo` directory or the `termcap` file.

On character-based systems, the `terminfo` directory and `termcap` file determine terminal-dependent keyboard and screen capabilities, such as the operation of function keys, color and intensity attributes in screen displays, and the definition of window borders and graphic characters.

### **setenv**INFORMIXTERM

#### **terminfo termcap**

If **INFORMIXTERM** is not set, the default setting is `terminfo`.

The `terminfo` directory contains a file for each terminal name that has been defined. The `terminfo` setting for **INFORMIXTERM** is supported only on computers that provide full support for the UNIX™ System V `terminfo` library. For details, see the machine notes file for your product.

When DB-Access is installed on your system, a `termcap` file is placed in the **etc** subdirectory of `$INFORMIXDIR`. This file is a superset of an operating-system **termcap** file. You can use the **termcap** file that the database server supplies, the system `termcap` file, or a `termcap` file that you create. You must set the **TERMCAP** environment variable if you do not use the default `termcap` file. For information about setting the **TERMCAP** environment variable, see [TERMCAP environment variable \(UNIX\) on page 1753](#).

## INF\_ROLE\_SEP environment variable

The **INF\_ROLE\_SEP** environment variable configures the security feature of role separation when the database server is installed or reinstalled on UNIX™ systems. Role separation enforces separating administrative tasks by people who run and audit the database server. After the installation is complete, **INF\_ROLE\_SEP** has no effect. If **INF\_ROLE\_SEP** is not set, then user **informix** (the default) can perform all administrative tasks.

### **setenv**INF\_ROLE\_SEPN

*n*

is any positive integer.

On Windows™, the install process asks whether you want to enable role separation regardless of the setting of **INF\_ROLE\_SEP**. To enable role separation for database servers on Windows™, select the role-separation option during installation.

If **INF\_ROLE\_SEP** is set when HCL Informix® is installed on a UNIX™ platform, role separation is implemented and a separate group is specified to serve each of the following responsibilities:

- The Database Server Administrator (DBSA)
- The Audit Analysis Officer (AAO)
- The standard user

On UNIX™, you can establish role separation by changing the group that owns the `aaodir`, `dbssdir`, or `etc` directories at any time after the installation is complete. You can disable role separation by resetting the group that owns these directories to **informix**. You can have role separation enabled, for example, for the Audit Analysis Officer (AAO) without having role separation enabled for the Database Server Administrator (DBSA).

For more information about the security feature of role separation, see the *Informix® Security Guide*. To learn how to configure role separation when you install your database server, see your *Informix® Installation Guide*.

## INTERACTIVE\_DESKTOP\_OFF environment variable (Windows™)

This environment variable lets you prevent interaction with the Windows™ desktop when an SPL routine executes a SYSTEM command.

**setenv**INTERACTIVE\_DESKTOP\_OFF

**1 0**

If **INTERACTIVE\_DESKTOP\_OFF** is **1** and an SPL routine attempts to interact with the desktop (for example, with the `notepad.exe` or `cmd.exe` program), the routine fails unless the user is a member of the **Administrators** group.

The valid settings (**1** or **0**) have the following effects:

**1**

Prevents the database server from acquiring desktop resources for the user executing the stored procedure

**0**

SYSTEM commands in a stored procedure can interact with the desktop. This is the default value.

Setting **INTERACTIVE\_DESKTOP\_OFF** to **1** allows an SPL routine that does not interact with the desktop to execute more quickly. This setting also allows the database server to simultaneously call a greater number of SYSTEM commands because the command no longer depends on a limited operating-system resource (Desktop and WindowStation handles).

## JAR\_TEMP\_PATH environment variable

Set the **JAR\_TEMP\_PATH** variable to specify a non-default local file system location where jar management procedures such as **install\_jar()** and **replace\_jar()** can store temporary **.jar** files of the Java™ virtual machine.

**setenv**JAR\_TEMP\_PATH`pathname`

**pathname**

specifies a local directory for temporary **.jar** files.

This directory must have read and write permissions for the user who starts the database server. If the **JAR\_TEMP\_PATH** environment variable is not set, temporary copies of **.jar** files are stored in the **/tmp** directory of the local file system for the database server.

## JAVA\_COMPILER environment variable

You can set the **JAVA\_COMPILER** environment variable in the Java™ virtual machine environment to disable JIT compilation.

**setenv**JAVA\_COMPILER

**none NONE**

The `NONE` and `none` settings are equivalent. On UNIX™ systems that support the C shell and on which `JAVA_COMPILER` has been set to `NONE` or `none`, you can enable the JIT compiler for the JVM environment by the following command:

```
unset JAVA_COMPILER
```

## JVM\_MAX\_HEAP\_SIZE environment variable

The `JVM_MAX_HEAP_SIZE` environment variable can set a non-default upper limit on the size of the heap for the Java™ virtual machine.

**setenv**`JVM_MAX_HEAP_SIZE` *size*

***size***

is a positive integer that specifies the maximum size (in megabytes).

For example, the following command sets the maximum heap size at 12 MB:

```
set JVM_MAX_HEAP_SIZE 12
```

If you do not set `JVM_MAX_HEAP_SIZE`, 16 MB is the default maximum size.

## LD\_LIBRARY\_PATH environment variable (UNIX™)

The `LD_LIBRARY_PATH` environment variable tells the shell on Solaris systems which directories to search for client or shared HCL Informix® general libraries. You must specify the directory that contains your client libraries before you can use the product.

**setenv**`LD_LIBRARY_PATH``$PATH`:

*pathname*

***pathname***

Specifies the search path for the library.

For INTERSOLV DataDirect ODBC Driver on AIX®, set `LIBPATH`. For INTERSOLV DataDirect ODBC Driver on HP-UX, set `SHLIB_PATH`.

The following example sets the `LD_LIBRARY_PATH` environment variable to the directory:

```
setenv LD_LIBRARY_PATH
${INFORMIXDIR}/lib:${INFORMIXDIR}/lib/esql:${LD_LIBRARY_PATH}
```

## LIBPATH environment variable (UNIX™)

The `LIBPATH` environment variable tells the shell on AIX® systems which directories to search for dynamic-link libraries for the INTERSOLV DataDirect ODBC Driver. You must specify the full path name for the directory where you installed the product.

### **setenvLIBPATH**

*: pathname*

***pathname***

Specifies the search path for the libraries.

On Solaris, set **LD\_LIBRARY\_PATH**. On HP-UX, set **SHLIB\_PATH**.

## NODEFDAC environment variable

Enabling NODEFDAC applies the ANSI-compliant restrictions on default access privileges for the PUBLIC group when tables or Owner-mode user-defined routines are created in databases that are not ANSI-compliant.

In a database that is not ANSI-compliant, when the **NODEFDAC** environment variable enabled by setting it to `yes`,

- the database server withholds default table access privileges from PUBLIC when a new table is created,
- and also withholds the default Execute privilege from PUBLIC when an owner-privileged UDR is created.

### **setenvNODEFDAC**

**yes**

**yes**

prevents default table privileges (Select, Insert, Update, and Delete) from being granted to PUBLIC on new tables in a database that is not ANSI-compliant. This setting also prevents the Execute privilege from being granted to PUBLIC by default when a new user-defined routine is created in Owner mode.

The `yes` setting is case sensitive, and is also sensitive to leading and trailing blank spaces. Including uppercase letters or blank spaces in the setting is equivalent to leaving **NODEFDAC** unset. When **NODEFDAC** is not set, or if it is set to any value besides `yes`, default privileges on tables and Owner-mode UDRs are granted to PUBLIC by default when the table or UDR is created in a database that is not ANSI-compliant. The setting `YES`, for example, disables **NODEFDAC**.

Enabling **NODEFDAC** has no effect in an ANSI-compliant databases.

**Important:** Enabling **NODEFDAC** withholds default table or routine privileges from PUBLIC when the object is created, but the **NODEFDAC** setting cannot prevent the PUBLIC group from being granted the same privileges by a user who holds the necessary access privileges on the new table or on the new UDR.

## ONCONFIG environment variable

The **ONCONFIG** environment variable specifies the name of the active file, called the `onconfig` file, which holds the configuration parameters for the database server.

This file is read as input during the initialization procedure. After you prepare your `onconfig` configuration file, set the **ONCONFIG** environment variable to the name of this file.

**setenv****ONCONFIG***filename*

**filename**

is the name of your `onconfig` file in the `%INFORMIXDIR%\etc\%ONCONFIG%` or `$INFORMIXDIR/etc/$ONCONFIG` directory

This file contains the configuration parameters for your database.

To prepare the `onconfig` file, make a copy of the `onconfig.std` file and modify the copy. Name the `onconfig` file so that it can easily be related to a specific database server. If you have multiple instances of a database server, each instance *must* have its own uniquely named `onconfig` file.

If the **ONCONFIG** environment variable is not set, the database server reads the configuration values from the `onconfig` file during initialization.

## ONINIT\_STDOUT environment variable (Windows™)

The **ONINIT\_STDOUT** environment variable specifies a path and file name in which output from the `oninit` command is stored.

While it is not generally necessary to view output from the `oninit` command, it might be necessary in certain situations, such as when using the `-v` (verbose) option or when you want to see output from an unhandled exception in a process launched within a virtual processor. When the value of **ONINIT\_STDOUT** is set to the name of a file, output from the `oninit` command is written to the file.

**set****ONINIT\_STDOUT***\path\filename*

You can set the **ONINIT\_STDOUT** environment variable as a system variable in **Control Panel > System > Advanced > Environment Variables**. If the HCL Informix® service is configured to log on as user **informix**, start the service using the `starts` command after setting the environment variable. Note, however, that because environment variables are read from the system when the service is started, if the service is set to log on as the local system user, you must restart your computer for the environment variable to take effect. Because the local system user is effectively logged on at all times, environment variables are refreshed only when the operating system is restarted.

For example, if the environment variable set to `C:\temp\oninit_out.txt`, you can start the server with the verbose option with the following command:

```
starts %INFORMIXSERVER% -v
```

The `oninit` messages are saved to the `C:\temp\oninit_out.txt` file.

**Important:** Only a single instance of the database can run on a Windows™ machine if the **ONINIT\_STDOUT** environment variable is set.

## OPTCOMPIND environment variable

You can set the **OPTCOMPIND** environment variable so that the optimizer can select the appropriate join method.

**setenv OPTCOMPIND**

**2 1 0**

**0**

A nested-loop join is preferred, where possible, over a sort-merge join or a hash join.

**1**

When the isolation level is *not* Repeatable Read, the optimizer behaves as in setting **2**; otherwise, the optimizer behaves as in setting **0**.

**2**

Nested-loop joins are not necessarily preferred. The optimizer bases its decision purely on costs, regardless of transaction isolation mode.

When **OPTCOMPIND** is not set, the database server uses the OPTCOMPIND value from the ONCONFIG configuration file.

When neither the environment variable nor the configuration parameter is set, the default value is **2**.

On HCL Informix®, the SET ENVIRONMENT OPTCOMPIND statement can set or reset **OPTCOMPIND** dynamically at runtime. This overrides the current **OPTCOMPIND** value (or the ONCONFIG configuration parameter OPTCOMPIND) for the current user session only. For more information about the SET ENVIRONMENT OPTCOMPIND statement of SQL see the *Informix® Guide to SQL: Syntax*.

For more information about the ONCONFIG configuration parameter OPTCOMPIND, see the . For more information about the different join methods that the optimizer uses, see your *Informix® Performance Guide*.

## OPTMSG environment variable

Set the **OPTMSG** environment variable at runtime before you start the Informix® ESQL/C application to enable (or disable) optimized message transfers (message chaining) for all SQL statements in the application.

**setenv OPTMSG**

**0 1**

**0**

disables optimized message transfers.

**1**

enables optimized message transfers and implements the feature for any subsequent connection.

The default value is **0** (zero), which explicitly disables message chaining. You might want, for example, to disable optimized message transfers for statements that require immediate replies, for debugging, or to ensure that the database server processes all messages before the application terminates.

When you set **OPTMSG** within an application, you can activate or deactivate optimized message transfers for each connection or within each thread. To enable optimized message transfers, you must set **OPTMSG** before you establish a connection.

For more information about setting **OPTMSG** and defining related global variables, see the *Informix® ESQL/C Programmer's Manual*.

## OPTOFC environment variable

Use the **OPTOFC** environment variable to enable optimize-OPEN-FETCH-CLOSE functionality in Informix® ESQL/C applications or other APIs (such as JDBC, ODBC, OLE DB, LIBDMI, and Lib C++) that use DECLARE and OPEN statements to establish a cursor.

### setenvOPTOFC

#### 0 1

**0**

disables **OPTOFC** for all threads of the application.

**1**

enables **OPTOFC** for every cursor in every thread of the application.

The default value is 0 (zero).

You can set the **OPTOFC** environment variable on the client or server. If this environment variable is set on the server, then any application that does not explicitly set this environment variable uses the value that is set on the server.

The **OPTOFC** environment variable reduces the number of message requests between the application and the database server.

If you set **OPTOFC** from the shell, you must set it before you start the Informix® ESQL/C application. For more information about enabling **OPTOFC** and related features, see the *Informix® ESQL/C Programmer's Manual*.

## OPT\_GOAL environment variable (UNIX™)

Set the **OPT\_GOAL** environment variable in the user environment, before you start an application, to specify the query performance goal for the optimizer.

### setenvOPT\_GOAL

#### 0 -1

**0**

Specifies user-response-time optimization.

**-1**

Specifies total-query-time optimization.

The default behavior is for the optimizer to use query plans that optimize the total query time.

You can also specify the optimization goal for individual queries with optimizer directives or for a session with the SET OPTIMIZATION statement.

Both methods take precedence over the **OPT\_GOAL** environment variable setting. You can also set the OPT\_GOAL configuration parameter for the HCL Informix® system; this method has the lowest level of precedence.

For more information about optimizing queries for your database server, see your *Informix® Performance Guide*. For information about the SET OPTIMIZATION statement, see the *Informix® Guide to SQL: Syntax*.

## PATH environment variable

The UNIX™ **PATH** environment variable tells the shell which directories to search for executable programs. You must add the directory containing your HCL Informix® product to your **PATH** setting before you can use the product.

**setenvPATH\$PATH:**

: *pathname*

***pathname***

Specifies the search path for the executable files.

Include a colon ( : ) separator between the path names on UNIX™ systems. (Use the semicolon ( ; ) separator between path names on Windows™ systems.)

You can specify the search path in various ways. The **PATH** environment variable tells the operating system where to search for executable programs. You must include the directory that contains your HCL Informix® product in your **path** setting before you can use the product. This directory should be located before \$INFORMIXDIR/bin, which you must also include.

For additional information about how to modify your path, see [Modifying an environment-variable setting on page 1681](#).

## PDQPRIORITY environment variable

The **PDQPRIORITY** environment variable determines the degree of parallelism that the database server uses and affects how the database server allocates resources, including memory, processors, and disk reads.

**setenvPDQPRIORITY**

**HIGH LOW OFF**

*resources*

***resources***

Is an integer in the range 0 to 100. The value 1 is the same as LOW, and 100 is the same as HIGH. Values lower than 0 are set to 0 (OFF), and values greater than 100 are set to 100 (HIGH).

Value 0 is the same as OFF (for HCL Informix® only).

Here the HIGH, LOW, and OFF keywords have the following effects:

**HIGH**

When the database server allocates resources among all users, it gives as many resources as possible to the query.

**LOW**

Data values are fetched from fragmented tables in parallel.

**OFF**

PDQ processing is turned off (for HCL Informix® only).

Usually, the more resources a database server uses, the better its performance for a given query. If the server uses too many resources, however, contention for the resources can take resources away from other queries, resulting in degraded performance. For more information about performance considerations for **PDQPRIORITY**, see the *Informix® Performance Guide*.

An application can override the setting of this environment variable when it issues the SQL statement SET PDQPRIORITY, as the *Informix® Guide to SQL: Syntax* describes.

## Using PDQPRIORITY with Informix®

The *resources* value specifies the query priority level and the amount of resources that the database server uses to process the query.

When **PDQPRIORITY** is not set, the default value is **OFF**.

When **PDQPRIORITY** is set to HIGH, HCL Informix® determines an appropriate value to use for **PDQPRIORITY** based on several criteria. These include the number of available processors, the fragmentation of tables queried, the complexity of the query, and additional factors.

## PSM\_ACT\_LOG environment variable

Use the **PSM\_ACT\_LOG** environment variable to specify the location of the Informix® Primary Storage Manager activity log for your environment, for example, for a single session.

**setenv**PSM\_ACT\_LOG *pathname*

***pathname***

The full path name for the location of the `$INFORMIXDIR/psm_act.log`. If you specify a file name only, the storage manager creates the activity log in the working directory in which you started the storage manager.

The **PSM\_ACT\_LOG** environment variable overrides the value of the PSM\_ACT\_LOG configuration parameter.

---

## PSM\_CATALOG\_PATH environment variable

Use the **PSM\_CATALOG\_PATH** environment variable to specify the location of the Informix® Primary Storage Manager catalog tables for your environment, for example, for a single session.

**setenv**PSM\_CATALOG\_PATH *pathname*

### ***pathname***

The full path name for the location of the catalog table, which contain information about the pools, devices, and objects managed by the storage manager.

The **PSM\_CATALOG\_PATH** environment variable overrides the value of the PSM\_CATALOG\_PATH configuration parameter.

---

## PSM\_DBS\_POOL environment variable

Use the **PSM\_DBS\_POOL** environment variable to change the name of the pool in which the Informix® Primary Storage Manager places backup and restore dbspace data for your environment, for example, for a single session.

**setenv**PSM\_DBS\_POOL *pool\_name*

### ***pool\_name***

The name of the storage manager pool.

The **PSM\_DBS\_POOL** environment variable overrides the value of the PSM\_DBS\_POOL configuration parameter.

---

## PSM\_DEBUG environment variable

Use the **PSM\_DEBUG** environment variable to specify the amount of debugging information that prints in the Informix® Primary Storage Manager debug log for your environment, for example, for a single session.

**setenv**PSM\_DEBUG *value*

### ***value***

**0** = No debugging messages.

**1** = Prints only internal errors.

**2** = Prints information about the entry and exit of functions and prints internal errors.

**3** = Prints the information specified by **1-2** with additional details.

**4** = Prints information about parallel operations and the information specified by **1-3**.

**5** = Prints information about internal states in the Informix® Primary Storage Manager.

6 = Prints the information specified by 1-5 with additional details.

7 = Prints information specified by 1-6 with additional details.

8 = Prints information specified by 1-7 with additional details.

9 = Prints all debugging information.

The **PSM\_DEBUG** environment variable overrides the value of the PSM\_DEBUG configuration parameter.

---

## PSM\_DEBUG\_LOG environment variable

Use the **PSM\_DEBUG\_LOG** environment variable to specify the location of the Informix® Primary Storage Manager debug log for your environment, for example, for a single session.

**setenvPSM\_DEBUG\_LOG** *pathname*

***pathname***

The full path name for the location of the `$INFORMIXDIR/psm_debug.log`. If you specify a file name only, the storage manager creates the debug log in the working directory in which you started the storage manager.

The **PSM\_DEBUG\_LOG** environment variable overrides the value of the PSM\_DEBUG\_LOG configuration parameter.

---

## PSM\_LOG\_POOL environment variable

Use the **PSM\_LOG\_POOL** environment variable to change the name of the pool in which the Informix® Primary Storage Manager places backup and restore log data for your environment, for example, for a single session.

**setenvPSM\_LOG\_POOL** *pool\_name*

***pool\_name***

The name of the storage manager log pool.

The **PSM\_LOG\_POOL** environment variable overrides the value of the PSM\_LOG\_POOL configuration parameter.

---

## PSORT\_DBTEMP environment variable

The **PSORT\_DBTEMP** environment variable specifies the location where the database server writes the temporary files that the **PSORT\_NPROCS** environment variable uses to perform a sort.

**setenvPSORT\_DBTEMP**

: *pathname*

***pathname***

The name of the UNIX™ directory used for intermediate writes during a sort.

To set the **PSORT\_DBTEMP** environment variable to specify the directory (for example, `/usr/leif/tempsort`), enter the following command:

```
setenv PSORT_DBTEMP /usr/leif/tempsort
```

For maximum performance, specify directories that are located in file systems on different disks.

You might also want to consider setting the environment variable **DBSPACETEMP** to place temporary files used in sorting in dbspaces rather than operating-system files. See the discussion of the **DBSPACETEMP** environment variable in [DBSPACETEMP environment variable on page 1716](#).

The database server uses the directory that **PSORT\_DBTEMP** specifies, even if the environment variable **PSORT\_NPROCS** is not set. For additional information about the **PSORT\_DBTEMP** environment variable, see your *Informix® Administrator's Guide* and your *Informix® Performance Guide*.

## PSORT\_NPROCS environment variable

The **PSORT\_NPROCS** environment variable enables the database server to improve the performance of the parallel-process sorting package by allocating more threads for sorting.

Before the sorting package performs a parallel sort, make sure that the database server has enough memory for the sort. **setenvPSORT\_NPROCS***threads*

***threads***

is an integer, specifying the maximum number of threads to be used to sort a query. This value cannot be greater than 10.

The following command sets **PSORT\_NPROCS** to 4:

```
setenv PSORT_NPROCS 4
```

To disable parallel sorting, enter the following command:

```
unsetenv PSORT_NPROCS
```

It is recommended that you initially set **PSORT\_NPROCS** to 2 when your computer has multiple CPUs. If subsequent CPU activity is lower than I/O activity, you can increase the value of **PSORT\_NPROCS**.

**Tip:** If the **PDQPRIORITY** environment variable is not set, the database server allocates the minimum amount of memory to sorting. This minimum memory is insufficient to start even two sort threads. If you have not set

**PDQPRIORITY**, check the available memory before you perform a large-scale sort (such as an index build) to make sure that you have enough memory.

## Default PSORT\_NPROCS values for detached indexes

If the **PSORT\_NPROCS** environment variable is set, the database server uses the specified number of sort threads as an upper limit for ordinary sorts. If **PSORT\_NPROCS** is not set, parallel sorting does not take place. If you have a single-CPU virtual processor, the database server uses one thread for the sort. If **PSORT\_NPROCS** is set to 0, the database server uses three threads for the sort.

## Default PSORT\_NPROCS values for attached indexes

The default number of threads is different for attached indexes.

If the **PSORT\_NPROCS** environment variable is set, you get the specified number of sort threads for each fragment of the index that is being built.

If **PSORT\_NPROCS** is not set, or if it is set to 0, you get two sort threads for each fragment of the index unless you have a single-CPU virtual processor. If you have a single-CPU virtual processor, you get one sort thread for each fragment of the index.

For additional information about the **PSORT\_NPROCS** environment variable, see your *Informix® Administrator's Guide* and your *Informix® Performance Guide*.

## RTREE\_COST\_ADJUST\_VALUE environment variable

The **RTREE\_COST\_ADJUST\_VALUE** environment variable specifies a coefficient that support functions of user-defined data types can use to estimate the cost of an R-tree index for queries on UDT columns.

**setenv**RTREE\_COST\_ADJUST\_VALUEvalue

### value

is a floating-point number, where  $1 \leq \text{value} \leq 1000$ , specifying a multiplier for estimating the cost of using an index on a UDT column.

For spatial queries, the I/O overhead tends to exceed by far the CPU cost, so by multiplying the uncorrected estimated cost by an appropriate *value* from this setting, the database server can make better cost-based decisions on how to implement queries on UDT columns for which an R-tree index exists.

## SHLIB\_PATH environment variable (UNIX™)

The **SHLIB\_PATH** environment variable tells the shell on HP-UX systems which directories to search for dynamic-link libraries. This is used, for example, with the INTERSOLV DataDirect ODBC Driver. You must specify the full pathname for the directory where you installed the product.

**setenvSHLIB\_PATH\$PATH:**

*: pathname*

**pathname**

Specifies the search path for the libraries.

On Solaris systems, set **LD\_LIBRARY\_PATH**. On AIX® systems, set **LIBPATH**.

## SRV\_FET\_BUF\_SIZE environment variable

Use the **SRV\_FET\_BUF\_SIZE** environment variable to specify the size of the fetch buffer that the local database server uses in distributed DML transactions across database servers.

**setenvSRV\_FET\_BUF\_SIZEsize**

**size**

is a positive integer that is no greater than 1048576 (1 MiB), specifying the size (in bytes) of the fetch buffer that holds data retrieved by a cross-server distributed query.

For example, to set a buffer size to 5,000 bytes on a UNIX™ system that uses the C shell, set **SRV\_FET\_BUF\_SIZE** by entering the following command:

```
setenv SRV_FET_BUF_SIZE 5000
```

When **SRV\_FET\_BUF\_SIZE** is set to a valid value, the new value overrides the default value (or any previously set value) of **SRV\_FET\_BUF\_SIZE**. The setting takes effect only when it is set in the starting environment of the database server.

When **SRV\_FET\_BUF\_SIZE** is not set, the default setting for the fetch buffer is dependent on row size.

No error is raised if **SRV\_FET\_BUF\_SIZE** is set to a value that is less than the default size, or that is greater than 1048576 (1MiB). If you specify a size for **SRV\_FET\_BUF\_SIZE** that is greater than 1048576, the value is set to 1048576. In older 11.70 releases, up to and including 11.70.xC4, the upper limit is 32767.

A valid **SRV\_FET\_BUF\_SIZE** setting is in effect only in cross-server DML transactions in which the local database server participates as the coordinator or as a subordinate database server.

- It has no effect, however, on queries that access only databases of the local server instance, and it does not affect the size of the fetch buffer in client-to-local-server communication.
- The processing of BYTE and TEXT objects is not affected by the **SRV\_FET\_BUF\_SIZE** setting.
- Setting **SRV\_FET\_BUF\_SIZE** for the environment of the local database server does not reset the fetch buffer size of remote server instances that coordinate or participate in cross-server DML transactions with the local server instance.

The greater the size of the buffer, the more rows can be returned, and the less frequently the local server must wait while the database server returns rows. A large buffer can improve performance when transferring a large amount of data between servers.

## STMT\_CACHE environment variable

Use the **STMT\_CACHE** environment variable to control the use of the shared-statement cache on a session.

This feature can reduce memory consumption and can speed query processing among different user sessions. Valid **STMT\_CACHE** values are `1` and `0`.

### **setenv**STMT\_CACHE

**1 0**

**1**

enables the SQL statement cache.

**0**

disables the SQL statement cache.

Set the **STMT\_CACHE** environment variable for applications that do not use the SET STMT\_CACHE statement to control the use of the SQL statement cache. By default, a statement cache is disabled, but can be enabled through the STMT\_CACHE parameter of the `onconfig.std` file or by the SET STMT\_CACHE statement.

This environment variable has no effect if the SQL statement cache is disabled through the configuration file setting. Values set by the SET STMT\_CACHE statement in the application override the **STMT\_CACHE** setting.

## TERM environment variable (UNIX™)

The **TERM** environment variable is used for terminal handling. It lets DB-Access (and other character-based applications) recognize and communicate with the terminal that you are using.

### **setenv**TERMtype

**type**

Specifies the terminal type.

The terminal type specified in the **TERM** setting must correspond to an entry in the `termcap` file or `terminfo` directory.

Before you can set the **TERM** environment variable, you must obtain the code for your terminal from the database administrator.

For example, to specify the vt100 terminal, set the **TERM** environment variable by entering the following command:

```
setenv TERM vt100
```

## TERMCAP environment variable (UNIX™)

The **TERMCAP** environment variable is used for terminal handling. It tells DB-Access (and other character-based applications) to communicate with the `termcap` file instead of the `terminfo` directory.

### **setenv**TERMCAPpathname

#### **pathname**

Specifies the location of the `termcap` file.

The `termcap` file contains a list of various types of terminals and their characteristics. For example, to provide DB-Access terminal-handling information, which is specified in the `/usr/informix/etc/termcap` file, enter the following command:

```
setenv TERMCAP /usr/informix/etc/termcap
```

You can use set **TERMCAP** in any of the following ways. If several `termcap` files exist, they have the following (descending) order of precedence:

1. The `termcap` file that you create
2. The `termcap` file that the database server supplies (that is, `$INFORMIXDIR/etc/termcap`)
3. The operating-system `termcap` file (that is, `/etc/termcap`)

If you set the **TERMCAP** environment variable, be sure that the **INFORMIXTERM** environment variable is set to `termcap`.

If you do not set the **TERMCAP** environment variable, the `terminfo` directory is used by default.

## TERMINFO environment variable (UNIX™)

The **TERMINFO** environment variable is used for terminal handling.

The environment variable is supported only on platforms that provide full support for the `terminfo` libraries that System V and Solaris UNIX™ systems provide.

### **setenv**TERMINFO/usr/lib/terminfo

**TERMINFO** tells DB-Access to communicate with the `terminfo` directory instead of the `termcap` file. The `terminfo` directory has subdirectories that contain files that pertain to terminals and their characteristics.

To set **TERMINFO**, enter the following command:

```
setenv TERMINFO /usr/lib/terminfo
```

## THREADLIB environment variable (UNIX™)

Use the **THREADLIB** environment variable to compile multithreaded Informix® ESQL/C applications. A multithreaded Informix® ESQL/C application lets you establish as many connections to one or more databases as there are threads. These connections can remain active while the application program executes.

The **THREADLIB** environment variable indicates which thread package to use when you compile an application. Currently only the Distributed Computing Environment (DCE) is supported.

**setenvTHREADLIBDCE**

The **THREADLIB** environment variable is checked when the `-thread` option is passed to the Informix® ESQL/C script when you compile a multithreaded Informix® ESQL/C application. When you use the `-thread` option while compiling, the Informix® ESQL/C script generates an error if **THREADLIB** is not set, or if **THREADLIB** is set to an unsupported thread package.

## TZ environment variable

The **TZ** environment variable is used for setting the time zone. It is used by various time functions to compute times relative to Coordinated Universal Time (UTC), formerly known as Greenwich Mean Time (GMT). The format is specified by the operating system.

**setenvTZtzn**

+ -

*hh*

:*mm*

:*ss*

*dzn*

**tzn**

Three-letter time zone name, such as PST. You must specify the correct offset from local time to UTC (Universal Time Coordinated).

**hh**

A one- or two-digit difference in hours between UTC and local time. Optionally signed.

**mm**

Two-digit difference in minutes between UTC and local time.

**ss**

Two-digit difference in seconds between UTC and local time.

**dzn**

Three-letter daylight-saving-time zone, such as PDT. If daylight saving time is never in effect in the locality, set **TZ** without a value for *dzn*.

For example, if you use Pacific Standard Time with Pacific daylight savings time, set the **TZ** environment variable to `PST8PDT`. For more information on setting the **TZ** environment variable, see your operating system documentation.

## USETABLENAME environment variable

The **USETABLENAME** environment variable can prevent users from using a synonym to specify the *table* in ALTER TABLE or DROP TABLE statements. Unlike most environment variables, **USETABLENAME** is not required to be set to a value. It takes effect if you set it to any value, or to no value.

### setenvUSETABLENAME

By default, ALTER TABLE or DROP TABLE statements accept a valid synonym for the name of the *table* to be altered or dropped. (In contrast, RENAME TABLE issues an error if you specify a synonym, as do the ALTER SEQUENCE, DROP SEQUENCE, and RENAME SEQUENCE statements, if you attempt to substitute a synonym for the *sequence* name in those statements.)

If you set **USETABLENAME**, an error results if a synonym is in ALTER TABLE or DROP TABLE statements. Setting **USETABLENAME** has no effect on the DROP VIEW statement, which accepts a valid synonym for the view.

## Appendixes

### The stores\_demo Database

The **stores\_demo** database contains a set of tables that describe an imaginary business and many of the examples in the HCL Informix® documentation are based on this database.

The **stores\_demo** database uses the default (U.S. English) locale and is not ANSI-compliant.

For information about how to create and populate the **stores\_demo** database, see the *Informix® DB-Access User's Guide*.

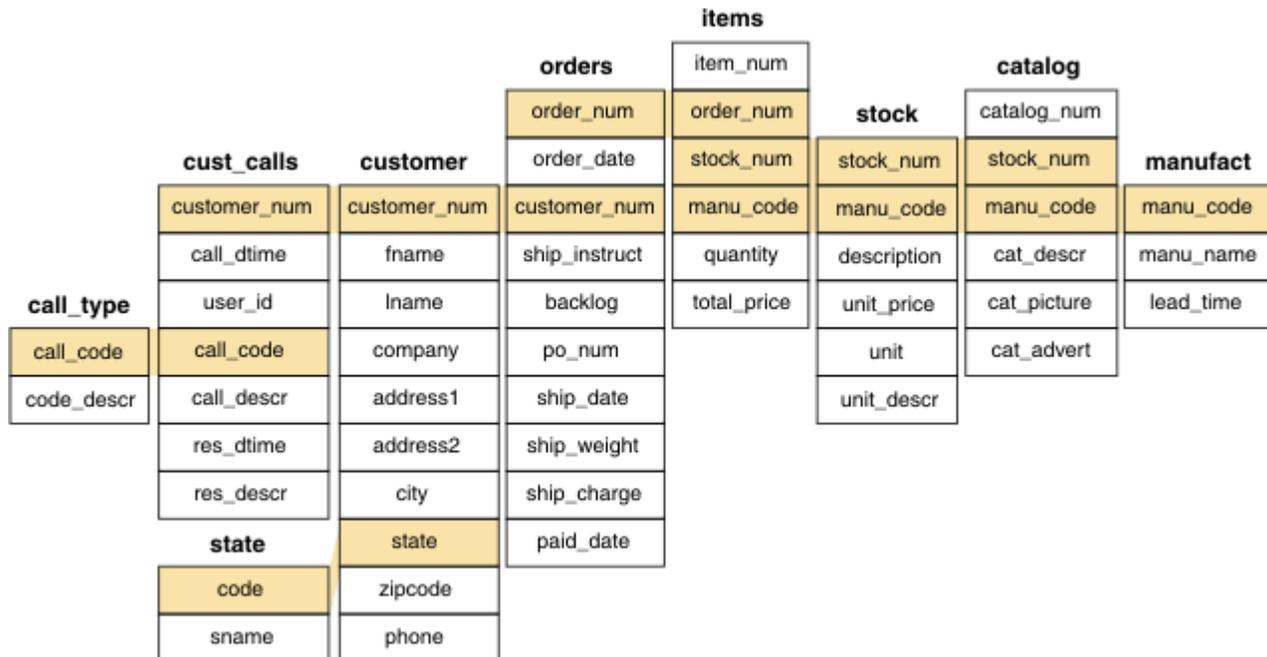

For information about how to design and implement a relational database, see the *Informix® Database Design and Implementation Guide*.

### The stores\_demo Database Map

Some of the tables in the **stores\_demo** database have relationships between them.

The following illustration displays the joins in the **stores\_demo** database between customers, catalog orders, and customer calls. The shading that connects a column in one table to a column with the same name in another table indicates the relationships, or *joins*, between tables.

Figure 19. Joins between customers and catalog orders

The **stores\_demo** database also contains tables that hold electricity meter data for customers. The **Customer\_ts\_data** and **ts\_data** tables contain time series data. The **customer** table and the **Customer\_ts\_data** table are joined by the **customer\_num** column. The **Customer\_ts\_data** table is joined to the **ts\_data** table by the **loc\_esi\_id**, **measure\_unit**, and **direction** columns. You can prevent the creation of these time series tables when you create the demonstration database.

## The superstores\_demo database

The **superstores\_demo** database illustrates an object-relational schema.

SQL files and user-defined routines (UDRs) that are provided with DB-Access let you derive the **superstores\_demo** object-relational database.

The **superstores\_demo** database uses the default locale and is not ANSI-compliant.

For information about how to create and populate the demonstration databases, including relevant SQL files, see the *Informix® DB-Access User's Guide*. For conceptual information about demonstration databases, see the *Informix® Database Design and Implementation Guide*.

## Structure of the superstores\_demo Tables

Although many of the tables in the **superstores\_demo** database have the same name as **stores\_demo** tables, they are different.

The **superstores\_demo** database includes the following tables. The tables are listed alphabetically, not in the order in which they are created.

- **call\_type**
- **catalog**
- **cust\_calls**
- **customer**
  - **retail\_customer**
  - **whlsale\_customer**
- **items**
- **location**
  - **location\_non\_us**
  - **location\_us**
- **manufact**
- **orders**
- **region**
- **sales\_rep**
- **state**
- **stock**
- **stock\_discount**
- **units**

## User-defined routines and extended data types

The **superstores\_demo** database uses user-defined routines (UDRs) and extended data types.

A UDR is a routine that you define that can be invoked within an SQL statement or another UDR. A UDR can either return values or not.

The data type system of HCL Informix® is an extensible and flexible system that supports the creation of following kinds of data types:

- Extensions of existing data types by, redefining some of the behavior for data types that the database server provides
- Definitions of customized data types by a user

For information about creating and using UDRs and extended data types, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

The **superstores\_demo** database creates the *distinct* data type, percent, in a UDR, as follows:

```
CREATE DISTINCT TYPE percent AS DECIMAL(5,5);
DROP CAST (DECIMAL(5,5) AS percent);
CREATE IMPLICIT CAST (DECIMAL(5,5) AS percent);
The superstores_demo database creates the following named row types:
```

- **location** hierarchy:
  - **location\_t**
  - **loc\_us\_t**
  - **loc\_non\_us\_t**
- **customer** hierarchy:
  - **name\_t**
  - **customer\_t**
  - **retail\_t**
  - **whlsale\_t**
- **orders** table
  - **ship\_t**

### location\_t definition

|                    |                            |
|--------------------|----------------------------|
| <b>location_id</b> | SERIAL                     |
| <b>loc_type</b>    | CHAR(2)                    |
| <b>company</b>     | VARCHAR(20)                |
| <b>street_addr</b> | LIST(VARCHAR(25) NOT NULL) |
| <b>city</b>        | VARCHAR(25)                |
| <b>country</b>     | VARCHAR(25)                |

### loc\_us\_t definition

|                   |                                    |
|-------------------|------------------------------------|
| <b>state_code</b> | CHAR(2)                            |
| <b>zip</b>        | ROW(code INTEGER, suffix SMALLINT) |
| <b>phone</b>      | CHAR(18)                           |

### loc\_non\_us\_t definition

|                      |          |
|----------------------|----------|
| <b>province_code</b> | CHAR(2)  |
| <b>zipcode</b>       | CHAR(9)  |
| <b>phone</b>         | CHAR(15) |

### name\_t definition

|              |             |
|--------------|-------------|
| <b>first</b> | VARCHAR(15) |
| <b>last</b>  | VARCHAR(15) |

### customer\_t definition

|                      |                                     |
|----------------------|-------------------------------------|
| <b>customer_num</b>  | SERIAL                              |
| <b>customer_type</b> | CHAR(1)                             |
| <b>customer_name</b> | name_t                              |
| <b>customer_loc</b>  | INTEGER                             |
| <b>contact_dates</b> | LIST(DATETIME YEAR TO DAY NOT NULL) |
| <b>cust_discount</b> | percent                             |
| <b>credit_status</b> | CHAR(1)                             |

### retail\_t definition

|                   |          |
|-------------------|----------|
| <b>credit_num</b> | CHAR(19) |
| <b>expiration</b> | DATE     |

### whsale\_t definition

|                       |          |
|-----------------------|----------|
| <b>resale_license</b> | CHAR(15) |
| <b>terms_net</b>      | SMALLINT |

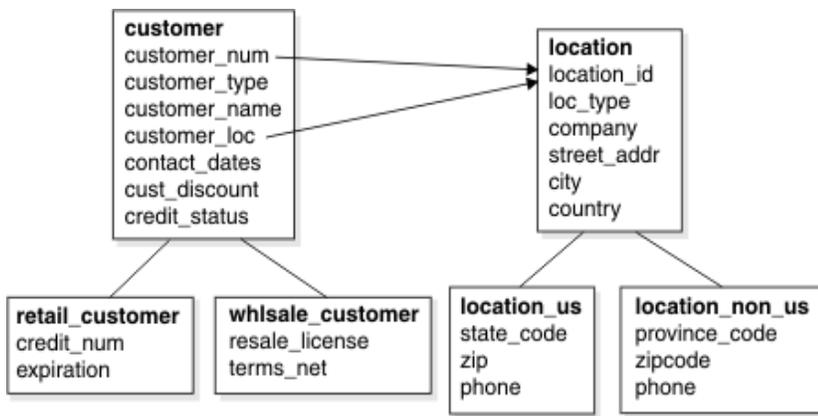

### ship\_t definition

|                 |              |
|-----------------|--------------|
| <b>date</b>     | DATE         |
| <b>weight</b>   | DECIMAL(8,2) |
| <b>charge</b>   | MONEY(6,2)   |
| <b>instruct</b> | VARCHAR(40)  |

## Table Hierarchies

The following illustration shows how the hierarchical tables of the **superstores\_demo** database are related. The foreign key and primary relationships between the two tables are indicated by shaded arrows that point from the **customer.custnum** and **customer.loc** columns to the **location.location\_id** columns.

Figure 20. Hierarchies of superstores\_demo Tables

## Guide to SQL: Tutorial

The *Informix® Guide to SQL: Tutorial* shows how to use basic and advanced structured query language (SQL) to access and manipulate the data in your databases. It discusses the data manipulation language (DML) statements as well as triggers and stored procedure language (SPL) routines, which DML statements often use.

This publication is written for the following users:

- Database users
- Database administrators
- Database-application programmers

This publication assumes that you have the following background:

- A working knowledge of your computer, your operating system, and the utilities that your operating system provides
- Some experience working with relational databases or exposure to database concepts
- Some experience with computer programming

This publication is one of a series of publications that discusses the Informix® implementation of SQL. The *Informix® Guide to SQL: Syntax* contains all the syntax descriptions for SQL and SPL. The *Informix® Guide to SQL: Reference* provides reference information for aspects of SQL other than the language statements. The *Informix® Database Design and Implementation Guide* shows how to use SQL to implement and manage your databases.

## Database concepts

This chapter describes fundamental database concepts and focuses on the following topics:

- Data models
- Multiple users
- Database terminology
- SQL (Structured Query Language)

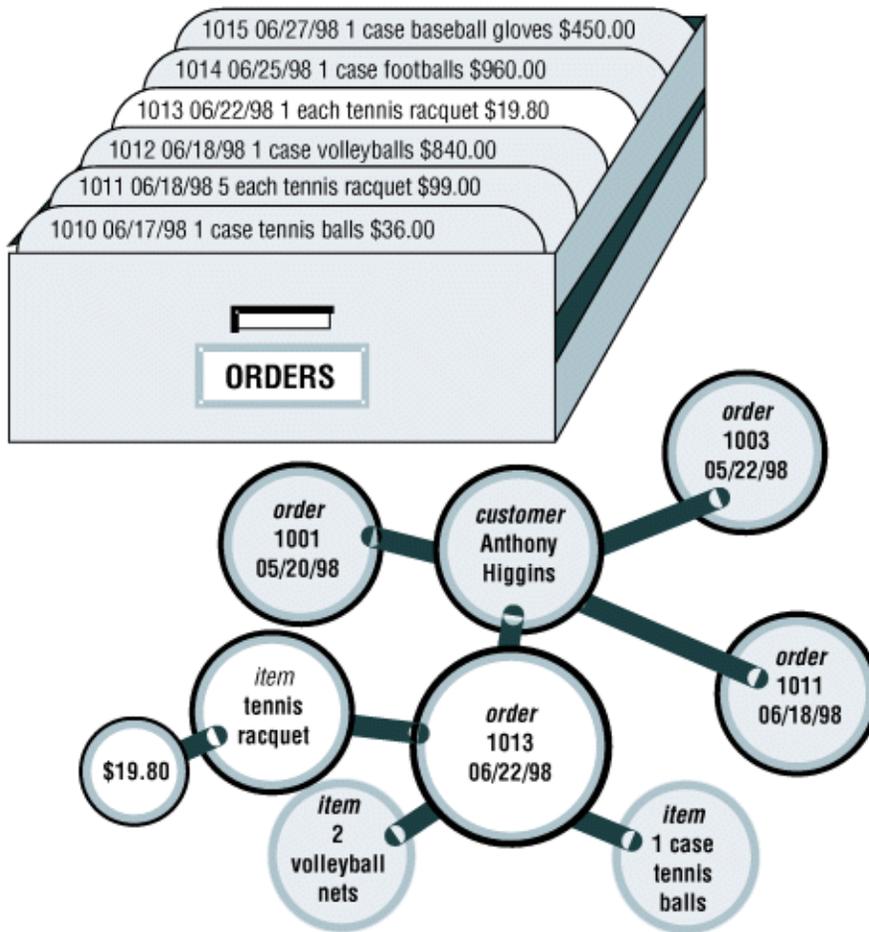

Your real use of a database begins with the SELECT statement, which [Compose SELECT statements on page 1773](#), describes.

## Illustration of a data model

The principal difference between information collected in a database versus information collected in a file is the way the data is organized. A flat file is organized physically; certain items precede or follow other items. But the contents of a database are organized according to a *data model*. A data model is a plan, or map, that defines the units of data and specifies how each unit relates to the others.

For example, a number can appear in either a file or a database. In a file, it is simply a number that occurs at a certain point in the file. A number in a database, however, has a role that the data model assigns to it. The role might be a *price* that is associated with a *product* that was sold as one *item* of an *order* that a *customer* placed. Each of these components, price, product, item, order, and customer, also has a role that the data model specifies. For an illustration of a data model, see the following figure.

Figure 21. The advantage of using a data model

You design the data model when you create the database. You then insert units of data according to the plan that the model lays out. Some books use the term *schema* instead of *data model*.

## Store data

Another difference between a database and a file is that the organization of the database is stored with the database.

A file can have a complex inner structure, but the definition of that structure is not within the file; it is in the programs that create or use the file. For example, a document file that a word-processing program stores might contain detailed structures that describe the format of the document. However, only the word-processing program can decipher the contents of the file, because the structure is defined within the program, not within the file.

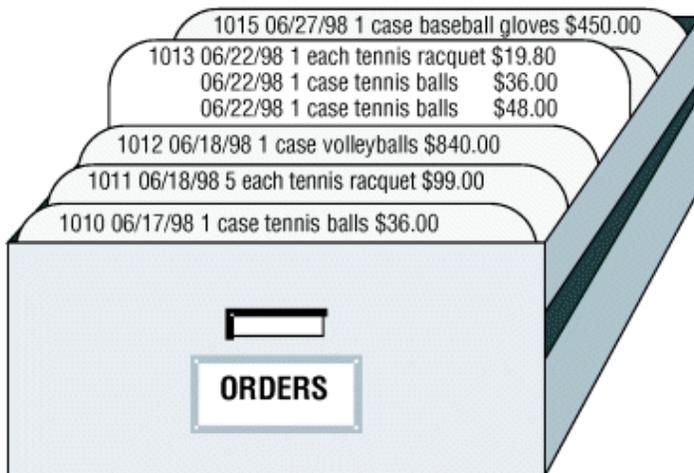

A data model, however, is contained in the database it describes. It travels with the database and is available to any program that uses the database. The model defines not only the names of the data items but also their data types, so a program can adapt itself to the database. For example, a program can find out that, in the current database, a price item is a decimal number with eight digits, two to the right of the decimal point; then it can allocate storage for a number of that type. How

programs work with databases is the subject of [SQL programming on page 1944](#), and [Modify data through SQL programs on page 1968](#).

## Query data

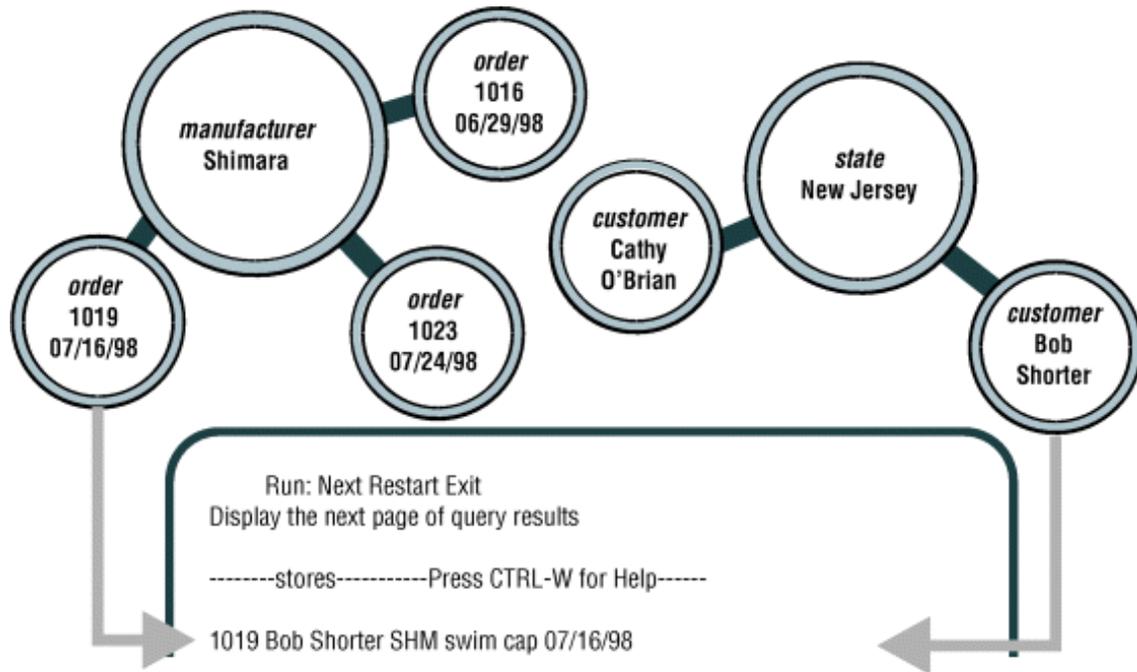

Another difference between a database and a file is the way you can access them. You can search a file sequentially, looking for particular values at particular physical locations in each line or record. That is, you might ask, *“What records have the number 1013 in the first field?”* The following figure shows this type of search.

Figure 22. Search a file sequentially

In contrast, when you query a database, you use the terms that the model defines. You can query the database with questions such as, *“What orders have been placed for products made by the Shimara Corporation, by customers in New Jersey, with ship dates in the third quarter?”* The following figure shows this type of query.

Figure 23. Query a database

In other words, when you access data that is stored in a file, you must state your question in terms of the physical layout of the file. When you query a database, you can ignore the arcane details of computer storage and state your query in terms that reflect the real world, at least to the extent that the data model reflects the real world.

[Compose SELECT statements on page 1773](#), and [Compose advanced SELECT statements on page 1862](#), discuss the language you use to make queries.

For information about how to build and implement your data model, see the *Informix® Database Design and Implementation Guide*.

## Modify data

The data model also makes it possible to modify the contents of the database with less chance for error. You can query the database with statements such as, “*Find every stock item with a manufacturer of Presta or Schraeder, and increase its price by 13 percent.*” You state changes in terms that reflect the meaning of the data. You do not have to waste time and effort thinking about details of fields within records in a file, so the chances for error are fewer.

The statements you use to modify stored data are covered in [Modify data on page 1901](#).

## Concurrent use and security

A database can be a common resource for many users. Multiple users can query and modify a database simultaneously. The database server (the program that manages the contents of all databases) ensures that the queries and modifications are done in sequence and without conflict.

Having concurrent users on a database provides great advantages but also introduces new problems of security and privacy. Some databases are private; individuals set them up for their own use. Other databases contain confidential material that must be shared, but only among a restricted group; still other databases provide public access.

## Control database use

Informix® database software provides the means to control database use. When you design a database, you can perform any of the following functions:

- Keep the database completely private
- Open its entire contents to all users or to selected users
- Restrict the selection of data that some users can view (different selections of data to different groups of users)
- Allow specified users to view certain items, but not modify them
- Allow specified users to add new data, but not modify old data
- Allow specified users to modify all, or specified items of, existing data
- Ensure that added or modified data conforms to the data model

## Access-management strategies

HCL Informix® supports two access-management systems:

### **Label-Based Access Control (LBAC)**

Label-Based Access Control is an implementation of Mandatory Access Control, which is typically used in databases that store highly sensitive data, such as systems maintained by armed forces or security services. The primary documentation of features relating to LBAC is the *Informix® Security Guide*. *Informix® Guide to SQL: Syntax* describes how LBAC security objects are created and maintained by the Database Security Administrator (DBSECADM). Only the Database Server Administrator (DBSA) can grant the DBSECADM role.

### **Discretionary Access Control (DAC)**

Discretionary Access Control is a simpler system that involves less overhead than LBAC. Based on access privileges and roles, DAC is enabled in all Informix® databases, including those that implement LBAC.

## Creating and granting a role

### **About this task**

To support DAC, the database administrator (DBA) can define *roles* and assign them to users to standardize the access privileges of groups of users who need access to the same database objects. When the DBA assigns privileges to that role,

every user who is granted role holds those privileges when that role is activated. In order to activate a specific role, a user must issue the SET ROLE statement. The SQL statements used for defining and manipulating roles include: CREATE ROLE, DROP ROLE, GRANT, REVOKE, and SET ROLE.

For more information on the SQL syntax statements for defining and manipulating roles, see the *Informix® Guide to SQL: Syntax*.

To create and grant a role:

1. Use the CREATE ROLE statement to create a new role in the current database.
2. Use the GRANT statement to grant access privileges to that role
3. Use the GRANT statement to grant the role to a user or to PUBLIC (all users).
4. The user must issue the SET ROLE statement to enable that role.

## Defining and granting privileges for a default role

### About this task

The DBA can also define a *default role* to assign to individual users or to the PUBLIC group for a specific database. The role is automatically activated when the user establishes a connection with that database, without the requiring the user to issue a SET ROLE statement. At connection time, each user who holds a default role has whatever access privileges are granted to the user individually, as well as the privileges of the default role.

Only one role that the CREATE ROLE statement defines can be in effect for a given user at a given time. If a user who holds both a default role and one or more other roles uses the SET ROLE statement to make a nondefault role the active role, then any access privileges that were granted only to the default role (and not to the user individually, nor to PUBLIC, nor to the new active role) are no longer in effect for that user. The same user can issue the SET ROLE DEFAULT statement to reactivate the default role, but this action disables any privileges that the user held only through the previously enabled nondefault role.

If different default roles are assigned to the user and to PUBLIC, the default role of the user takes precedence.

To define and grant privileges for a default role:

1. Use the CREATE ROLE statement to create a new role in the current database.
2. Use the GRANT statement to grant privileges to the role.
3. Grant the role to a user and set the role as the default user or PUBLIC role using the one of the following syntax:

#### Choose from:

- `GRANT DEFAULT ROLE rolename TO username;`
- `GRANT DEFAULT ROLE rolename TO PUBLIC;`

4. Use the REVOKE DEFAULT ROLE statement to disassociate a default role from a user.

**Restriction:** Only the DBA or the database owner can remove the default role.

5. Use the SET ROLE DEFAULT statement to reset the current role back to the default role.

## Built-in roles

For security reasons, HCL Informix® supports certain built-in roles that are in effect for any user who is granted the role and is connected to the database, regardless of whether any other role is also active.

For example, in a database in which the IFX\_EXTEND\_ROLE configuration parameter is set to ON, only the Database Server Administrator (DBSA) or users to whom the DBSA has granted the built-in EXTEND role can create or drop UDRs that are defined with the EXTERNAL keyword.

Similarly, in a database that implements LBAC security policies, the DBSA can grant the built-in DBSECADM role. The grantee of this role becomes the Database Security Administrator, who can define and implement LBAC security policies and can assign security labels to data and to users.

Unlike user-defined roles, built-in roles cannot be destroyed by the DROP ROLE statement. The SET ROLE statement has no effect on a built-in role, because it is always active while users are connected to a database in which they have been granted the built-in role.

For more information on the External Routine Reference segment or SQL statements for defining and manipulating roles, see the *Informix® Guide to SQL: Syntax*.

For more information on the DBSECADM role or SQL statements for defining and manipulating LBAC security objects, see the *Informix® Security Guide*.

For more information on default roles, see the *Informix® Administrator's Guide*.

For more information about how to grant and limit access to your database, see the *Informix® Database Design and Implementation Guide*.

## Centralized management

Databases that many people use are valuable and must be protected as important business assets. You create a significant problem when you compile a store of valuable data and simultaneously allow many employees to access it. You handle this problem by protecting data while maintaining performance. The database server lets you centralize these tasks.

Databases must be guarded against loss or damage. The hazards are many: failures in software and hardware, and the risks of fire, flood, and other natural disasters. Losing an important database creates a huge potential for damage. The damage could include not only the expense and difficulty of re-creating the lost data, but also the loss of productive time by the database users as well as the loss of business and goodwill while users cannot work. A plan for regular backups helps avoid or mitigate these potential disasters.

A large database that many people use must be maintained and tuned. Someone must monitor its use of system resources, chart its growth, anticipate bottlenecks, and plan for expansion. Users will report problems in the application programs; someone must diagnose these problems and correct them. If rapid response is important, someone must analyze the performance of the system and find the causes of slow responses.

## Important database terms

You should know a number of terms before you begin the next chapter. Depending on the database server you use, a different set of terms can describe the database and the data model that apply.

## The relational database model

The databases you create with the Informix® database server are *object-relational* databases. In practical terms this means that all data is presented in the form of *tables* with *rows* and *columns* where the following simple corresponding relationships apply.

### Relationship

#### Description

#### table = entity

A table represents all that the database knows about one subject or kind of thing.

#### column = attribute

A column represents one feature, characteristic, or fact that is true of the table subject.

#### row = instance

A row represents one individual instance of the table subject.

Some rules apply about how you choose entities and attributes, but they are important only when you are designing a new database. (For more information about database design, see the *Informix® Database Design and Implementation Guide*.) The data model in an existing database is already set. To use the database, you need to know only the names of the tables and columns and how they correspond to the real world.

## Tables

A *database* is a collection of information that is grouped into one or more tables. A table is an array of data *items* organized into rows and columns. A demonstration database is distributed with every Informix® database server product. A partial table from the demonstration database follows.

| stock_num | manu_code | description     | unit_price | unit | unit_descr     |
|-----------|-----------|-----------------|------------|------|----------------|
| ...       | ...       | ...             | ...        | ...  | ...            |
| 1         | HRO       | baseball gloves | 250.00     | case | 10 gloves/case |
| 1         | HSK       | baseball gloves | 800.00     | case | 10 gloves/case |
| 1         | SMT       | baseball gloves | 450.00     | case | 10 gloves/case |
| 2         | HRO       | baseball        | 126.00     | case | 24/case        |
| 3         | HSK       | baseball bat    | 240.00     | case | 12/case        |

| stock_num | manu_code | description    | unit_price | unit | unit_descr |
|-----------|-----------|----------------|------------|------|------------|
| 4         | HSK       | football       | 960.00     | case | 24/case    |
| 4         | HRO       | football       | 480.00     | case | 24/case    |
| 5         | NRG       | tennis racquet | 28.00      | each | each       |
| ...       | ...       | ...            | ...        | ...  | ...        |
| 313       | ANZ       | swim cap       | 60.00      | case | 12/box     |

A table represents all that the database administrator (DBA) wants to store about one *entity*, one type of thing that the database describes. The example table, **stock**, represents all that the DBA wants to store about the merchandise that a sporting goods store stocks. Other tables in the demonstration database represent such entities as **customer** and **orders**.

## Columns

Each column of a table contains one *attribute*, which is one characteristic, feature, or fact that describes the subject of the table. The **stock** table has columns for the following facts about items of merchandise: stock numbers, manufacturer codes, descriptions, prices, and units of measure.

## Rows

Each row of a table is one *instance* of the subject of the table, which is one particular example of that entity. Each row of the **stock** table stands for one item of merchandise that the sporting goods store sells.

## Views

A *view* is a virtual table based on a specified SELECT statement. A view is a dynamically controlled picture of the contents in a database and allows a programmer to determine what information the user sees and manipulates. Different users can be given different views of the contents of a database, and their access to those contents can be restricted in several ways.

## Sequences

A *sequence* is a database object that generates a sequence of whole numbers within a defined range. The sequence of numbers can run in either ascending or descending order, and is monotonic. For more information about sequences, see the *Informix® Guide to SQL: Syntax*.

## Operations on tables

Because a database is really a collection of tables, database operations are operations on tables. The object-relational model supports three fundamental operations: selection, projection, and joining. The following figure shows the selection and projection operations. (All three operations are defined in detail, with many examples, in the following topics.)

Figure 24. Illustration of selection and projection

**stock table**

| stock_num | manu_code | description     | unit_price | unit | unit_descr     |
|-----------|-----------|-----------------|------------|------|----------------|
| 1         | HRO       | baseball gloves | 250.00     | case | 10 gloves/case |
| 1         | HSK       | baseball gloves | 800.00     | case | 10 gloves/case |
| 1         | SMT       | baseball gloves | 450.00     | case | 10 gloves/case |
| 2         | HRO       | baseball        | 126.00     | case | 24/case        |
| 3         | HSK       | baseball bat    | 240.00     | case | 12/case        |
| 4         | HSK       | football        | 960.00     | case | 24/case        |
| 4         | HRO       | football        | 480.00     | case | 24/case        |
| 5         | NRG       | tennis racquet  | 28.00      | each | each           |
| 313       | ANZ       | swim cap        | 60.00      | case | 12/box         |

SELECTION

P R O J E C T I O N

When you *select* data from a table, you are choosing certain rows and ignoring others. For example, you can query the **stock** table by asking the database management system to, “*Select all rows in which the manufacturer code is HSK and the unit price is between 200.00 and 300.00.*”

When you *project* from a table, you are choosing certain columns and ignoring others. For example, you can query the **stock** table by asking the database management system to “*project the stock\_num, unit\_descr, and unit\_price columns.*”

A table contains information about only one entity; when you want information about multiple entities, you must *join* their tables. You can join tables in many ways. For more information about join operations, refer to [Compose advanced SELECT statements on page 1862](#).

## The object-relational model

HCL Informix® (Informix®) allows you to build *object-relational* databases. In addition to supporting alphanumeric data such as character strings, integers, date, and decimal, an object-relational database extends the features of a relational model with the following object-oriented capabilities:

### Extensibility

You can extend the capability of the database server by defining new data types (and the access methods and functions to support them) and user-defined routines (UDRs) that allow you to store and manage images, audio, video, large text documents, and so forth.

, as well as third-party vendors, packages some data types and access methods into DataBlade® modules or shared class libraries, that you can add on to the database server, if it suits your needs. A DataBlade® module enables you to store non-traditional data types such as two-dimensional spatial objects (lines, polygons, ellipses, and circles) and to access them through R-tree indexes. A DataBlade® module might also provide new types of access to large text documents, including phrase matching, fuzzy searches, and synonym matching.

You can also extend the database server on your own by using the features of that enable you to add data types and access methods. For more information, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

You can create UDRs in SPL and the C programming language to encapsulate application logic or to enhance the functionality of the Informix®. For more information, see [Create and use SPL routines on page 1998](#).

### Complex types

You can define new data types that combine one or more existing data types. Complex types enable greater flexibility in organizing data at the level of columns and tables. For example, with complex types, you can define columns that contain collections of values of a single type and columns that contain multiple component types.

### Inheritance

You can define objects (types and tables) that acquire the properties of other objects and add new properties that are specific to the object that you define.

Informix® provides object-oriented capabilities beyond those of the relational model but represents all data in the form of tables with rows and columns. Although the object-relational model extends the capabilities of the relational model, you can implement your data model as a traditional relational database if you choose.

Some rules apply about how you choose entities and attributes, but they are important only when you are designing a new database. For more information about object-relational database design, see the *Informix® Database Design and Implementation Guide*.

## Structured Query Language

Most computer software has not yet reached a point where you can literally ask a database, “*What orders have been placed by customers in New Jersey with ship dates in the third quarter?*” You must still phrase questions in a restricted syntax that the software can easily parse. You can pose the same question to the demonstration database in the following terms:

```
SELECT * FROM customer, orders
WHERE customer.customer_num = orders.customer_num
AND customer.state = 'NJ'
AND orders.ship_date
BETWEEN DATE('7/1/98') AND DATE('9/30/98');
```

This question is a sample of Structured Query Language (SQL). It is the language that you use to direct all operations on the database. SQL is composed of statements, each of which begins with one or two keywords that specify a function. The Informix® implementation of SQL includes a large number of SQL statements, from ALLOCATE DESCRIPTOR to WHENEVER.

You will use most of the statements only when you set up or tune your database. You will use three or four statements regularly to query or update your database. For details on SQL statements, see the *Informix® Guide to SQL: Syntax*.

One statement, SELECT, is in almost constant use. SELECT is the only statement that you can use to retrieve data from the database. It is also the most complicated statement, and the next two chapters of this book explore its many uses.

## General programming

You can write programs that incorporate SQL statements and exchange data with the database server. That is, you can write a program to retrieve data from the database and format it however you choose. You can also write programs that take data from any source in any format, prepare it, and insert it into the database.

You can also write programs called stored routines to work with database data and objects. The stored routines that you write are stored directly in a database in tables. You can then execute a stored routine from DB-Access or an SQL Application Programming Interface (API) such as Informix® ESQL/C.

[SQL programming on page 1944](#), and [Modify data through SQL programs on page 1968](#), present an overview of how SQL is used in programs.

## ANSI-compliant databases

Use the MODE ANSI keywords when you create a database to designate it as ANSI compliant. Within such a database, certain characteristics of the ANSI/ISO standard apply. For example, all actions that modify data take place within a transaction automatically, which means that the changes are made in their entirety or not at all. Differences in the behavior of ANSI-compliant databases are noted, where appropriate, in the statement descriptions in the *Informix® Guide to SQL: Syntax*. For a detailed discussion of ANSI-compliant databases, see the *Informix® Database Design and Implementation Guide*.

## Global Language Support

Informix® database server products provide the Global Language Support (GLS) feature. In addition to U.S. ASCII English, GLS allows you to work in other locales and use non-ASCII characters in SQL data and identifiers. You can use the GLS feature to conform to the customs of a specific locale. The locale files contain culture-specific information, such as money and date formats and collation orders. For more GLS information, see the *Informix® GLS User's Guide*.

## Summary

A database contains a collection of related information but differs in a fundamental way from other methods of storing data. The database contains not only the data, but also a data model that defines each data item and specifies its meaning with respect to the other items and to the real world.

More than one user can access and modify a database at the same time. Each user has a different view of the contents of a database, and each user's access to those contents can be restricted in several ways.

A relational database consists of tables, and the tables consist of columns and rows. The relational model supports three fundamental operations on tables: selections, projections, and joins.

An object-relational database extends the features of a relational database. You can define new data types to store and manage audio, video, large text documents, and so forth. You can define complex types that combine one or more existing data types to provide greater flexibility in how you organize your data in columns and tables. You can define types and tables that inherit the properties of other database objects and add new properties that are specific to the object that you define.

To manipulate and query a database, use SQL. IBM® pioneered SQL and ANSI standardized it. Informix® extensions that you can use to your advantage add to the ANSI-defined language. Informix® tools also make it possible to maintain strict compliance with ANSI standards.

Two layers of software mediate all your work with databases. The bottom layer is always a database server that executes SQL statements and manages the data on disk and in computer memory. The top layer is one of many applications, some from IBM® and some written by you, by other vendors, or your colleagues. Middleware is the component that links the database server to the application, and is provided by the database vendor to bind the client programs with the database server. Informix® Stored Procedure Language (SPL) is an example of such a tool.

## Compose SELECT statements

The SELECT statement is the most important and the most complex SQL statement. You can use it and the SQL statements INSERT, UPDATE, and DELETE to manipulate data. You can use the SELECT statement to retrieve data from a database, as part of an INSERT statement to produce new rows, or as part of an UPDATE statement to update information.

The SELECT statement is the primary way to query information in a database. It is your key to retrieving data in a program, report, form, or spreadsheet. You can use SELECT statements with a query tool such as DB-Access or embed SELECT statements in an application.

This chapter introduces the basic methods for using the SELECT statement to query and retrieve data from relational databases. It discusses how to tailor your statements to select columns or rows of information from one or more tables, how to include expressions and functions in SELECT statements, and how to create various join conditions between database tables. The syntax and usage for the SELECT statement are described in detail in the *Informix® Guide to SQL: Syntax*.

Most examples in this publication come from the tables in the **stores\_demo** database, which is included with the software for your Informix® SQL API or database utility. In the interest of brevity, the examples show only part of the data that is retrieved for each SELECT statement. For information on the structure and contents of the demonstration database, see the *Informix® Guide to SQL: Reference*. For emphasis, keywords are shown in uppercase letters in the examples, although SQL is not case sensitive.

## SELECT statement overview

The SELECT statement is constructed of clauses that let you look at data in a relational database. These clauses let you select columns and rows from one or more database tables or views, specify one or more conditions, order and summarize the data, and put the selected data in a temporary table.

This chapter shows how to use five SELECT statement clauses. If you include all five of these clauses, they must appear in the SELECT statement in the following order:

1. Projection clause
2. FROM clause
3. WHERE clause
4. ORDER BY clause
5. INTO TEMP clause

Only the Projection clause and FROM clause are required. These two clauses form the basis for every database query, because they specify the column values to be retrieved, and the tables that contain those columns. Use one or more of the other clauses from the following list:

- Add a WHERE clause to select specific rows or create a *join* condition.
- Add an ORDER BY clause to change the order in which data is produced.
- Add an INTO TEMP clause to save the results as a table for further queries.

Two additional SELECT statement clauses, GROUP BY and HAVING, let you perform more complex data retrieval. They are introduced in [Compose advanced SELECT statements on page 1862](#). Another clause, INTO, specifies the program or host variable to receive data from a SELECT statement in an application program. Complete syntax and rules for using the SELECT statement are in the *Informix® Guide to SQL: Syntax*.

## Output from SELECT statements

Although the syntax remains the same across all Informix® products, the formatting and display of the resulting output depends on the application. The examples in this chapter and in [Compose advanced SELECT statements on page 1862](#) display the SELECT statements and their output as they appear when you use the interactive Query-language option in DB-Access.

## Output from large object data types

When you issue a SELECT statement that includes a large object, DB-Access displays the results as follows:

- For a TEXT column or CLOB column, the contents of the column are displayed.
- For a BYTE column, the words `<BYTE value>` are displayed instead of the actual value.
- For a BLOB column, the words `<SBlob data>` are displayed instead of the actual value.

## Output from user-defined data types

DB-Access uses special conventions to display output from columns that contain complex or opaque data types. For more information about these data types, refer to the *Informix® Database Design and Implementation Guide*.

## Output in non-default code sets

You can issue a SELECT statement that queries NCHAR columns instead of CHAR columns or NVARCHAR columns instead of VARCHAR columns.

For more Global Language Support (GLS) information, see the *Informix® GLS User's Guide*. For additional information on using NCHAR and NVARCHAR data types with non-default code sets, see the *Informix® Database Design and Implementation Guide* and the *Informix® Guide to SQL: Reference*.

## Some basic concepts

The SELECT statement, unlike INSERT, UPDATE, and DELETE statements, does not modify the data in a database. It simply queries the data. Whereas only one user at a time can modify data, multiple users can query or select the data concurrently. For more information about statements that modify data, see [Modify data on page 1901](#). The syntax descriptions of the INSERT, UPDATE, and DELETE statements appear in the *Informix® Guide to SQL: Syntax*.

In a relational database, a *column* is a data element that contains a particular type of information that occurs in every row in the table. A *row* is a group of related items of information about a single entity across all columns in a database table.

You can select columns and rows from a database table; from a *system catalog table*, a special table that contains information on the database; or from a *view*, a virtual table created to contain a customized set of data. System catalog tables are described in the *Informix® Guide to SQL: Reference*. Views are discussed in the *Informix® Database Design and Implementation Guide*.

## Privileges

Before you make a query against data, make sure you have the Connect privilege on the database and the Select privilege on the table. These privileges are normally granted to all users. Database access privileges are discussed in the *Informix® Database Design and Implementation Guide* and in the GRANT and REVOKE statements in the *Informix® Guide to SQL: Syntax*.

## Relational operations

A *relational operation* involves manipulating one or more tables, or *relations*, to result in another table. The three kinds of relational operations are selection, projection, and join. This chapter includes examples of selection, projection, and simple joining.

## Selection and projection

In relational terminology, *selection* is defined as taking the horizontal subset of rows of a single table that satisfies a particular condition. This kind of SELECT statement returns some of the rows and all the columns in a table. Selection is implemented through the WHERE clause of a SELECT statement, as the following figure shows.

Figure 25. Query

```
SELECT * FROM customer WHERE state = 'NJ';
```

The result contains the same number of columns as the **customer** table, but only a subset of its rows. In this example, DB-Access displays the data from each column on a separate line.

Figure 26. Query result

```
customer_num 119
fname       Bob
lname       Shorter
company     The Triathletes Club
address1    2405 Kings Highway
address2
city        Cherry Hill
state       NJ
zipcode     08002
phone       609-663-6079

customer_num 122
fname       Cathy
lname       O'Brian
company     The Sporting Life
address1    543d Nassau
address2
city        Princeton
state       NJ
zipcode     08540
phone       609-342-0054
```

In relational terminology, *projection* is defined as taking a vertical subset from the columns of a single table that retains the unique rows. This kind of SELECT statement returns some of the columns and all the rows in a table.

Projection is implemented through the *projection list* in the Projection clause of a SELECT statement, as the following figure shows.

Figure 27. Query

```
SELECT city, state, zipcode FROM customer;
```

The result contains the same number of rows as the **customer** table, but it *projects* only a subset of the columns in the table. Because only a small amount of data is selected from each row, DB-Access is able to display all of the data from the row on one line.

Figure 28. Query result

| city          | state | zipcode |
|---------------|-------|---------|
| Sunnyvale     | CA    | 94086   |
| San Francisco | CA    | 94117   |
| Palo Alto     | CA    | 94303   |
| Redwood City  | CA    | 94026   |
| Los Altos     | CA    | 94022   |
| Mountain View | CA    | 94063   |
| Palo Alto     | CA    | 94304   |
| Redwood City  | CA    | 94063   |
| Sunnyvale     | CA    | 94086   |
| Redwood City  | CA    | 94062   |
| Sunnyvale     | CA    | 94085   |
| Oakland       | CA    | 94609   |
| Cherry Hill   | NJ    | 08002   |
| Phoenix       | AZ    | 85016   |
| Wilmington    | DE    | 19898   |
| Princeton     | NJ    | 08540   |
| Jacksonville  | FL    | 32256   |
| Bartlesville  | OK    | 74006   |

The most common kind of SELECT statement uses both selection and projection. A query of this kind returns some of the rows and some of the columns in a table, as the following figure shows.

Figure 29. Query

```
SELECT UNIQUE city, state, zipcode
FROM customer
WHERE state = 'NJ';
```

Figure 30: Query result on page 1777 contains a subset of the rows and a subset of the columns in the **customer** table.

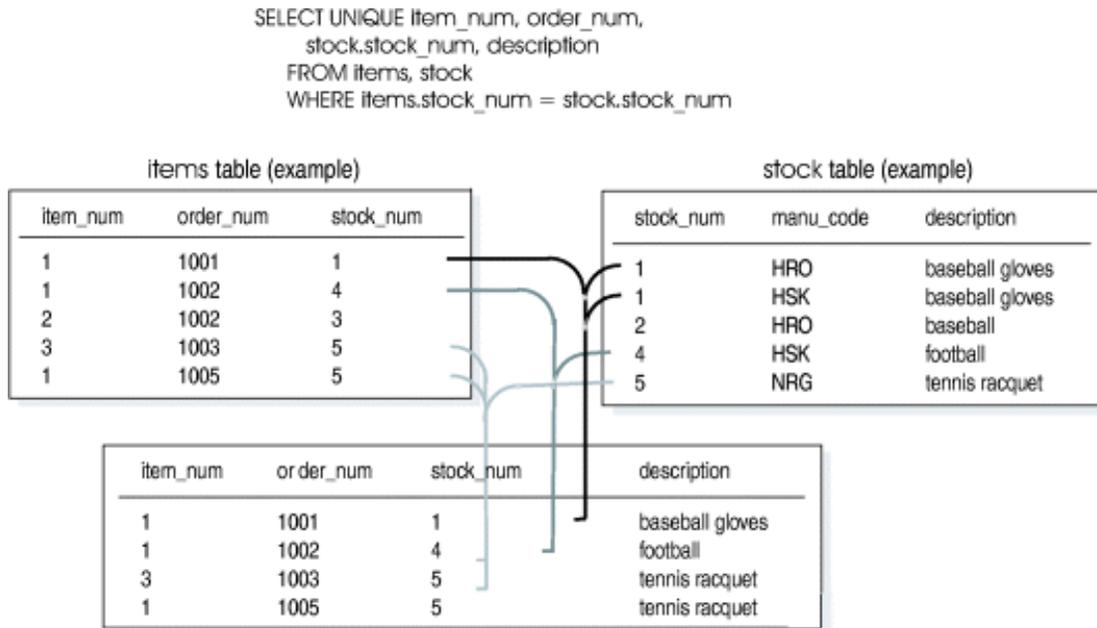

Figure 30. Query result

| city        | state | zipcode |
|-------------|-------|---------|
| Cherry Hill | NJ    | 08002   |
| Princeton   | NJ    | 08540   |

## Join

A join occurs when two or more tables are connected by one or more columns in common, which creates a new table of results. The following figure shows a query that uses a subset of the **items** and **stock** tables to illustrate the concept of a join.

Figure 31. A join between two tables

The following query joins the **customer** and **state** tables.

Figure 32. Query

```

SELECT UNIQUE city, state, zipcode, sname
FROM customer, state
WHERE customer.state = state.code;
    
```

The result consists of specified rows and columns from both the **customer** and **state** tables.

Figure 33. Query result

| city          | state | zipcode | sname         |
|---------------|-------|---------|---------------|
| Bartlesville  | OK    | 74006   | Oklahoma      |
| Blue Island   | NY    | 60406   | New York      |
| Brighton      | MA    | 02135   | Massachusetts |
| Cherry Hill   | NJ    | 08002   | New Jersey    |
| Denver        | CO    | 80219   | Colorado      |
| Jacksonville  | FL    | 32256   | Florida       |
| Los Altos     | CA    | 94022   | California    |
| Menlo Park    | CA    | 94025   | California    |
| Mountain View | CA    | 94040   | California    |
| Mountain View | CA    | 94063   | California    |
| Oakland       | CA    | 94609   | California    |
| Palo Alto     | CA    | 94303   | California    |
| Palo Alto     | CA    | 94304   | California    |
| Phoenix       | AZ    | 85008   | Arizona       |
| Phoenix       | AZ    | 85016   | Arizona       |
| Princeton     | NJ    | 08540   | New Jersey    |
| Redwood City  | CA    | 94026   | California    |
| Redwood City  | CA    | 94062   | California    |
| Redwood City  | CA    | 94063   | California    |
| San Francisco | CA    | 94117   | California    |
| Sunnyvale     | CA    | 94085   | California    |
| Sunnyvale     | CA    | 94086   | California    |
| Wilmington    | DE    | 19898   | Delaware      |

## Single-table SELECT statements

You can query a single table in a database in many ways. You can tailor a SELECT statement to perform the following actions:

- Retrieve all or specific columns
- Retrieve all or specific rows
- Perform computations or other functions on the retrieved data
- Order the data in various ways

The most basic SELECT statement contains only the two required clauses, the Projection clause and FROM.

## The asterisk symbol (\*)

The following query specifies all the columns in the **manufact** table in a projection list. An *explicit* projection list is a list of the column names or expressions that you want to project from a table.

Figure 34. Query

```
SELECT manu_code, manu_name, lead_time FROM manufact;
```

The following query uses the *wildcard* asterisk symbol (\*) as shorthand in the projection list to represent the names of all the columns in the table. You can use the asterisk symbol (\*) when you want all the columns in their defined order. An *implicit* select list uses the asterisk symbol.

Figure 35. Query

```
SELECT * FROM manufact;
```

Because the **manufact** table has only three columns, [Figure 34: Query on page 1779](#) and [Figure 35: Query on page 1780](#) are equivalent and display the same results; that is, a list of every column and row in the **manufact** table. The following figure shows the results.

Figure 36. Query result

| manu_code | manu_name | lead_time |
|-----------|-----------|-----------|
| SMT       | Smith     | 3         |
| ANZ       | Anza      | 5         |
| NRG       | Norge     | 7         |
| HSK       | Husky     | 5         |
| HRO       | Hero      | 4         |
| SHM       | Shimara   | 30        |
| KAR       | Karsten   | 21        |
| NKL       | Nikolus   | 8         |
| PRC       | ProCycle  | 9         |

## Reorder the columns

The following query shows how you can change the order in which the columns are listed by changing their order in your projection list.

Figure 37. Query

```
SELECT manu_name, manu_code, lead_time FROM manufact;
```

The query result includes the same columns as the previous query result, but because the columns are specified in a different order, the display is also different.

Figure 38. Query result

| manu_name | manu_code | lead_time |
|-----------|-----------|-----------|
| Smith     | SMT       | 3         |
| Anza      | ANZ       | 5         |
| Norge     | NRG       | 7         |
| Husky     | HSK       | 5         |
| Hero      | HRO       | 4         |
| Shimara   | SHM       | 30        |
| Karsten   | KAR       | 21        |
| Nikolus   | NKL       | 8         |
| ProCycle  | PRC       | 9         |

## The ORDER BY clause to sort the rows

The results from a query are not arranged in any particular order. For example, [Figure 28: Query result on page 1777](#) and [Figure 38: Query result on page 1780](#) appear to be in random order.

You can add an ORDER BY clause to your SELECT statement to direct the system to sort the data in a specific order. The ORDER BY clause is a list of column names from any remote or local table or view. Any expressions that are allowed in the projection list are allowed in the ORDER BY list. If a column used in the ORDER BY list has a Select trigger on it, the trigger will not be activated.

The following query returns every row from the **manu\_code**, **manu\_name**, and **lead\_time** columns in the **manufact** table, sorted according to **lead\_time**.

Figure 39. Query

```
SELECT manu_code, manu_name, lead_time
FROM manufact
ORDER BY lead_time;
```

For , you do not need to include the columns that you want to use in the ORDER BY clause in the projection list. That is, you can sort the data according to a column that is not retrieved in the projection list. The following query returns every row from the **manu\_code** and **manu\_name** columns in the **manufact** table, sorted according to **lead\_time**. The **lead\_time** column is in the ORDER BY clause although it is not included in the projection list.

Figure 40. Query

```
SELECT manu_code, manu_name
FROM manufact
ORDER BY lead_time;
```

## Ascending order

The retrieved data is sorted and displayed, by default, in *ascending* order. In the ASCII character set, ascending order is uppercase **A** to lowercase **z** for character data types, and lowest to highest value for numeric data types. DATE and DATETIME data is sorted from earliest to latest, and INTERVAL data is ordered from shortest to longest span of time.

## Descending order

*Descending* order is the opposite of ascending order, from lowercase **z** to uppercase **A** for character types, and from highest to lowest for numeric data types. DATE and DATETIME data is sorted from latest to earliest, and INTERVAL data is ordered from longest to shortest span of time. The following query shows an example of descending order.

Figure 41. Query

```
SELECT * FROM manufact ORDER BY lead_time DESC;
```

The keyword DESC following a column name causes the retrieved data to be sorted in descending order, as the result shows.

Figure 42. Query result

| manu_code | manu_name | lead_time |
|-----------|-----------|-----------|
| SHM       | Shimara   | 30        |
| KAR       | Karsten   | 21        |
| PRC       | ProCycle  | 9         |
| NKL       | Nikolus   | 8         |
| NRG       | Norge     | 7         |
| HSK       | Husky     | 5         |
| ANZ       | Anza      | 5         |
| HRO       | Hero      | 4         |
| SMT       | Smith     | 3         |

You can specify any column of a built-in data type (except TEXT, BYTE, BLOB, or CLOB) in the ORDER BY clause, and the database server sorts the data based on the values in that column.

## Sorting on multiple columns

You can also ORDER BY two or more columns, which creates a *nested sort*. The default is still ascending, and the column that is listed first in the ORDER BY clause takes precedence.

The following query and [Figure 45: Query on page 1783](#) and the corresponding query results show nested sorts. To modify the order in which selected data is displayed, change the order of the two columns that are named in the ORDER BY clause.

Figure 43. Query

```
SELECT stock_num, manu_code, description, unit_price
FROM stock
ORDER BY manu_code, unit_price;
```

In the query result, the **manu\_code** column data appears in alphabetical order and, within each set of rows with the same **manu\_code** (for example, ANZ, HRO), the **unit\_price** is listed in ascending order.

Figure 44. Query result

| stock_num | manu_code | description     | unit_price |
|-----------|-----------|-----------------|------------|
| 5         | ANZ       | tennis racquet  | \$19.80    |
| 9         | ANZ       | volleyball net  | \$20.00    |
| 6         | ANZ       | tennis ball     | \$48.00    |
| 313       | ANZ       | swim cap        | \$60.00    |
| 201       | ANZ       | golf shoes      | \$75.00    |
| 310       | ANZ       | kick board      | \$84.00    |
| :         |           |                 |            |
| 111       | SHM       | 10-spd, assmbld | \$499.99   |
| 112       | SHM       | 12-spd, assmbld | \$549.00   |
| 113       | SHM       | 18-spd, assmbld | \$685.90   |
| 5         | SMT       | tennis racquet  | \$25.00    |
| 6         | SMT       | tennis ball     | \$36.00    |
| 1         | SMT       | baseball gloves | \$450.00   |

The following query shows the reverse order of the columns in the ORDER BY clause.

Figure 45. Query

```
SELECT stock_num, manu_code, description, unit_price
FROM stock
ORDER BY unit_price, manu_code;
```

In the query result, the data appears in ascending order of **unit\_price** and, where two or more rows have the same **unit\_price** (for example, \$20.00, \$48.00, \$312.00), the **manu\_code** is in alphabetical order.

Figure 46. Query result

| stock_num | manu_code | description     | unit_price |
|-----------|-----------|-----------------|------------|
| 302       | HRO       | ice pack        | \$4.50     |
| 302       | KAR       | ice pack        | \$5.00     |
| 5         | ANZ       | tennis racquet  | \$19.80    |
| 9         | ANZ       | volleyball net  | \$20.00    |
| 103       | PRC       | frnt derailleur | \$20.00    |
| :         |           |                 |            |
| 108       | SHM       | crankset        | \$45.00    |
| 6         | ANZ       | tennis ball     | \$48.00    |
| 305       | HRO       | first-aid kit   | \$48.00    |
| 303       | PRC       | socks           | \$48.00    |
| 311       | SHM       | water gloves    | \$48.00    |
| :         |           |                 |            |
| 113       | SHM       | 18-spd, assmbld | \$685.90   |
| 1         | HSK       | baseball gloves | \$800.00   |
| 8         | ANZ       | volleyball      | \$840.00   |
| 4         | HSK       | football        | \$960.00   |

The order of the columns in the ORDER BY clause is important, and so is the position of the DESC keyword. Although the statements in the following query contain the same components in the ORDER BY clause, each produces a different result (not shown).

Figure 47. Query

```
SELECT * FROM stock ORDER BY manu_code, unit_price DESC;
SELECT * FROM stock ORDER BY unit_price, manu_code DESC;
SELECT * FROM stock ORDER BY manu_code DESC, unit_price;
SELECT * FROM stock ORDER BY unit_price DESC, manu_code;
```

## Select specific columns

The previous section shows how to select and order all data from a table. However, often all you want to see is the data in one or more specific columns. Again, the formula is to use the Projection and FROM clauses, specify the columns and table, and perhaps order the data in ascending or descending order with an ORDER BY clause.

If you want to find all the customer numbers in the **orders** table, use a statement such as the one in the following query.

Figure 48. Query

```
SELECT customer_num FROM orders;
```

The result shows how the statement simply selects all data in the **customer\_num** column in the **orders** table and lists the customer numbers on all the orders, including duplicates.

Figure 49. Query result

```
customer_num
104
101
104
:
122
123
124
126
127
```

The output includes several duplicates because some customers have placed more than one order. Sometimes you want to see duplicate rows in a projection. At other times, you want to see only the distinct values, not how often each value appears.

To suppress duplicate rows, you can include the keyword **DISTINCT** or its synonym **UNIQUE** at the start of the select list, once in each level of a query, as the following query shows.

Figure 50. Query

```
SELECT DISTINCT customer_num FROM orders;

SELECT UNIQUE customer_num FROM orders;
```

To produce a more readable list, [Figure 50: Query on page 1784](#) limits the display to show each customer number in the **orders** table only once, as the result shows.

Figure 51. Query result

```
customer_num
101
104
106
110
111
112
115
116
117
119
120
121
122
123
124
126
127
```

Suppose you are handling a customer call, and you want to locate purchase order number DM354331. To list all the purchase order numbers in the **orders** table, use a statement such as the following query shows.

Figure 52. Query

```
SELECT po_num FROM orders;
```

The result shows how the statement retrieves data in the **po\_num** column in the **orders** table.

Figure 53. Query result

```
po_num
B77836
9270
B77890
8006
2865
Q13557
278693
:
```

However, the list is not in a useful order. You can add an ORDER BY clause to sort the column data in ascending order and make it easier to find that particular **po\_num**, as shown in the following query.

Figure 54. Query

```
SELECT po_num FROM orders ORDER BY po_num;
```

Figure 55. Query result

```
po_num
278693
278701
2865
429Q
4745
8006
8052
9270
B77836
B77890
:
```

To select multiple columns from a table, list them in the projection list in the Projection clause. The following query shows that the order in which the columns are selected is the order in which they are retrieved, from left to right.

Figure 56. Query

```
SELECT ship_date, order_date, customer_num,
       order_num, po_num
FROM orders
ORDER BY order_date, ship_date;
```

As [Sorting on multiple columns on page 1782](#) shows, you can use the ORDER BY clause to sort the data in ascending or descending order and perform nested sorts. The result shows ascending order.

Figure 57. Query result

| ship_date  | order_date | customer_num | order_num | po_num   |
|------------|------------|--------------|-----------|----------|
| 06/01/1998 | 05/20/1998 | 104          | 1001      | B77836   |
| 05/26/1998 | 05/21/1998 | 101          | 1002      | 9270     |

| 07/16/1998 | 07/11/1998 | 122          | 1019      | Z55709   |
| 07/16/1998 | 07/11/1998 | 123          | 1020      | W2286    |
| 07/25/1998 | 07/23/1998 | 124          | 1021      | C3288    |
| 07/30/1998 | 07/24/1998 | 126          | 1022      | W9925    |
| 07/30/1998 | 07/24/1998 | 127          | 1023      | KF2961   |

When you use `SELECT` and `ORDER BY` on several columns in a table, you might find it helpful to use integers to refer to the position of the columns in the `ORDER BY` clause. When an integer is an element in the `ORDER BY` list, the database server treats it as the position in the projection list. For example, using 3 in the `ORDER BY` list (`ORDER BY 3`) refers to the third item in the projection list. The statements in the following query retrieve and display the same data, as [Figure 59: Query result on page 1787](#) shows.

Figure 58. Query

```
SELECT customer_num, order_num, po_num, order_date
FROM orders
ORDER BY 4, 1;

SELECT customer_num, order_num, po_num, order_date
FROM orders
ORDER BY order_date, customer_num;
```

Figure 59. Query result

| customer_num | order_num | po_num   | order_date |
|--------------|-----------|----------|------------|
| 104          | 1001      | B77836   | 05/20/1998 |
| 101          | 1002      | 9270     | 05/21/1998 |
| 104          | 1003      | B77890   | 05/22/1998 |
| 106          | 1004      | 8006     | 05/22/1998 |
| 116          | 1005      | 2865     | 05/24/1998 |
| 112          | 1006      | Q13557   | 05/30/1998 |
| 117          | 1007      | 278693   | 05/31/1998 |
| 110          | 1008      | LZ230    | 06/07/1998 |
| 111          | 1009      | 4745     | 06/14/1998 |
| 115          | 1010      | 429Q     | 06/17/1998 |
| 104          | 1011      | B77897   | 06/18/1998 |
| 117          | 1012      | 278701   | 06/18/1998 |
| 104          | 1013      | B77930   | 06/22/1998 |
| 106          | 1014      | 8052     | 06/25/1998 |
| 110          | 1015      | MA003    | 06/27/1998 |
| 119          | 1016      | PC6782   | 06/29/1998 |
| 120          | 1017      | DM354331 | 07/09/1998 |
| 121          | 1018      | S22942   | 07/10/1998 |
| 122          | 1019      | Z55709   | 07/11/1998 |
| 123          | 1020      | W2286    | 07/11/1998 |
| 124          | 1021      | C3288    | 07/23/1998 |
| 126          | 1022      | W9925    | 07/24/1998 |
| 127          | 1023      | KF2961   | 07/24/1998 |

You can include the DESC keyword in the ORDER BY clause when you assign integers to column names, as the following query shows.

Figure 60. Query

```
SELECT customer_num, order_num, po_num, order_date
FROM orders
ORDER BY 4 DESC, 1;
```

In this case, data is first sorted in descending order by **order\_date** and in ascending order by **customer\_num**.

## Select substrings

To select part of the value of a character column, include a *substring* in the projection list. Suppose your marketing department is planning a mailing to your customers and wants their geographical distribution based on zip codes. You could write a query similar to the following.

Figure 61. Query

```
SELECT zipcode[1,3], customer_num
FROM customer
ORDER BY zipcode;
```

The query uses a substring to select the first three characters of the **zipcode** column (which identify the state) and the full **customer\_num**, and lists them in ascending order by zip code, as the result shows.

Figure 62. Query result

| zipcode | customer_num |
|---------|--------------|
| 021     | 125          |
| 080     | 119          |
| 085     | 122          |
| 198     | 121          |
| 322     | 123          |
| :       |              |
| 943     | 103          |
| 943     | 107          |
| 946     | 118          |

## The WHERE clause

The set of rows that a SELECT statement returns is its *active set*. A *singleton* SELECT statement returns a single row. You can add a WHERE clause to a SELECT statement if you want to see only specific rows. For example, you use a WHERE clause to restrict the rows that the database server returns to only the orders that a particular customer placed or the calls that a particular customer service representative entered.

You can use the WHERE clause to set up a comparison condition or a join condition. This section demonstrates only the first use. Join conditions are described in a later section and in the next chapter.

## Create a comparison condition

The WHERE clause of a SELECT statement specifies the rows that you want to see. A comparison condition employs specific *keywords* and *operators* to define the search criteria.

For example, you might use one of the keywords BETWEEN, IN, LIKE, or MATCHES to test for equality, or the keywords IS NULL to test for null values. You can combine the keyword NOT with any of these keywords to specify the opposite condition.

The following table lists the relational operators that you can use in a WHERE clause in place of a keyword to test for equality.

### Operator

#### Operation

=

equals

!= or <>

does not equal

>

greater than

&gt;=

greater than or equal to

&lt;

less than

&lt;=

less than or equal to

For CHAR expressions, greater than means *after* in ASCII collating order, where lowercase letters are after uppercase letters, and both are after numerals. See the ASCII Character Set chart in the *Informix® Guide to SQL: Syntax*. For DATE and DATETIME expressions, greater than means *later in time*, and for INTERVAL expressions, it means *of longer duration*.

You cannot use TEXT or BYTE columns to create a comparison condition, except when you use the IS NULL or IS NOT NULL keywords to test for NULL values.

You cannot specify BLOB or CLOB columns to create a comparison condition on , except when you use the IS NULL or IS NOT NULL keywords to test for NULL values.

You can use the preceding keywords and operators in a WHERE clause to create comparison-condition queries that perform the following actions:

- Include values
- Exclude values
- Find a range of values
- Find a subset of values
- Identify NULL values

To perform variable text searches using the following criteria, use the preceding keywords and operators in a WHERE clause to create comparison-condition queries:

- Exact-text comparison
- Single-character wildcards
- Restricted single-character wildcards
- Variable-length wildcards
- Subscripting

The following section contains examples that illustrate these types of queries.

## Include rows

Use the equal sign (=) relational operator to include rows in a WHERE clause, as the following query shows.

Figure 63. Query

```
SELECT customer_num, call_code, call_dtime, res_dtime
FROM cust_calls
WHERE user_id = 'maryj';
```

The query returns the set of rows that is shown.

Figure 64. Query result

| customer_num | call_code | call_dtime       | res_dtime        |
|--------------|-----------|------------------|------------------|
| 106          | D         | 1998-06-12 08:20 | 1998-06-12 08:25 |
| 121          | O         | 1998-07-10 14:05 | 1998-07-10 14:06 |
| 127          | I         | 1998-07-31 14:30 |                  |

## Exclude rows

Use the relational operators `!=` or `<>` to exclude rows in a `WHERE` clause.

The following query assumes that you are selecting from an ANSI-compliant database; the statements specify the owner or login name of the creator of the **customer** table. This qualifier is not required when the creator of the table is the current user, or when the database is not ANSI compliant. However, you can include the qualifier in either case. For a detailed discussion of owner naming, see the *Informix® Guide to SQL: Syntax*.

Figure 65. Query

```
SELECT customer_num, company, city, state
FROM odin.customer
WHERE state != 'CA';

SELECT customer_num, company, city, state
FROM odin.customer
WHERE state <> 'CA';
```

Both statements in the query exclude values by specifying that, in the **customer** table that the user **odin** owns, the value in the **state** column should not be equal to `CA`, as the result shows.

Figure 66. Query result

| customer_num | company              | city         | state |
|--------------|----------------------|--------------|-------|
| 119          | The Triathletes Club | Cherry Hill  | NJ    |
| 120          | Century Pro Shop     | Phoenix      | AZ    |
| 121          | City Sports          | Wilmington   | DE    |
| 122          | The Sporting Life    | Princeton    | NJ    |
| 123          | Bay Sports           | Jacksonville | FL    |
| 124          | Putnum's Putters     | Bartlesville | OK    |
| 125          | Total Fitness Sports | Brighton     | MA    |
| 126          | Neelie's Discount Sp | Denver       | CO    |
| 127          | Big Blue Bike Shop   | Blue Island  | NY    |
| 128          | Phoenix College      | Phoenix      | AZ    |

## Specify a range of rows

The following query shows two ways to specify a range of rows in a WHERE clause.

Figure 67. Query

```
SELECT catalog_num, stock_num, manu_code, cat_advert
FROM catalog
WHERE catalog_num BETWEEN 10005 AND 10008;

SELECT catalog_num, stock_num, manu_code, cat_advert
FROM catalog
WHERE catalog_num >= 10005 AND catalog_num <= 10008;
```

Each statement in the query specifies a range for **catalog\_num** from 10005 through 10008, inclusive. The first statement uses keywords, and the second statement uses relational operators to retrieve the rows, as the result shows.

Figure 68. Query result

```
catalog_num 10005
stock_num   3
manu_code   HSK
cat_advert  High-Technology Design Expands the Sweet Spot

catalog_num 10006
stock_num   3
manu_code   SHM
cat_advert  Durable Aluminum for High School and Collegiate Athletes

catalog_num 10007
stock_num   4
manu_code   HSK
cat_advert  Quality Pigskin with Joe Namath Signature

catalog_num 10008
stock_num   4
manu_code   HRO
cat_advert  Highest Quality Football for High School
           and Collegiate Competitions
```

Although the **catalog** table includes a column with the BYTE data type, that column is not included in this SELECT statement because the output would show only the words `<BYTE value>` by the column name. You can write an SQL API application to display TEXT and BYTE values.

## Exclude a range of rows

The following query uses the keywords NOT BETWEEN to exclude rows that have the character range 94000 through 94999 in the **zipcode** column, as the result shows.

Figure 69. Query

```
SELECT fname, lname, city, state
FROM customer
WHERE zipcode NOT BETWEEN '94000' AND '94999'
ORDER BY state;
```

Figure 70. Query result

| fname  | lname   | city         | state |
|--------|---------|--------------|-------|
| Frank  | Lessor  | Phoenix      | AZ    |
| Fred   | Jewell  | Phoenix      | AZ    |
| Eileen | Neelie  | Denver       | CO    |
| Jason  | Wallack | Wilmington   | DE    |
| Marvin | Hanlon  | Jacksonville | FL    |
| James  | Henry   | Brighton     | MA    |
| Bob    | Shorter | Cherry Hill  | NJ    |
| Cathy  | O'Brian | Princeton    | NJ    |
| Kim    | Satifer | Blue Island  | NY    |
| Chris  | Putnum  | Bartlesville | OK    |

## Use a WHERE clause to find a subset of values

Like [Exclude rows on page 1790](#), the following query assumes the use of an ANSI-compliant database. The owner qualifier is in quotation marks to preserve the case sensitivity of the literal string.

Figure 71. Query

```
SELECT lname, city, state, phone
  FROM 'Aleta'.customer
 WHERE state = 'AZ' OR state = 'NJ'
 ORDER BY lname;

SELECT lname, city, state, phone
  FROM 'Aleta'.customer
 WHERE state IN ('AZ', 'NJ')
 ORDER BY lname;
```

Each statement in the query retrieves rows that include the subset of `AZ` or `NJ` in the **state** column of the **Aleta.customer** table.

Figure 72. Query result

| lname   | city        | state | phone        |
|---------|-------------|-------|--------------|
| Jewell  | Phoenix     | AZ    | 602-265-8754 |
| Lessor  | Phoenix     | AZ    | 602-533-1817 |
| O'Brian | Princeton   | NJ    | 609-342-0054 |
| Shorter | Cherry Hill | NJ    | 609-663-6079 |

You cannot test TEXT or BYTE columns with the IN keyword.

Also, when you use `,` you cannot test BLOB or CLOB columns with the IN keyword.

In the example of a query on an ANSI-compliant database, no quotation marks exist around the table owner name. Whereas the two statements in [Figure 71: Query on page 1792](#) searched the **Aleta.customer** table, the following query searches the table **ALETA.customer**, which is a different table, because of the way ANSI-compliant databases look at owner names.

Figure 73. Query

```
SELECT lname, city, state, phone
FROM Aleta.customer
WHERE state NOT IN ('AZ', 'NJ')
ORDER BY state;
```

The previous query adds the keywords NOT IN, so the subset changes to exclude the subsets **AZ** and **NJ** in the **state** column.

The following figure shows the results in order of the **state** column.

Figure 74. Query result

| lname     | city          | state | phone        |
|-----------|---------------|-------|--------------|
| Pauli     | Sunnyvale     | CA    | 408-789-8075 |
| Sadler    | San Francisco | CA    | 415-822-1289 |
| Currie    | Palo Alto     | CA    | 415-328-4543 |
| Higgins   | Redwood City  | CA    | 415-368-1100 |
| Vector    | Los Altos     | CA    | 415-776-3249 |
| Watson    | Mountain View | CA    | 415-389-8789 |
| Ream      | Palo Alto     | CA    | 415-356-9876 |
| Quinn     | Redwood City  | CA    | 415-544-8729 |
| Miller    | Sunnyvale     | CA    | 408-723-8789 |
| Jaeger    | Redwood City  | CA    | 415-743-3611 |
| Keyes     | Sunnyvale     | CA    | 408-277-7245 |
| Lawson    | Los Altos     | CA    | 415-887-7235 |
| Beatty    | Menlo Park    | CA    | 415-356-9982 |
| Albertson | Redwood City  | CA    | 415-886-6677 |

| Parmelee  | Mountain View | CA    | 415-534-8822 |
| Sipes     | Redwood City  | CA    | 415-245-4578 |
| Baxter    | Oakland       | CA    | 415-655-0011 |
| Neelie    | Denver        | CO    | 303-936-7731 |
| Wallack   | Wilmington    | DE    | 302-366-7511 |
| Hanlon    | Jacksonville  | FL    | 904-823-4239 |
| Henry     | Brighton      | MA    | 617-232-4159 |
| Satifer   | Blue Island   | NY    | 312-944-5691 |
| Putnum    | Bartlesville  | OK    | 918-355-2074 |

## Identify NULL values

Use the IS NULL or IS NOT NULL option to check for NULL values. A NULL value represents either the absence of data or an unknown value. A NULL value is not the same as a zero or a blank.

The following query returns all rows that have a null **paid\_date**, as the result shows.

Figure 75. Query

```
SELECT order_num, customer_num, po_num, ship_date
FROM orders
WHERE paid_date IS NULL
ORDER BY customer_num;
```

Figure 76. Query result

| order_num | customer_num | po_num   | ship_date  |
|-----------|--------------|----------|------------|
| 1004      | 106          | 8006     | 05/30/1998 |
| 1006      | 112          | Q13557   |            |
| 1007      | 117          | 278693   | 06/05/1998 |
| 1012      | 117          | 278701   | 06/29/1998 |
| 1016      | 119          | PC6782   | 07/12/1998 |
| 1017      | 120          | DM354331 | 07/13/1998 |

## Form compound conditions

To connect two or more comparison conditions, or *Boolean expressions*, use the logical operators AND, OR, and NOT. A Boolean expression evaluates as `true` or `false` or, if NULL values are involved, as `unknown`.

In the following query, the operator AND combines two comparison expressions in the WHERE clause.

Figure 77. Query

```
SELECT order_num, customer_num, po_num, ship_date
FROM orders
WHERE paid_date IS NULL
AND ship_date IS NOT NULL
ORDER BY customer_num;
```

The query returns all rows that have NULL paid\_date or a NOT NULL ship\_date.

Figure 78. Query result

| order_num | customer_num | po_num   | ship_date  |
|-----------|--------------|----------|------------|
| 1004      | 106          | 8006     | 05/30/1998 |
| 1007      | 117          | 278693   | 06/05/1998 |
| 1012      | 117          | 278701   | 06/29/1998 |
| 1017      | 120          | DM354331 | 07/13/1998 |

## Exact-text comparisons

The following examples include a WHERE clause that searches for exact-text comparisons by using the keyword LIKE or MATCHES or the equal sign (=) relational operator. Unlike earlier examples, these examples illustrate how to query a table that is not in the current database. You can access a table that is not in the current database only if the database that contains the table has the same ANSI compliance status as the current database. If the current database is an ANSI-compliant database, the table you want to access must also reside in an ANSI-compliant database. If the current database is not an ANSI-compliant database, the table you want to access must also reside in a database that is not an ANSI-compliant database.

Although the database used previously in this chapter is the demonstration database, the FROM clause in the following examples specifies the **manatee** table, created by the owner **bubba**, which resides in an ANSI-compliant database named

**syzygy**. For more information on how to access tables that are not in the current database, see the *Informix® Guide to SQL: Syntax*.

Each statement in the following query retrieves all the rows that have the single word *helmet* in the **description** column, as the result shows.

Figure 79. Query

```
SELECT stock_no, mfg_code, description, unit_price
  FROM syzygy:bubba.manatee
 WHERE description = 'helmet'
 ORDER BY mfg_code;

SELECT stock_no, mfg_code, description, unit_price
  FROM syzygy:bubba.manatee
 WHERE description LIKE 'helmet'
 ORDER BY mfg_code;

SELECT stock_no, mfg_code, description, unit_price
  FROM syzygy:bubba.manatee
 WHERE description MATCHES 'helmet'
 ORDER BY mfg_code;
```

The results might look like the following figure.

Figure 80. Query result

| stock_no | mfg_code | description | unit_price |
|----------|----------|-------------|------------|
| 991      | ABC      | helmet      | \$222.00   |
| 991      | BKE      | helmet      | \$269.00   |
| 991      | HSK      | helmet      | \$311.00   |
| 991      | PRC      | helmet      | \$234.00   |
| 991      | SPR      | helmet      | \$245.00   |

## Variable-text searches

You can use the keywords **LIKE** and **MATCHES** for variable-text queries that are based on substring searches of fields. Include the keyword **NOT** to indicate the opposite condition.

The keyword **LIKE** complies with the ISO/ANSI standard for SQL, whereas **MATCHES** is the Informix® extension.

Variable-text search strings can include the wildcard symbols that are listed with the keywords **LIKE** or **MATCHES** in the following table.

| Keyword | Symbol | Explanation                                    |
|---------|--------|--|
| LIKE    | %      | Evaluates to zero or more characters           |
| LIKE    | _      | Evaluates to a single character                |
| LIKE    | \      | Escapes special significance of next character |

| Keyword | Symbol | Explanation  |
|---------|--------|--|
| MATCHES | *      | Evaluates to zero or more characters               |
| MATCHES | ?      | Evaluates to a single character (except null)      |
| MATCHES | [ ]    | Evaluates to a single character or range of values |
| MATCHES | \      | Escapes special significance of next character     |

You cannot test BLOB, CLOB, TEXT, or BYTE columns with the LIKE or MATCHES operators.

## A single-character wildcard

The statements in the following query illustrate the use of a single-character wildcard in a WHERE clause. Further, they demonstrate a query on a table that is not in the current database. The **stock** table is in the database **sloth**. Besides being outside the current demonstration database, **sloth** is on a separate database server called **meerkat**.

For more information, see [Access and modify data in an external database on page 1940](#) and the *Informix® Guide to SQL: Syntax*.

Figure 81. Query

```
SELECT stock_num, manu_code, description, unit_price
FROM sloth@meerkat:stock
WHERE manu_code LIKE '_R_'
      AND unit_price >= 100
ORDER BY description, unit_price;

SELECT stock_num, manu_code, description, unit_price
FROM sloth@meerkat:stock
WHERE manu_code MATCHES '?R?'
      AND unit_price >= 100
ORDER BY description, unit_price;
```

Each statement in the query retrieves only those rows for which the middle letter of the **manu\_code** is **R**, as the result shows. The comparison **'\_R\_'** (for LIKE) or **'?R?'** (for MATCHES) specifies, from left to right, the following items:

- Any single character
- The letter **R**
- Any single character

Figure 82. Query result

| stock_num | manu_code | description     | unit_price |
|-----------|-----------|-----------------|------------|
| 205       | HRO       | 3 golf balls    | \$312.00   |
| 2         | HRO       | baseball        | \$126.00   |
| 1         | HRO       | baseball gloves | \$250.00   |
| 7         | HRO       | basketball      | \$600.00   |
| 102       | PRC       | bicycle brakes  | \$480.00   |
| 114       | PRC       | bicycle gloves  | \$120.00   |
| 4         | HRO       | football        | \$480.00   |
| 110       | PRC       | helmet          | \$236.00   |
| 110       | HRO       | helmet          | \$260.00   |
| 307       | PRC       | infant jogger   | \$250.00   |
| 306       | PRC       | tandem adapter  | \$160.00   |
| 308       | PRC       | twin jogger     | \$280.00   |
| 304       | HRO       | watch           | \$280.00   |

## WHERE clause to specify a range of initial characters

The following query selects only those rows where the **manu\_code** begins with **A** through **H** and returns the rows that the result shows. The test '**[A-H]**' specifies any single letter from **A** through **H**, inclusive. No equivalent wildcard symbol exists for the LIKE keyword.

Figure 83. Query

```
SELECT stock_num, manu_code, description, unit_price
FROM stock
WHERE manu_code MATCHES '[A-H]*'
ORDER BY description, manu_code;
```

Figure 84. Query result

| stock_num | manu_code | description     | unit_price |
|-----------|-----------|-----------------|------------|
| 205       | ANZ       | 3 golf balls    | \$312.00   |
| 205       | HRO       | 3 golf balls    | \$312.00   |
| 2         | HRO       | baseball        | \$126.00   |
| 3         | HSK       | baseball bat    | \$240.00   |
| 1         | HRO       | baseball gloves | \$250.00   |
| 1         | HSK       | baseball gloves | \$800.00   |
| 7         | HRO       | basketball      | \$600.00   |
| 313       | ANZ       | swim cap        | \$60.00    |
| 6         | ANZ       | tennis ball     | \$48.00    |
| 5         | ANZ       | tennis racquet  | \$19.80    |
| 8         | ANZ       | volleyball      | \$840.00   |
| 9         | ANZ       | volleyball net  | \$20.00    |
| 304       | ANZ       | watch           | \$170.00   |

## WHERE clause with variable-length wildcard

The statements in the following query use a wildcard at the end of a string to retrieve all the rows where the **description** begins with the characters `bicycle`.

Figure 85. Query

```

SELECT stock_num, manu_code, description, unit_price
  FROM stock
 WHERE description LIKE 'bicycle%'
 ORDER BY description, manu_code;

SELECT stock_num, manu_code, description, unit_price
  FROM stock
 WHERE description MATCHES 'bicycle*'
 ORDER BY description, manu_code;

```

Either statement returns the following rows.

Figure 86. Query result

| stock_num | manu_code | description    | unit_price |
|-----------|-----------|----------------|------------|
| 102       | PRC       | bicycle brakes | \$480.00   |
| 102       | SHM       | bicycle brakes | \$220.00   |
| 114       | PRC       | bicycle gloves | \$120.00   |
| 107       | PRC       | bicycle saddle | \$70.00    |
| 106       | PRC       | bicycle stem   | \$23.00    |
| 101       | PRC       | bicycle tires  | \$88.00    |
| 101       | SHM       | bicycle tires  | \$68.00    |
| 105       | PRC       | bicycle wheels | \$53.00    |
| 105       | SHM       | bicycle wheels | \$80.00    |

The comparison `'bicycle%'` or `'bicycle*'` specifies the characters `bicycle` followed by any sequence of zero or more characters. It matches `bicycle stem` with `stem` matched by the wildcard. It matches to the characters `bicycle` alone, if a row exists with that description.

The following query narrows the search by adding another comparison condition that excludes a **manu\_code** of `PRC`.

Figure 87. Query

```

SELECT stock_num, manu_code, description, unit_price
  FROM stock
 WHERE description LIKE 'bicycle%'
   AND manu_code NOT LIKE 'PRC'
 ORDER BY description, manu_code;

```

The statement retrieves only the following rows.

Figure 88. Query result

| stock_num | manu_code | description    | unit_price |
|-----------|-----------|----------------|------------|
| 102       | SHM       | bicycle brakes | \$220.00   |
| 101       | SHM       | bicycle tires  | \$68.00    |
| 105       | SHM       | bicycle wheels | \$80.00    |

When you select from a large table and use an initial wildcard in the comparison string (such as `'%cycle'`), the query often takes longer to execute. Because indexes cannot be used, every row is searched.

## Protect special characters

The following query uses the keyword `ESCAPE` with `LIKE` or `MATCHES` so you can protect a special character from misinterpretation as a wildcard symbol.

Figure 89. Query

```
SELECT * FROM cust_calls
WHERE res_descr LIKE '%!%' ESCAPE '!';
```

The `ESCAPE` keyword designates an escape character (! in this example) that protects the next character so that it is interpreted as data and not as a wildcard. In the example, the escape character causes the middle percent sign (%) to be treated as data. By using the `ESCAPE` keyword, you can search for occurrences of a percent sign (%) in the `res_descr` column by using the `LIKE` wildcard percent sign (%). The query retrieves the following row.

Figure 90. Query result

```
customer_num  116
call_dtime    1997-12-21 11:24
user_id       mannyn
call_code     I
call_descr    Second complaint from this customer!
              Received two cases righthanded outfielder
              glove (1 HRO) instead of one case lefties.
res_dtime     1997-12-27 08:19
res_descr     Memo to shipping (Ava Brown) to send case
              of lefthanded gloves, pick up wrong case;
              memo to billing requesting 5% discount to
              placate customer due to second offense
              and lateness of resolution because of
              holiday.
```

## Subscripting in a WHERE clause

You can use *subscripting* in the `WHERE` clause of a `SELECT` statement to specify a range of characters or numbers in a column, as the following query shows.

Figure 91. Query

```
SELECT catalog_num, stock_num, manu_code, cat_advert,
       cat_descr
FROM catalog
WHERE cat_advert[1,4] = 'High';
```

The subscript `[1,4]` causes the query to retrieve all rows in which the first four letters of the `cat_advert` column are `High`, as result shows.

Figure 92. Query result

```
catalog_num 10004
stock_num   2
manu_code   HRO
cat_advert  Highest Quality Ball Available, from Hand-Sti
           tching to the Robinson Signature
cat_descr   Jackie Robinson signature ball. Highest professional quality,
           used by National League.

catalog_num 10005
stock_num   3
manu_code   HSK
cat_advert  High-Technology Design Expands the Sweet Spot
cat_descr   Pro-style wood. Available in sizes: 31, 32, 33, 34, 35.
           :
catalog_num 10045
stock_num   204
manu_code   KAR
cat_advert  High-Quality Beginning Set of Irons. Appropriate
           for High School Competitions
cat_descr   Ideally balanced for optimum control. Nylon covered shaft.

catalog_num 10068
stock_num   310
manu_code   ANZ
cat_advert  High-Quality Kickboard
cat_descr   White. Standard size.
```

## FIRST clause to select specific rows

You can include a `FIRST max` specification in the Projection clause of a `SELECT` statement, where *max* has an integer value, to instruct the query to return no more than the first *max* rows that match the conditions of the `SELECT` statement. You can also use the keyword `LIMIT` as a synonym for `FIRST` in this context (and only in this context). The rows that a `SELECT` statement with a `FIRST` clause returns might depend on whether the statement also includes an `ORDER BY` clause.

The keyword `SKIP`, followed by an unsigned integer, can precede the `FIRST` or `LIMIT` keyword in the Projection clause. The `SKIP offset` clause instructs the database server to exclude the first *offset* qualifying rows from the result set of the query before returning the number of rows that the `FIRST` clause specifies. In SPL routines, the parameter of `SKIP`, `FIRST`, or `LIMIT` can be a literal integer or a local SPL variable. If the Projection clause includes `SKIP offset` but no `FIRST` or `LIMIT` specification, then the query returns all of the qualifying rows except for the first *offset* rows.

The Projection clause cannot include the `SKIP`, `FIRST`, or `LIMIT` keywords in these contexts:

- when the SELECT statement is part of a view definition
- in a subquery, except in the FROM clause of the outer query
- in a cross-server distributed query in which a participating database server does not support the SKIP, FIRST, or LIMIT keywords.

For information about restrictions on use of the FIRST clause, see the description of the Projection clause of the SELECT statement in the *Informix® Guide to SQL: Syntax*.

## FIRST clause without an ORDER BY clause

If you do not include an ORDER BY clause in a SELECT statement with a FIRST clause, any rows that match the conditions of the SELECT statement might be returned. In other words, the database server determines which of the qualifying rows to return, and the query result can vary depending on the query plan that the optimizer chooses.

The following query uses the FIRST clause to return the first five rows from the **state** table.

Figure 93. Query

```
SELECT FIRST 5 * FROM state;
```

Figure 94. Query result

| code | sname      |
|------|------------|
| AK   | Alaska     |
| HI   | Hawaii     |
| CA   | California |
| OR   | Oregon     |
| WA   | Washington |

You can use a FIRST clause when you simply want to know the names of all the columns and the type of data that a table contains, or to test a query that otherwise would return many rows. The following query shows how to use the FIRST clause to return column values for the first row of a table.

Figure 95. Query

```
SELECT FIRST 1 * FROM orders;
```

Figure 96. Query result

|               |            |
|---------------|------------|
| order_num     | 1001       |
| order_date    | 05/20/1998 |
| customer_num  | 104        |
| ship_instruct | express    |
| backlog       | n          |
| po_num        | B77836     |
| ship_date     | 06/01/1998 |
| ship_weight   | 20.40      |
| ship_charge   | \$10.00    |
| paid_date     | 07/22/1998 |

## FIRST clause with an ORDER BY clause

You can include an ORDER BY clause in a SELECT statement with a FIRST clause to return rows that contain the highest or lowest values for a specified column. The following query shows a query that includes an ORDER BY clause to return (by alphabetical order) the first five states contained in the **state** table. The query, which is the same as [Figure 93: Query on page 1801](#) except for the ORDER BY clause, returns a different set of rows than [Figure 93: Query on page 1801](#).

Figure 97. Query

```
SELECT FIRST 5 * FROM state ORDER BY sname;
```

Figure 98. Query result

| code | sname      |
|------|------------|
| AL   | Alabama    |
| AK   | Alaska     |
| AZ   | Arizona    |
| AR   | Arkansas   |
| CA   | California |

The following query shows how to use a FIRST clause in a query with an ORDER BY clause to find the 10 most expensive items listed in the **stock** table.

Figure 99. Query

```
SELECT FIRST 10 description, unit_price
FROM stock ORDER BY unit_price DESC;
```

Figure 100. Query result

| description     | unit_price |
|-----------------|------------|
| football        | \$960.00   |
| volleyball      | \$840.00   |
| baseball gloves | \$800.00   |
| 18-spd, assmbld | \$685.90   |
| irons/wedge     | \$670.00   |
| basketball      | \$600.00   |
| 12-spd, assmbld | \$549.00   |
| 10-spd, assmbld | \$499.99   |
| football        | \$480.00   |
| bicycle brakes  | \$480.00   |

Applications can use the SKIP and FIRST keywords of the Projection clause, in conjunction with the ORDER BY clause, to perform successive queries that incrementally retrieve all of the qualifying rows in subsets of some fixed size (for example, the maximum number of rows that are visible without scrolling a screen display). You can accomplish this by incrementing the *offset* parameter of the SKIP clause by the *max* parameter of the FIRST clause after each query. By imposing a unique order on the qualifying rows, the ORDER BY clause ensures that each query returns a disjunct subset of the qualifying rows.

The following query shows a query that includes SKIP, FIRST, and ORDER BY specifications to return (by alphabetical order) the sixth through tenth states in the **state** table, but not the first five states. This query resembles [Figure 93: Query on page 1801](#), except that the SKIP 5 specification instructs the database server to return a different set of rows than [Figure 93: Query on page 1801](#).

Figure 101. Query

```
SELECT SKIP 5 FIRST 5 * FROM state ORDER BY sname;
```

Figure 102. Query result

```
code sname
CO Colorado
CT Connecticut
DE Delaware
FL Florida
GA Georgia
```

If you use the SKIP, FIRST, or LIMIT keywords, you must take care to specify parameters that correspond to the design goals of your application. If the *offset* parameter of skip is larger than the number of qualifying rows, then any FIRST or LIMIT specification has no effect, and the query returns nothing.

## Expressions and derived values

You are not limited to selecting columns by name. You can list an *expression* in the Projection clause of a SELECT statement to perform computations on column data and to display information *derived* from the contents of one or more columns.

An expression consists of a column name, a constant, a quoted string, a keyword, or any combination of these items connected by operators. It can also include host variables (program data) when the SELECT statement is embedded in a program.

## Arithmetic expressions

An arithmetic expression contains at least one of the arithmetic operators listed in the following table and produces a number.

| Operator | Operation      |
|----------|----------------|
| +        | addition       |
| -        | subtraction    |
| *        | multiplication |
| /        | division       |

You cannot use TEXT or BYTE columns in arithmetic expressions.

With , you cannot specify BLOB or CLOB in arithmetic expressions.

Arithmetic operations enable you to see the results of proposed computations without actually altering the data in the database. You can add an INTO TEMP clause to save the altered data in a temporary table for further reference, computations, or impromptu reports. The following query calculates a 7 percent sales tax on the **unit\_price** column when the **unit\_price** is \$400 or more (but does not update it in the database).

Figure 103. Query

```
SELECT stock_num, description, unit_price, unit_price * 1.07
FROM stock
WHERE unit_price >= 400;
```

The result appears in the **expression** column.

Figure 104. Query result

| stock_num | description     | unit_price | (expression) |
|-----------|-----------------|------------|--------------|
| 1         | baseball gloves | \$800.00   | \$856.00     |
| 1         | baseball gloves | \$450.00   | \$481.50     |
| 4         | football        | \$960.00   | \$1027.20    |
| 4         | football        | \$480.00   | \$513.60     |
| 7         | basketball      | \$600.00   | \$642.00     |
| 8         | volleyball      | \$840.00   | \$898.80     |
| 102       | bicycle brakes  | \$480.00   | \$513.60     |
| 111       | 10-spd, assmbld | \$499.99   | \$534.99     |
| 112       | 12-spd, assmbld | \$549.00   | \$587.43     |
| 113       | 18-spd, assmbld | \$685.90   | \$733.91     |
| 203       | irons/wedge     | \$670.00   | \$716.90     |

The following query calculates a surcharge of \$6.50 on orders when the quantity ordered is less than 5.

Figure 105. Query

```
SELECT item_num, order_num, quantity,
       total_price, total_price + 6.50
FROM items
WHERE quantity < 5;
```

The result appears in the **expression** column.

Figure 106. Query result

| item_num | order_num | quantity | total_price | (expression) |
|----------|-----------|----------|-------------|--------------|
| 1        | 1001      | 1        | \$250.00    | \$256.50     |
| 1        | 1002      | 1        | \$960.00    | \$966.50     |
| 2        | 1002      | 1        | \$240.00    | \$246.50     |
| 1        | 1003      | 1        | \$20.00     | \$26.50      |
| 2        | 1003      | 1        | \$840.00    | \$846.50     |
| 1        | 1004      | 1        | \$250.00    | \$256.50     |
| 2        | 1004      | 1        | \$126.00    | \$132.50     |
| 3        | 1004      | 1        | \$240.00    | \$246.50     |
| 4        | 1004      | 1        | \$800.00    | \$806.50     |
| 1        | 1023      | 2        | \$40.00     | \$46.50      |
| 2        | 1023      | 2        | \$116.00    | \$122.50     |
| 3        | 1023      | 1        | \$80.00     | \$86.50      |
| 4        | 1023      | 1        | \$228.00    | \$234.50     |
| 5        | 1023      | 1        | \$170.00    | \$176.50     |
| 6        | 1023      | 1        | \$190.00    | \$196.50     |

The following query calculates and displays in the **expression** column the interval between when the customer call was received (**call\_dtime**) and when the call was resolved (**res\_dtime**), in days, hours, and minutes.

Figure 107. Query

```
SELECT customer_num, call_code, call_dtime,
       res_dtime - call_dtime
FROM cust_calls
ORDER BY customer_num;
```

Figure 108. Query result

| customer_num | call_code | call_dtime       | (expression) |
|--------------|-----------|------------------|--------------|
| 106          | D         | 1998-06-12 08:20 | 0 00:05      |
| 110          | L         | 1998-07-07 10:24 | 0 00:06      |
| 116          | I         | 1997-11-28 13:34 | 0 03:13      |
| 116          | I         | 1997-12-21 11:24 | 5 20:55      |
| 119          | B         | 1998-07-01 15:00 | 0 17:21      |
| 121          | O         | 1998-07-10 14:05 | 0 00:01      |
| 127          | I         | 1998-07-31 14:30 |              |

## Display labels

You can assign a *display label* to a computed or derived data column to replace the default column header **expression**. In [Figure 103: Query on page 1804](#), [Figure 105: Query on page 1804](#), and [Figure 109: Query on page 1806](#), the derived data appears in the **expression** column. The following query also presents derived values, but the column that displays the derived values has the descriptive header **taxed**.

Figure 109. Query

```
SELECT stock_num, description, unit_price,
       unit_price * 1.07 taxed
FROM stock
WHERE unit_price >= 400;
```

The result shows that the label **taxed** is assigned to the expression in the projection list that displays the results of the operation `unit_price * 1.07`.

Figure 110. Query result

| stock_num | description     | unit_price | taxed     |
|-----------|-----------------|------------|-----------|
| 1         | baseball gloves | \$800.00   | \$856.00  |
| 1         | baseball gloves | \$450.00   | \$481.50  |
| 4         | football        | \$960.00   | \$1027.20 |
| 4         | football        | \$480.00   | \$513.60  |
| 7         | basketball      | \$600.00   | \$642.00  |
| 8         | volleyball      | \$840.00   | \$898.80  |
| 102       | bicycle brakes  | \$480.00   | \$513.60  |
| 111       | 10-spd, assmbld | \$499.99   | \$534.99  |
| 112       | 12-spd, assmbld | \$549.00   | \$587.43  |
| 113       | 18-spd, assmbld | \$685.90   | \$733.91  |
| 203       | irons/wedge     | \$670.00   | \$716.90  |

In the following query, the label **surcharge** is defined for the column that displays the results of the operation `total_price + 6.50`.

Figure 111. Query

```
SELECT item_num, order_num, quantity,
       total_price, total_price + 6.50 surcharge
FROM items
WHERE quantity < 5;
```

The **surcharge** column is labeled in the output.

Figure 112. Query result

| item_num | order_num | quantity | total_price | surcharge |
|----------|-----------|----------|-------------|-----------|
| 1        | 1001      | 1        | \$250.00    | \$256.50  |
| 1        | 1002      | 1        | \$960.00    | \$966.50  |
| 2        | 1002      | 1        | \$240.00    | \$246.50  |
| 1        | 1003      | 1        | \$20.00     | \$26.50   |
| 2        | 1003      | 1        | \$840.00    | \$846.50  |
| 1        | 1023      | 2        | \$40.00     | \$46.50   |
| 2        | 1023      | 2        | \$116.00    | \$122.50  |
| 3        | 1023      | 1        | \$80.00     | \$86.50   |
| 4        | 1023      | 1        | \$228.00    | \$234.50  |
| 5        | 1023      | 1        | \$170.00    | \$176.50  |
| 6        | 1023      | 1        | \$190.00    | \$196.50  |

The following query assigns the label **span** to the column that displays the results of subtracting the DATETIME column `call_dtime` from the DATETIME column `res_dtime`.

Figure 113. Query

```
SELECT customer_num, call_code, call_dtime,
       res_dtime - call_dtime span
FROM cust_calls
ORDER BY customer_num;
```

The **span** column is labeled in the output.

Figure 114. Query result

| customer_num | call_code | call_dtime       | span    |
|--------------|-----------|------------------|---------|
| 106          | D         | 1998-06-12 08:20 | 0 00:05 |
| 110          | L         | 1998-07-07 10:24 | 0 00:06 |
| 116          | I         | 1997-11-28 13:34 | 0 03:13 |
| 116          | I         | 1997-12-21 11:24 | 5 20:55 |
| 119          | B         | 1998-07-01 15:00 | 0 17:21 |
| 121          | O         | 1998-07-10 14:05 | 0 00:01 |
| 127          | I         | 1998-07-31 14:30 |         |

## CASE expressions

A CASE expression is a conditional expression, which is similar to the concept of the CASE statement in programming languages. You can use a CASE expression when you want to change the way data is represented. The CASE expression allows a statement to return one of several possible results, depending on which of several condition tests evaluates to TRUE.

TEXT or BYTE values are not allowed in a CASE expression.

Consider a column that represents marital status numerically as 1, 2, 3, 4 with the corresponding values meaning single, married, divorced, widowed. In some cases, you might prefer to store the short values (1, 2, 3, 4) for database efficiency, but employees in human resources might prefer the more descriptive values (single, married, divorced, widowed). The CASE expression makes such conversions between different sets of values easy.

In , the CASE expression also supports extended data types and cast expressions.

The following example shows a CASE expression with multiple WHEN clauses that returns more descriptive values for the **manu\_code** column of the **stock** table. If none of the WHEN conditions is true, NULL is the default result. (You can omit the ELSE NULL clause.)

```
SELECT
  CASE
    WHEN manu_code = "HRO" THEN "Hero"
    WHEN manu_code = "SHM" THEN "Shimara"
    WHEN manu_code = "PRC" THEN "ProCycle"
    WHEN manu_code = "ANZ" THEN "Anza"
    ELSE NULL
  END
FROM stock;
```

You must include at least one WHEN clause within the CASE expression; subsequent WHEN clauses and the ELSE clause are optional. If no WHEN condition evaluates to true, the resulting value is NULL. You can use the IS NULL expression to handle NULL results. For information on handling NULL values, see the *Informix® Guide to SQL: Syntax*.

The following query shows a simple CASE expression that returns a character string value to flag any orders from the **orders** table that have not been shipped to the customer.

Figure 115. Query

```
SELECT order_num, order_date,
       CASE
         WHEN ship_date IS NULL
          THEN "order not shipped"
        END
FROM orders;
```

Figure 116. Query result

```
order_num order_date (expression)

1001 05/20/1998
1002 05/21/1998
1003 05/22/1998
1004 05/22/1998
1005 05/24/1998
1006 05/30/1998 order not shipped
1007 05/31/1998

1019 07/11/1998
1020 07/11/1998
1021 07/23/1998
1022 07/24/1998
1023 07/24/1998
```

For information about how to use the CASE expression to update a column, see [CASE expression to update a column on page 1920](#).

## Sorting on derived columns

When you want to use ORDER BY on an expression, you can use either the display label assigned to the expression or an integer, as [Figure 117: Query on page 1808](#) and [Figure 119: Query on page 1809](#) show.

Figure 117. Query

```
SELECT customer_num, call_code, call_dtime,
       res_dtime - call_dtime span
FROM cust_calls
ORDER BY span;
```

The query retrieves the same data from the **cust\_calls** table as [Figure 113: Query on page 1807](#). In the query, the ORDER BY clause causes the data to be displayed in ascending order of the derived values in the **span** column, as the result shows.

Figure 118. Query result

| customer_num | call_code | call_dtime       | span    |
|--------------|-----------|------------------|---------|
| 127          | I         | 1998-07-31 14:30 |         |
| 121          | O         | 1998-07-10 14:05 | 0 00:01 |
| 106          | D         | 1998-06-12 08:20 | 0 00:05 |
| 110          | L         | 1998-07-07 10:24 | 0 00:06 |
| 116          | I         | 1997-11-28 13:34 | 0 03:13 |
| 119          | B         | 1998-07-01 15:00 | 0 17:21 |
| 116          | I         | 1997-12-21 11:24 | 5 20:55 |

The following query uses an integer to represent the result of the operation `res_dtime - call_dtime` and retrieves the same rows that appear in the above result.

Figure 119. Query

```
SELECT customer_num, call_code, call_dtime,
       res_dtime - call_dtime span
FROM cust_calls
ORDER BY 4;
```

## Rowid values in SELECT statements

The database server assigns a unique *rowid* to rows in nonfragmented tables. The *rowid* is, in effect, a hidden column in every table. The sequential values of *rowid* have no special significance and can vary depending on the location of the physical data in the chunk. You can use a *rowid* to locate the internal record number that is associated with a row in a table. Rows in fragmented tables do not automatically contain the *rowid* column.

It is recommended that you use primary keys as a method of access in your applications rather than *rowids*. Because primary keys are defined in the ANSI specification of SQL, using them to access data makes your applications more portable. In addition, the database server requires less time to access data in a fragmented table when it uses a primary key than it requires to access the same data when it uses *rowid*.

For more information about *rowids*, see the *Informix® Database Design and Implementation Guide* and your *Informix® Administrator's Guide*.

The following query uses the *rowid* and the wildcard asterisk symbol (\*) in the Projection clause to retrieve each row in the **manufact** table and its corresponding *rowid*.

Figure 120. Query

```
SELECT rowid, * FROM manufact;
```

Figure 121. Query result

| rowid | manu_code | manu_name | lead_time |
|-------|-----------|-----------|-----------|
| 257   | SMT       | Smith     | 3         |
| 258   | ANZ       | Anza      | 5         |
| 259   | NRG       | Norge     | 7         |
| 260   | HSK       | Husky     | 5         |
| 261   | HRO       | Hero      | 4         |
| 262   | SHM       | Shimara   | 30        |
| 263   | KAR       | Karsten   | 21        |
| 264   | NKL       | Nikolus   | 8         |
| 265   | PRC       | ProCycle  | 9         |

Never store a rowid in a permanent table or attempt to use it as a foreign key. If a table is dropped and then reloaded from external data, all the rowids will be different.

## Multiple-table SELECT statements

To select data from two or more tables, specify the table names in the FROM clause. Add a WHERE clause to create a join condition between at least one related column in each table. This WHERE clause creates a temporary composite table in which each pair of rows that satisfies the join condition is linked to form a single row.

A *simple join* combines information from two or more tables based on the relationship between one column in each table. A *composite join* is a join between two or more tables based on the relationship between two or more columns in each table.

To create a join, you must specify a relationship, called a *join condition*, between at least one column from each table. Because the columns are being compared, they must have compatible data types. When you join large tables, performance improves when you index the columns in the join condition.

Data types are described in the *Informix® Guide to SQL: Reference* and the *Informix® Database Design and Implementation Guide*. Indexing is discussed in detail in the *Informix® Administrator's Guide*.

## Create a Cartesian product

When you perform a multiple-table query that does not explicitly state a join condition among the tables, you create a *Cartesian product*. A Cartesian product consists of every possible combination of rows from the tables. This result is usually large and unwieldy.

The following query selects from two tables and produces a Cartesian product.

Figure 122. Query

```
SELECT * FROM customer, state;
```

Although only 52 rows exist in the **state** table and 28 rows in the **customer** table, the effect of the query is to multiply the rows of one table by the rows of the other and retrieve an impractical 1,456 rows, as the result shows.

Figure 123. Query result

```

customer_num 101
fname       Ludwig
lname       Pauli
company      All Sports Supplies
address1     213 Erswild Court
address2
city         Sunnyvale
state        CA
zipcode      94086
phone        408-789-8075
code         AK
sname        Alaska

customer_num 101
fname       Ludwig
lname       Pauli
company      All Sports Supplies
address1     213 Erswild Court
address2
city         Sunnyvale
state        CA
zipcode      94086
phone        408-789-8075
code         HI
sname        Hawaii

customer_num 101
fname       Ludwig
lname       Pauli
company      All Sports Supplies
address1     213 Erswild Court
address2
city         Sunnyvale
state        CA
zipcode      94086
phone        408-789-8075
code         CA
sname        California
:

```

In addition, some of the data that is displayed in the concatenated rows is contradictory. For example, although the **city** and **state** from the **customer** table indicate an address in California, the **code** and **sname** from the **state** table might be for a different state.

## Create a join

Conceptually, the first stage of any join is the creation of a Cartesian product. To refine or constrain this Cartesian product and eliminate meaningless combinations of rows of data, include a **WHERE** clause with a valid join condition in your **SELECT** statement.

This section illustrates *cross joins*, *equi-joins*, *natural joins*, and *multiple-table joins*. Additional complex forms, such as *self-joins* and *outer joins*, are discussed in [Compose advanced SELECT statements on page 1862](#).

## Cross join

A *cross join* combines all rows in all tables selected and creates a Cartesian product. The results of a cross join can be very large and difficult to manage.

The following query uses ANSI join syntax to create a cross join.

Figure 124. Query

```
SELECT * FROM customer CROSS JOIN state;
```

The results of the query are identical to the results of [Figure 122: Query on page 1810](#). In addition, you can filter a cross join by specifying a WHERE clause.

For more information about Cartesian products, see [Create a Cartesian product on page 1810](#). For more information about ANSI syntax, see [ANSI join syntax on page 1872](#).

## Equi-join

An *equi-join* is a join based on equality or matching column values. This equality is indicated with an equal sign (=) as the comparison operator in the WHERE clause, as the following query shows.

Figure 125. Query

```
SELECT * FROM manufact, stock
WHERE manufact.manu_code = stock.manu_code;
```

The query joins the **manufact** and **stock** tables on the **manu\_code** column. It retrieves only those rows for which the values of the two columns are equal, some of which the result shows.

Figure 126. Query result

```

manu_code    SMT
manu_name    Smith
lead_time    3
stock_num    1
manu_code    SMT
description  baseball gloves
unit_price   $450.00
unit         case
unit_descr   10 gloves/case

manu_code    SMT
manu_name    Smith
lead_time    3
stock_num    5
manu_code    SMT
description  tennis racquet
unit_price   $25.00
unit         each
unit_descr   each

manu_code    SMT
manu_name    Smith
lead_time    3
stock_num    6
manu_code    SMT
description  tennis ball
unit_price   $36.00
unit         case
unit_descr   24 cans/case

manu_code    ANZ
manu_name    Anza
lead_time    5
stock_num    5
manu_code    ANZ
description  tennis racquet
unit_price   $19.80
unit         each
unit_descr   each
:
```

In this equi-join, the result includes the **manu\_code** column from both the **manufact** and **stock** tables because the select list requested every column.

You can also create an equi-join with additional constraints, where the comparison condition is based on the inequality of values in the joined columns. These joins use a relational operator in addition to the equal sign (=) in the comparison condition that is specified in the WHERE clause.

To join tables that contain columns with the same name, qualify each column name with the name of its table and a period (.), as the following query shows.

Figure 127. Query

```
SELECT order_num, order_date, ship_date, cust_calls.*
FROM orders, cust_calls
WHERE call_dtime >= ship_date
AND cust_calls.customer_num = orders.customer_num
ORDER BY orders.customer_num;
```

The query joins the **customer\_num** column and then selects only those rows where the **call\_dtime** in the **cust\_calls** table is greater than or equal to the **ship\_date** in the **orders** table. The result shows the combined rows that it returns.

Figure 128. Query result

```
order_num      1004
order_date     05/22/1998
ship_date      05/30/1998
customer_num   106
call_dtime     1998-06-12 08:20
user_id        maryj
call_code      D
call_descr     Order received okay, but two of the cans of
                ANZ tennis balls within the case were empty
res_dtime      1998-06-12 08:25
res_descr      Authorized credit for two cans to customer,
                issued apology. Called ANZ buyer to report
                the qa problem.

order_num      1008
order_date     06/07/1998
ship_date      07/06/1998
customer_num   110
call_dtime     1998-07-07 10:24
user_id        richc
call_code      L
call_descr     Order placed one month ago (6/7) not received.
res_dtime      1998-07-07 10:30
res_descr      Checked with shipping (Ed Smith). Order out
                yesterday-was waiting for goods from ANZ.
                Next time will call with delay if necessary.

order_num      1023
order_date     07/24/1998
ship_date      07/30/1998
customer_num   127
call_dtime     1998-07-31 14:30
user_id        maryj
call_code      I
call_descr     Received Hero watches (item # 304) instead
                of ANZ watches
res_dtime
res_descr      Sent memo to shipping to send ANZ item 304
                to customer and pickup HRO watches. Should
                be done tomorrow, 8/1
```

## Natural join

A *natural join* is a type of equi-join and is structured so that the join column does not display data redundantly, as the following query shows.

Figure 129. Query

```
SELECT manu_name, lead_time, stock.*
   FROM manufact, stock
  WHERE manufact.manu_code = stock.manu_code;
```

Like the example for equi-join, the query joins the **manufact** and **stock** tables on the **manu\_code** column. Because the Projection list is more closely defined, the **manu\_code** is listed only once for each row retrieved, as the result shows.

Figure 130. Query result

```
manu_name    Smith
lead_time     3
stock_num     1
manu_code     SMT
description   baseball gloves
unit_price    $450.00
unit          case
unit_descr    10 gloves/case

manu_name    Smith
lead_time     3
stock_num     5
manu_code     SMT
description   tennis racquet
unit_price    $25.00
unit          each
unit_descr    each

manu_name    Smith
lead_time     3
stock_num     6
manu_code     SMT
description   tennis ball
unit_price    $36.00
unit          case
unit_descr    24 cans/case

manu_name    Anza
lead_time     5
stock_num     5
manu_code     ANZ
description   tennis racquet
unit_price    $19.80
unit          each
unit_descr    each
```

All joins are *associative*; that is, the order of the joining terms in the WHERE clause does not affect the meaning of the join.

Both statements in the following query create the same natural join.

Figure 131. Query

```

SELECT catalog.*, description, unit_price, unit, unit_descr
  FROM catalog, stock
 WHERE catalog.stock_num = stock.stock_num
       AND catalog.manu_code = stock.manu_code
       AND catalog_num = 10017;

SELECT catalog.*, description, unit_price, unit, unit_descr
  FROM catalog, stock
 WHERE catalog_num = 10017
       AND catalog.manu_code = stock.manu_code
       AND catalog.stock_num = stock.stock_num;

```

Each statement retrieves the following row.

Figure 132. Query result

```

catalog_num  10017
stock_num    101
manu_code    PRC
cat_descr
Reinforced, hand-finished tubular. Polyurethane belted.
Effective against punctures. Mixed tread for super wear
and road grip.
cat_picture  <BYTE value>

cat_advert   Ultimate in Puncture Protection, Tires
            Designed for In-City Riding
description  bicycle tires
unit_price   $88.00
unit         box
unit_descr   4/box

```

Figure 131: Query on page 1816 includes a TEXT column, **cat\_descr**; a BYTE column, **cat\_picture**; and a VARCHAR column, **cat\_advert**.

## Multiple-table join

A *multiple-table join* connects more than two tables on one or more associated columns; it can be an equi-join or a natural join.

The following query creates an equi-join on the **catalog**, **stock**, and **manufact** tables.

Figure 133. Query

```

SELECT * FROM catalog, stock, manufact
 WHERE catalog.stock_num = stock.stock_num
       AND stock.manu_code = manufact.manu_code
       AND catalog_num = 10025;

```

The query retrieves the following rows.

Figure 134. Query result

```

catalog_num  10025
stock_num    106
manu_code    PRC
cat_descr
Hard anodized alloy with pearl finish; 6mm hex bolt hard ware.
Available in lengths of 90-140mm in 10mm increments.
cat_picture  <BYTE value>

cat_advert   ProCycle Stem with Pearl Finish
stock_num    106
manu_code    PRC
description  bicycle stem
unit_price   $23.00
unit         each
unit_descr   each
manu_code    PRC
manu_name    ProCycle
lead_time    9

```

The **manu\_code** is repeated three times, once for each table, and **stock\_num** is repeated twice.

To avoid the considerable duplication of a multiple-table query such as [Figure 133: Query on page 1816](#), include specific columns in the projection list to define the SELECT statement more closely, as the following query shows.

Figure 135. Query

```

SELECT catalog.*, description, unit_price, unit,
       unit_descr, manu_name, lead_time
FROM catalog, stock, manufact
WHERE catalog.stock_num = stock.stock_num
      AND stock.manu_code = manufact.manu_code
      AND catalog_num = 10025;

```

The query uses a wildcard to select all columns from the table with the most columns and then specifies columns from the other two tables. The result shows the natural join that the query produces. It displays the same information as the previous example, but without duplication.

Figure 136. Query result

```

catalog_num  10025
stock_num    106
manu_code    PRC
cat_descr
Hard anodized alloy with pearl finish. 6mm hex bolt
hardware. Available in lengths of 90-140mm in 10mm increments.
cat_picture  <BYTE value>

cat_advert   ProCycle Stem with Pearl Finish
description  bicycle stem
unit_price   $23.00
unit         each
unit_descr   each
manu_name    ProCycle
lead_time    9

```

## Some query shortcuts

You can use aliases, the INTO TEMP clause, and display labels to speed your way through joins and multiple-table queries and to produce output for other uses.

### Aliases

You can assign aliases to the tables in the FROM clause of a SELECT statement to make multiple-table queries shorter and more readable. You can use an alias wherever the table name would be used, for instance, as a prefix to the column names in the other clauses.

Figure 137. Query

```
SELECT s.stock_num, s.manu_code, s.description,
       s.unit_price, c.catalog_num,
       c.cat_advert, m.lead_time
FROM stock s, catalog c, manufact m
WHERE s.stock_num = c.stock_num
      AND s.manu_code = c.manu_code
      AND s.manu_code = m.manu_code
      AND s.manu_code IN ('HRO', 'HSK')
      AND s.stock_num BETWEEN 100 AND 301
ORDER BY catalog_num;
```

The associative nature of the SELECT statement allows you to use an alias before you define it. In the query above, the aliases **s** for the **stock** table, **c** for the **catalog** table, and **m** for the **manufact** table are specified in the FROM clause and used throughout the SELECT and WHERE clauses as column prefixes.

Compare the length of [Figure 137: Query on page 1818](#) with the following query, which does not use aliases.

Figure 138. Query

```
SELECT stock.stock_num, stock.manu_code, stock.description,
       stock.unit_price, catalog.catalog_num,
       catalog.cat_advert,
       manufact.lead_time
FROM stock, catalog, manufact
WHERE stock.stock_num = catalog.stock_num
      AND stock.manu_code = catalog.manu_code
      AND stock.manu_code = manufact.manu_code
      AND stock.manu_code IN ('HRO', 'HSK')
      AND stock.stock_num BETWEEN 100 AND 301
ORDER BY catalog_num;
```

[Figure 137: Query on page 1818](#) and [Figure 138: Query on page 1818](#) are equivalent and retrieve the data that the following query shows.

Figure 139. Query result

```

stock_num    110
manu_code    HRO
description   helmet
unit_price   $260.00
catalog_num  10033
cat_advert   Lightweight Plastic with Vents Assures Cool
             Comfort Without Sacrificing Protection
lead_time    4

stock_num    110
manu_code    HSK
description   helmet
unit_price   $308.00
catalog_num  10034
cat_advert   Teardrop Design Used by Yellow Jerseys; You
             Can Time the Difference
lead_time    5

```

You cannot use the ORDER BY clause for the TEXT column **cat\_descr** or the BYTE column **cat\_picture**.

You can use aliases to shorten your queries on tables that are not in the current database.

The following query joins columns from two tables that reside in different databases and systems, neither of which is the current database or system.

Figure 140. Query

```

SELECT order_num, lname, fname, phone
FROM masterdb@central:customer c, sales@western:orders o
WHERE c.customer_num = o.customer_num
AND order_num <= 1010;

```

By assigning the aliases *c* and *o* to the long *database@system:table* names, **masterdb@central:customer** and **sales@western:orders**, respectively, you can use the aliases to shorten the expression in the WHERE clause and retrieve the data, as the result shows.

Figure 141. Query result

| order_num | lname    | fname    | phone        |
|-----------|----------|----------|--------------|
| 1001      | Higgins  | Anthony  | 415-368-1100 |
| 1002      | Pauli    | Ludwig   | 408-789-8075 |
| 1003      | Higgins  | Anthony  | 415-368-1100 |
| 1004      | Watson   | George   | 415-389-8789 |
| 1005      | Parmelee | Jean     | 415-534-8822 |
| 1006      | Lawson   | Margaret | 415-887-7235 |
| 1007      | Sipes    | Arnold   | 415-245-4578 |
| 1008      | Jaeger   | Roy      | 415-743-3611 |
| 1009      | Keyes    | Frances  | 408-277-7245 |
| 1010      | Grant    | Alfred   | 415-356-1123 |

For more information on how to access tables that are not in the current database, see [Access other database servers on page 1940](#) and the *Informix® Guide to SQL: Syntax*.

You can also use synonyms as shorthand references to the long names of tables that are not in the current database as well as current tables and views. For details on how to create and use synonyms, see the *Informix® Database Design and Implementation Guide*.

## The INTO TEMP clause

By adding an INTO TEMP clause to your SELECT statement, you can temporarily save the results of a multiple-table query in a separate table that you can query or manipulate without modifying the database. Temporary tables are dropped when you end your SQL session or when your program or report terminates.

The following query creates a temporary table called **stockman** and stores the results of the query in it. Because all columns in a temporary table must have names, the alias **adj\_price** is required.

Figure 142. Query

```
SELECT DISTINCT stock_num, manu_name, description,
               unit_price, unit_price * 1.05 adj_price
FROM stock, manufact
WHERE manufact.manu_code = stock.manu_code
INTO TEMP stockman;
SELECT * from stockman;
```

Figure 143. Query result

| stock_num | manu_name | description     | unit_price | adj_price   |
|-----------|-----------|-----------------|------------|-------------|
| 1         | Hero      | baseball gloves | \$250.00   | \$262.5000  |
| 1         | Husky     | baseball gloves | \$800.00   | \$840.0000  |
| 1         | Smith     | baseball gloves | \$450.00   | \$472.5000  |
| 2         | Hero      | baseball        | \$126.00   | \$132.3000  |
| 3         | Husky     | baseball bat    | \$240.00   | \$252.0000  |
| 4         | Hero      | football        | \$480.00   | \$504.0000  |
| 4         | Husky     | football        | \$960.00   | \$1008.0000 |
| 306       | Shimara   | tandem adapter  | \$190.00   | \$199.5000  |
| 307       | ProCycle  | infant jogger   | \$250.00   | \$262.5000  |
| 308       | ProCycle  | twin jogger     | \$280.00   | \$294.0000  |
| 309       | Hero      | ear drops       | \$40.00    | \$42.0000   |
| 309       | Shimara   | ear drops       | \$40.00    | \$42.0000   |
| 310       | Anza      | kick board      | \$84.00    | \$88.2000   |
| 310       | Shimara   | kick board      | \$80.00    | \$84.0000   |
| 311       | Shimara   | water gloves    | \$48.00    | \$50.4000   |
| 312       | Hero      | racer goggles   | \$72.00    | \$75.6000   |
| 312       | Shimara   | racer goggles   | \$96.00    | \$100.8000  |
| 313       | Anza      | swim cap        | \$60.00    | \$63.0000   |
| 313       | Shimara   | swim cap        | \$72.00    | \$75.6000   |

You can query this table and join it with other tables, which avoids a multiple sort and lets you move more quickly through the database. For more information on temporary tables, see the *Informix® Guide to SQL: Syntax* and the *Informix® Administrator's Guide*.

## Summary

This chapter presented syntax examples and results for basic kinds of SELECT statements that are used to query a relational database. The section [Single-table SELECT statements on page 1779](#) shows how to perform the following actions:

- Select columns and rows from a table with the Projection and FROM clauses
- Select rows from a table with the Projection, FROM, and WHERE clauses
- Use the DISTINCT or UNIQUE keyword in the Projection clause to eliminate duplicate rows from query results
- Sort retrieved data with the ORDER BY clause and the DESC keyword
- Select and order data values that contain non-English characters
- Use the BETWEEN, IN, MATCHES, and LIKE keywords and various relational operators in the WHERE clause to create comparison conditions
- Create comparison conditions that include values, exclude values, find a range of values (with keywords, relational operators, and subscripting), and find a subset of values
- Use exact-text comparisons, variable-length wildcards, and restricted and unrestricted wildcards to perform variable text searches
- Use the logical operators AND, OR, and NOT to connect search conditions or Boolean expressions in a WHERE clause
- Use the ESCAPE keyword to protect special characters in a query
- Search for NULL values with the IS NULL and IS NOT NULL keywords in the WHERE clause
- Use the FIRST clause to specify that a query returns only a specified number of the rows that match the conditions of the SELECT statement
- Use arithmetic operators in the Projection clause to perform computations on number fields and display derived data
- Assign display labels to computed columns as a formatting tool for reports

This chapter also introduced simple join conditions that enable you to select and display data from two or more tables. The section [Multiple-table SELECT statements on page 1810](#) describes how to perform the following actions:

- Create a Cartesian product
- Create a CROSS JOIN, which creates a Cartesian product
- Include a WHERE clause with a valid join condition in your query to constrain a Cartesian product
- Define and create a natural join and an equi-join
- Join two or more tables on one or more columns
- Use aliases as a shortcut in multiple-table queries
- Retrieve selected data into a separate, temporary table with the INTO TEMP clause to perform computations outside the database

## Select data from complex types

This chapter describes how to query *complex data types*. A complex data type is built from a combination of other data types with an SQL type constructor. An SQL statement can access individual components within the complex type. Complex data types are *row types* or *collection types*.

*ROW types* have instances that combine one or more related data fields. The two kinds of ROW types are *named* and *unnamed*.

*Collection types* have instances where each collection value contains a group of elements of the same data type, which can be any fundamental or complex data type. A collection can consist of a LIST, SET, or MULTISSET datatype.

 **Important:** There is no cross-database support for complex data types. They can only be manipulated in local databases.

For a more complete description of the data types that the database server supports, see the chapter on data types in the *Informix® Guide to SQL: Reference*.

For information about how to create and use complex types, see the *Informix® Database Design and Implementation Guide*, *Informix® Guide to SQL: Reference*, and *Informix® Guide to SQL: Syntax*.

## Select row-type data

This section describes how to query data that is defined as row-type data. A ROW type is a complex type that combines one or more related data fields.

The two kinds of ROW types are as follows:

### Named ROW type

A named ROW type can define tables, columns, fields of another row-type column, program variables, statement local variables, and routine return values.

### Unnamed ROW type

An unnamed ROW type can define columns, fields of another row-type column, program variables, statement local variables, routine return values, and constants.

The examples used throughout this section use the named ROW types **zip\_t**, **address\_t**, and **employee\_t**, which define the **employee** table. The following figure shows the SQL syntax that creates the ROW types and table.

Figure 144. SQL syntax that creates the ROW types and table.

```

CREATE ROW TYPE zip_t
(
  z_code    CHAR(5),
  z_suffix  CHAR(4)
)

CREATE ROW TYPE address_t
(
  street    VARCHAR(20),
  city      VARCHAR(20),
  state     CHAR(2),
  zip       zip_t
)

CREATE ROW TYPE employee_t
(
  name      VARCHAR(30),
  address   address_t,
  salary    INTEGER
)

CREATE TABLE employee OF TYPE employee_t

```

The named ROW types **zip\_t**, **address\_t** and **employee\_t** serve as templates for the fields and columns of the typed table, **employee**. A *typed table* is a table that is defined on a named ROW type. The **employee\_t** type that serves as the template for the **employee** table uses the **address\_t** type as the data type of the **address** field. The **address\_t** type uses the **zip\_t** type as the data type of the **zip** field.

The following figure shows the SQL syntax that creates the **student** table. The **s\_address** column of the **student** table is defined on an unnamed ROW type. (The **s\_address** column could also have been defined as a named ROW type.)

Figure 145. SQL syntax that creates the student table.

```

CREATE TABLE student
(
  s_name     VARCHAR(30),
  s_address  ROW(street VARCHAR(20), city VARCHAR(20),
                state CHAR(2), zip VARCHAR(9)),
  grade_point_avg DECIMAL(3,2)
)

```

## Select columns of a typed table

A query on a typed table is no different from a query on any other table. For example, the following query uses the asterisk (\*) to specify a SELECT statement that returns all columns of the **employee** table.

Figure 146. Query

```
SELECT * FROM employee
```

The SELECT statement on the **employee** table returns all rows for all columns.

Figure 147. Query result

```

name      Paul, J.
address   ROW(102 Ruby, Belmont, CA, 49932, 1000)
salary    78000

name      Davis, J.
address   ROW(133 First, San Jose, CA, 85744, 4900)
salary    75000
:
```

The following query shows how to construct a query that returns rows for the **name** and **address** columns of the **employee** table.

Figure 148. Query

```
SELECT name, address FROM employee
```

Figure 149. Query result

```

name      Paul, J.
address   ROW(102 Ruby, Belmont, CA, 49932, 1000)

name      Davis, J.
address   ROW(133 First, San Jose, CA, 85744, 4900)
:
```

## Select columns that contain row-type data

A *row-type column* is a column that is defined on a named ROW type or unnamed ROW type. You use the same SQL syntax to query a named ROW type and an unnamed row-type column.

A query on a row-type column returns data from all the fields of the ROW type. A *field* is a component data type within a ROW type. For example, the **address** column of the **employee** table contains the **street**, **city**, **state**, and **zip** fields. The following query shows how to construct a query that returns all fields of the **address** column.

Figure 150. Query

```
SELECT address FROM employee
```

Figure 151. Query result

```

address   ROW(102 Ruby, Belmont, CA, 49932, 1000)
address   ROW(133 First, San Jose, CA, 85744, 4900)
address   ROW(152 Topaz, Willits, CA, 69445, 1000)
```

To access individual fields that a column contains, use single-dot notation to project the individual fields of the column. For example, suppose you want to access specific fields from the **address** column of the **employee** table. The following SELECT statement projects the **city** and **state** fields from the **address** column.

Figure 152. Query

```
SELECT address.city, address.state FROM employee
```

Figure 153. Query result

| city     | state |
|----------|-------|
| Belmont  | CA    |
| San Jose | CA    |
| Willits  | CA    |

You construct a query on an unnamed row-type column in the same way you construct a query on a named row-type column. For example, suppose you want to access data from the **s\_address** column of the **student** table in [Figure 145: SQL syntax that creates the student table. on page 1823](#). You can use *dot notation* to query the individual fields of a column that are defined on an unnamed row type. The following query shows how to construct a SELECT statement on the **student** table that returns rows for the **city** and **state** fields of the **s\_address** column.

Figure 154. Query

```
SELECT s_address.city, s_address.state FROM student
```

Figure 155. Query result

| city           | state |
|----------------|-------|
| Belmont        | CA    |
| Mount Prospect | IL    |
| Greeley        | CO    |

## Field projections

Do not confuse fields with columns. Columns are only associated with tables, and column projections use conventional dot notation of the form `name_1.name2` for a table and column, respectively. A *field* is a component data type within a ROW type. With ROW types (and the capability to assign a ROW type to a single column), you can project individual fields of a column with single dot notation of the form: `name_a.name_b.name_c.name_d`. Informix® database servers use the following precedence rules to interpret dot notation:

1. table\_name\_a . column\_name\_b . field\_name\_c . field\_name\_d
2. column\_name\_a . field\_name\_b . field\_name\_c . field\_name\_d

When the meaning of a particular identifier is ambiguous, the database server uses precedence rules to determine which database object the identifier specifies. Consider the following two statements:

```
CREATE TABLE b (c ROW(d INTEGER, e CHAR(2)))
CREATE TABLE c (d INTEGER)
```

In the following SELECT statement, the expression `c.d` references column **d** of table **c** (rather than field **d** of column **c** in table **b**) because a table identifier has a higher precedence than a column identifier:

```
SELECT * FROM b,c WHERE c.d = 10
```

To avoid referencing the wrong database object, you can specify the full notation for a field projection. Suppose, for example, you want to reference field **d** of column **c** in table **b** (not column **d** of table **c**). The following statement specifies the table, column, and field identifiers of the object you want to reference:

```
SELECT * FROM b,c WHERE b.c.d = 10
```

**Important:** Although precedence rules reduce the chance of the database server misinterpreting field projections, it is recommended that you use unique names for all table, column, and field identifiers.

## Field projections to select nested fields

Typically the row type is a column, but you can use any row-type expression for field projection. When the row-type expression itself contains other row types, the expression contains nested fields. To access nested fields within an expression or individual fields, use dot notation. To access all the fields of the row type, use an asterisk (\*). This section describes both methods of row-type access.

For a discussion of how to use dot notation and asterisk notation with row-type expressions, see the Expression segment in the *Informix® Guide to SQL: Syntax*.

## Select individual fields of a row type

Consider the **address** column of the **employee** table, which contains the fields **street**, **city**, **state**, and **zip**. In addition, the **zip** field contains the nested fields: **z\_code** and **z\_suffix**. (You might want to review the row type and table definitions of [Figure 144: SQL syntax that creates the ROW types and table. on page 1823.](#)) A query on the **zip** field returns rows for the **z\_code** and **z\_suffix** fields. However, you can specify that a query returns only specific nested fields. The following query shows how to use dot notation to construct a SELECT statement that returns rows for the **z\_code** field of the **address** column only.

Figure 156. Query

```
SELECT address.zip.z_code FROM employee
```

Figure 157. Query result

```
z_code
39444
6500
76055
19004
:
```

## Asterisk notation to access all fields of a row type

Asterisk notation is supported only within the select list of a SELECT statement. When you specify the column name for a row-type column in a projection list, the database server returns values for all fields of the column. You can also use asterisk notation when you want to project all the fields within a ROW type.

The following query uses asterisk notation to return all fields of the **address** column in the **employee** table.

Figure 158. Query

```
SELECT address.* FROM employee;
```

Figure 159. Query result

```
address  ROW(102 Ruby, Belmont, CA, 49932, 1000)
address  ROW(133 First, San Jose, CA, 85744, 4900)
address  ROW(152 Topaz, Willits, CA, 69445, 1000)
:
```

The asterisk notation makes it easier to perform some SQL tasks. Suppose you create a function `new_row()` that returns a row-type value and you want to call this function and insert the row that is returned into a table. The database server provides no easy way to handle such operations. However, the following query shows how to use asterisk notation to return all fields of `new_row()` and insert the returned fields into the **tab\_2** table.

Figure 160. Query

```
INSERT INTO tab_2 SELECT new_row(exp).* FROM tab_1
```

For information about how to use the `INSERT` statement, see [Modify data on page 1901](#).

**Important:** An expression that uses the `.*` notation is evaluated only once.

## Select from a collection

This section describes how to query columns that are defined on collection types. A *collection type* is a complex data type in which each collection value contains a group of elements of the same data type. For a detailed description of collection data types, see the *Informix® Database Design and Implementation Guide*. For information about how to access the individual elements that a collection contains, see [Handle collections in SELECT statements on page 1888](#).

The following figure shows the **manager** table, which is used in examples throughout this section. The **manager** table contains both simple and nested collection types. A *simple collection* is a collection type that does not contain any fields that are themselves collection types. The **direct\_reports** column of the **manager** table is a simple collection. A *nested collection* is a collection type that contains another collection type. The **projects** column of the **manager** table is a nested collection.

Figure 161. The manager table

```
CREATE TABLE manager
(
  mgr_name      VARCHAR(30),
  department    VARCHAR(12),
  direct_reports SET(VARCHAR(30) NOT NULL),
  projects      LIST(ROW(pro_name VARCHAR(15),
                        pro_members SET(VARCHAR(20) NOT NULL)
                        ) NOT NULL)
)
```

A query on a column that is a collection type returns, for each row in the table, all the elements that the particular collection contains. For example, the following query shows a query that returns data in the **department** column and all elements in the **direct\_reports** column for each row of the **manager** table.

Figure 162. Query

```
SELECT department, direct_reports FROM manager
```

Figure 163. Query result

```
department      marketing
direct_reports  SET {Smith, Waters, Adams, Davis, Kurasawa}

department      engineering
direct_reports  SET {Joshi, Davis, Smith, Waters, Fosmire, Evans, Jones}

department      publications
direct_reports  SET {Walker, Fremont, Porat, Johnson}

department      accounting
direct_reports  SET {Baker, Freeman, Jacobs}
```

The output of a query on a collection type always includes the type constructor that specifies whether the collection is a SET, MULTiset, or LIST. For example, in the result, the SET constructor precedes the elements of each collection. Braces ({} ) demarcate the elements of a collection; commas separate individual elements of a collection.

## Select nested collections

The **projects** column of the **manager** table (see [Figure 161: The manager table on page 1827](#)) is a nested collection. A query on a nested collection type returns all the elements that the particular collection contains. The following query shows a query that returns all elements from the **projects** column for a specified row. The WHERE clause limits the query to a single row in which the value in the **mgr\_name** column is `Sayles`.

Figure 164. Query

```
SELECT projects
FROM manager
WHERE mgr_name = 'Sayles'
```

The query result shows a **project** column collection for a single row of the **manager** table. The query returns the names of those projects that the manager `Sayles` oversees. The collection contains, for each element in the LIST, the project name (**pro\_name**) and the SET of individuals (**pro\_members**) who are assigned to each project.

Figure 165. Query result

```
projects LIST {ROW(voyager_project, SET{Simonian, Waters, Adams, Davis})}

projects LIST {ROW(horizon_project, SET{Freeman, Jacobs, Walker, Cannan})}

projects LIST {ROW(sapphire_project, SET{Villers, Reeves, Doyle, Strongin})}
:
```

## The IN keyword to search for elements in a collection

You can use the IN keyword in the WHERE clause of an SQL statement to determine whether a collection contains a certain element. For example, the following query shows how to construct a query that returns values for **mgr\_name** and **department** where `Adams` is an element of a collection in the **direct\_reports** column.

Figure 166. Query

```
SELECT mgr_name, department
FROM manager
WHERE 'Adams' IN direct_reports
```

Figure 167. Query result

|            |           |
|------------|-----------|
| mgr_name   | Sayles    |
| department | marketing |

Although you can use a WHERE clause with the IN keyword to search for a particular element in a simple collection, the query always returns the complete collection. For example, the following query returns all the elements of the collection where `Adams` is an element of a collection in the **direct\_reports** column.

Figure 168. Query

```
SELECT mgr_name, direct_reports
FROM manager
WHERE 'Adams' IN direct_reports
```

Figure 169. Query result

|                |   |
|----------------|---|
| mgr_name       | Sayles                                      |
| direct_reports | SET {Smith, Waters, Adams, Davis, Kurasawa} |

As the result shows, a query on a collection column returns the entire collection, not a particular element within the collection.

You can use the IN keyword in a WHERE clause to reference a simple collection only. You cannot use the IN keyword to reference a collection that contains fields that are themselves collections. For example, you cannot use the IN keyword to reference the **projects** column in the **manager** table because **projects** is a nested collection.

You can combine the NOT and IN keywords in the WHERE clause of a SELECT statement to search for collections that do not contain a certain element. For example, the following query shows a query that returns values for **mgr\_name** and **department** where `Adams` is not an element of a collection in the **direct\_reports** column.

Figure 170. Query

```
SELECT mgr_name, department
FROM manager
WHERE 'Adams' NOT IN direct_reports
```

Figure 171. Query result

|            |              |
|------------|--------------|
| mgr_name   | Williams     |
| department | engineering  |
| mgr_name   | Lyman        |
| department | publications |
| mgr_name   | Cole         |
| department | accounting   |

For information about how to count the elements in a collection column, see [Cardinality function on page 1845](#).

## Select rows within a table hierarchy

This section describes how to query rows from tables within a table hierarchy. For more information about how to create and use a table hierarchy, see the *Informix® Database Design and Implementation Guide*.

The following figure shows the statements that create the type and table hierarchies that the examples in this section use.

Figure 172. Statements that create the type and table hierarchies.

```

CREATE ROW TYPE address_t
(
  street  VARCHAR (20),
  city    VARCHAR(20),
  state   CHAR(2),
  zip     VARCHAR(9)
)

CREATE ROW TYPE person_t
(
  name    VARCHAR(30),
  address address_t,
  soc_sec CHAR(9)
)

CREATE ROW TYPE employee_t
(
  salary  INTEGER
)
UNDER person_t

CREATE ROW TYPE sales_rep_t
(
  rep_num   SERIAL8,
  region_num INTEGER
)
UNDER employee_t

CREATE TABLE person OF TYPE person_t

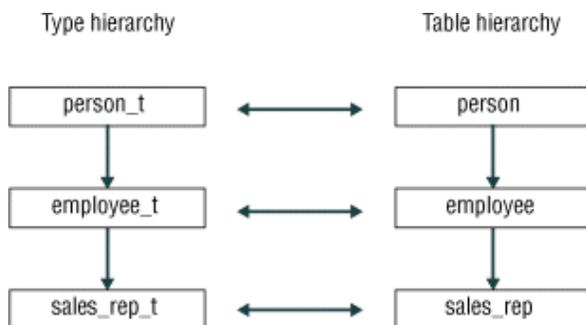

CREATE TABLE employee OF TYPE employee_t
UNDER person

CREATE TABLE sales_rep OF TYPE sales_rep_t
UNDER employee

```

The following figure shows the hierarchical relationships of the row types and tables in the previous figure.

Figure 173. Type and table hierarchies

## Select rows of the supertable without the ONLY keyword

A table hierarchy allows you to construct, in a single SQL statement, a query whose scope is a supertable and its subtables. A query on a supertable returns rows from both the supertable and its subtables. The following query shows a query on the **person** table, which is the root supertable in the table hierarchy.

Figure 174. Query

```
SELECT * FROM person
```

Figure 55: Query result on page 1785 returns all columns in the supertable and those columns in subtables (**employee** and **sales\_rep**) that are inherited from the supertable. A query on a supertable does not return columns from subtables that are not in the supertable. The query result shows the **name**, **address**, and **soc\_sec** columns in the **person**, **employee**, and **sales\_rep** tables.

Figure 175. Query result

```
name      Rogers, J.
address   ROW(102 Ruby Ave, Belmont, CA, 69055)
soc_sec   454849344

name      Sallie, A.
address   ROW(134 Rose St, San Carlos, CA, 69025)
soc_sec   348441214
:
```

## Select rows from a supertable with the ONLY keyword

Although a SELECT statement on a supertable returns rows from both the supertable and its subtables, you cannot tell which rows come from the supertable and which rows come from the subtables. To limit the results of a query to the supertable only, you must include the ONLY keyword in the SELECT statement. For example, the following query returns rows in the **person** table only.

Figure 176. Query

```
SELECT * FROM ONLY(person);
```

Figure 177. Query result

```
name      Rogers, J.
address   ROW(102 Ruby Ave, Belmont, CA, 69055)
soc_sec   454849344
:
```

## An alias for a supertable

An *alias* is a word that immediately follows the name of a table in the FROM clause. You can specify an alias for a typed table in a SELECT or UPDATE statement and then use the alias (in the same SELECT or UPDATE statement) as an expression by itself. If you create an alias for a supertable, the alias can represent values from the supertable or the subtables that inherit

from the supertable. In DB-Access, the following query returns row values for all instances of the **person**, **employee**, and **sales\_rep** tables.

Figure 178. Query

```
SELECT p FROM person p;
```

Informix® ESQL/C does not recognize this construct. In Informix® ESQL/C programs, the query returns an error.

## Summary

This chapter introduced sample syntax and results for selecting data from complex types using SELECT statements to query a relational database. The section [Select row-type data on page 1822](#) shows how to perform the following actions:

- Select row-type data from typed tables and columns
- Use row-type expressions for field projections

The section [Select from a collection on page 1827](#) shows how to perform the following actions:

- Query columns that are defined on collection types
- Search for elements in a collection
- Query columns that are defined on nested collection types

The section [Select rows within a table hierarchy on page 1830](#) shows how to perform the following actions:

- Query a supertable with or without the ONLY keyword
- Specify an alias for a supertable

## Functions in SELECT statements

In addition to column names and operators, an expression can also include one or more functions. This chapter shows how to use functions in SELECT statements to perform more complex database queries and data manipulation.

For information about the syntax of the following SQL functions and other SQL functions, see the Expressions segment in the *Informix® Guide to SQL: Syntax*.

**Tip:** You can also use functions that you create yourself. For information about user-defined functions, see [Create and use SPL routines on page 1998](#), and *Informix® User-Defined Routines and Data Types Developer's Guide*.

## Functions in SELECT statements

You can use any basic type of expression (column, constant, function, aggregate function, and procedure), or combination thereof, in the select list.

A function expression uses a function that is evaluated for each row in the query. All function expressions require arguments. This set of expressions contains the time function and the length function when they are used with a column name as an argument.

## Aggregate functions

An aggregate function returns one value for a set of queried rows. The aggregate functions take on values that depend on the set of rows that the WHERE clause of the SELECT statement returns. In the absence of a WHERE clause, the aggregate functions take on values that depend on all the rows that the FROM clause forms.

You cannot use aggregate functions for expressions that contain the following data types:

- TEXT
- BYTE
- CLOB
- BLOB
- Collection data types (LIST, MULTISET, and SET)
- ROW types
- Opaque data types (except with user-defined aggregate functions that support opaque types)

Aggregates are often used to summarize information about groups of rows in a table. This use is discussed in [Compose advanced SELECT statements on page 1862](#). When you apply an aggregate function to an entire table, the result contains a single row that summarizes all the selected rows.

All Informix® database servers support the following aggregate functions.

## The AVG function

The following query computes the average **unit\_price** of all rows in the **stock** table.

Figure 179. Query

```
SELECT AVG (unit_price) FROM stock;
```

Figure 180. Query result

```
(avg)
$197.14
```

The following query computes the average **unit\_price** of just those rows in the **stock** table that have a **manu\_code** of **SHM**.

Figure 181. Query

```
SELECT AVG (unit_price) FROM stock WHERE manu_code = 'SHM';
```

Figure 182. Query result

```
(avg)
$204.93
```

## The COUNT function

The following query counts and displays the total number of rows in the **stock** table.

Figure 183. Query

```
SELECT COUNT(*) FROM stock;
```

Figure 184. Query result

```
(count(*))
73
```

The following query includes a WHERE clause to count specific rows in the **stock** table, in this case, only those rows that have a **manu\_code** of SHM.

Figure 185. Query

```
SELECT COUNT (*) FROM stock WHERE manu_code = 'SHM';
```

Figure 186. Query result

```
(count(*))
17
```

By including the keyword DISTINCT (or its synonym UNIQUE) and a column name in the following query, you can tally the number of different manufacturer codes in the **stock** table.

Figure 187. Query

```
SELECT COUNT (DISTINCT manu_code) FROM stock;
```

Figure 188. Query result

```
(count)
9
```

## The MAX and MIN functions

You can combine aggregate functions in the same SELECT statement. For example, you can include both the MAX and the MIN functions in the select list, as the following query shows.

Figure 189. Query

```
SELECT MAX (ship_charge), MIN (ship_charge) FROM orders;
```

The query finds and displays both the highest and lowest **ship\_charge** in the **orders** table.

Figure 190. Query result

| (max)   | (min)  |
|---------|--------|
| \$25.20 | \$5.00 |

## The RANGE function

The RANGE function computes the difference between the maximum and the minimum values for the selected rows.

You can apply the RANGE function only to numeric columns. The following query finds the range of prices for items in the **stock** table.

Figure 191. Query

```
SELECT RANGE(unit_price) FROM stock;
```

Figure 192. Query result

| (range) |
|---------|
| 955.50  |

As with other aggregates, the RANGE function applies to the rows of a group when the query includes a GROUP BY clause, which the following query shows.

Figure 193. Query

```
SELECT RANGE(unit_price) FROM stock
GROUP BY manu_code;
```

Figure 194. Query result

| (range) |
|---------|
| 820.20  |
| 595.50  |
| 720.00  |
| 225.00  |
| 632.50  |
| 0.00    |
| 460.00  |
| 645.90  |
| 425.00  |

## The STDEV function

The STDEV function computes the standard deviation for the column of the selected rows without *Bessel correction*. It has the aliases STDEV\_POP, STDDEV and STDDEV\_POP - the "pop" part of the name indicating that this is the population standard deviation. It is returning the square root of the VARIANCE of the selected columns.

You can apply the STDEV function only to numeric columns. The following query finds the standard deviation on a population:

```
SELECT STDEV(age) FROM u_pop WHERE age > 21;
```

As with the other aggregates, the STDEV function applies to the rows of a group when the query includes a GROUP BY clause, as the following example shows:

```
SELECT STDEV(age) FROM u_pop
GROUP BY state
WHERE STDEV(age) > 21;
```

Nulls are ignored unless every value in the specified column is null. If every column value is null, the STDEV function returns a null for that column. For more information about the STDEV function, see the Expression segment in the *Informix® Guide to SQL: Syntax*.

## The SUM function

The following query calculates the total **ship\_weight** of orders that were shipped on July 13, 1998.

Figure 195. Query

```
SELECT SUM (ship_weight) FROM orders
WHERE ship_date = '07/13/1998';
```

Figure 196. Query result

```
(sum)
130.5
```

## The VARIANCE function

The VARIANCE function returns the variance for the column of the selected rows without Bessel correction. This is the population variance. The function has an according alias VARIANCE\_POP. It computes the following value:

$$\frac{(\text{SUM}(X_i^{**2}) - (\text{SUM}(X_i)**2)/N)}{(N-1)}$$

In this example,  $X_i$  is each value in the column and  $N$  is the total number of values in the column. You can apply the VARIANCE function only to numeric columns. The following query finds the variance on a population:

```
SELECT VARIANCE(age) FROM u_pop WHERE age > 21;
```

As with the other aggregates, the VARIANCE function applies to the rows of a group when the query includes a GROUP BY clause, which the following example shows:

```
SELECT VARIANCE(age) FROM u_pop
GROUP BY birth
WHERE VARIANCE(age) > 21;
```

Nulls are ignored unless every value in the specified column is null. If every column value is null, the `VARIANCE` function returns a null for that column. For more information about the `VARIANCE` function, see the Expression segment in the *Informix® Guide to SQL: Syntax*.

## Apply aggregate functions to expressions

The following query shows how you can apply aggregate functions to arithmetic expressions, and declare display labels for their results:

Figure 197. Query

```
SELECT MAX (res_dtime - call_dtime) maximum,
       MIN (res_dtime - call_dtime) minimum,
       AVG (res_dtime - call_dtime) average
FROM cust_calls;
```

The query finds and displays the maximum, minimum, and average amounts of time (in days, hours, and minutes) between the reception and resolution of a customer call, and labels the derived values appropriately. The query result shows these aggregate time-interval values that the query calculates:

Figure 198. Query result

| maximum | minimum | average |
|---------|---------|---------|
| 5 20:55 | 0 00:01 | 1 02:56 |

## Time functions

You can use the time functions `DAY`, `MONTH`, `WEEKDAY`, and `YEAR` in either the Projection clause or the `WHERE` clause of a query. These functions return a value that corresponds to the expressions or arguments that you use to call the function. You can also use the `CURRENT` or `SYSDATE` function to return a value with the current date and time, or use the **EXTEND** function to adjust the precision of a `DATE` or `DATETIME` value.

### The `DAY` and `CURRENT` functions

The following query returns the day of the month for the `call_dtime` and `res_dtime` columns in two *expression* columns.

Figure 199. Query

```
SELECT customer_num, DAY (call_dtime), DAY (res_dtime)
FROM cust_calls;
```

Figure 200. Query result

| customer_num | (expression) | (expression) |
|--------------|--------------|--------------|
| 106          | 12           | 12           |
| 110          | 7            | 7            |
| 119          | 1            | 2            |
| 121          | 10           | 10           |
| 127          | 31           |              |
| 116          | 28           | 28           |
| 116          | 21           | 27           |

The following query uses the DAY and CURRENT functions to compare column values to the current day of the month. It selects only those rows where the value is earlier than the current day. In this example, the CURRENT day is 15.

Figure 201. Query

```
SELECT customer_num, DAY (call_dtime), DAY (res_dtime)
FROM cust_calls
WHERE DAY (call_dtime) < DAY (CURRENT);
```

Figure 202. Query result

| customer_num | (expression) | (expression) |
|--------------|--------------|--------------|
| 106          | 12           | 12           |
| 110          | 7            | 7            |
| 119          | 1            | 2            |
| 121          | 10           | 10           |

The following query uses the CURRENT function to select all calls except those that came in today.

Figure 203. Query

```
SELECT customer_num, call_code, call_descr
FROM cust_calls
WHERE call_dtime < CURRENT YEAR TO DAY;
```

Figure 204. Query result

```
customer_num 106
call_code    D
call_descr   Order was received, but two of the cans of ANZ tennis balls
              within the case were empty

customer_num 110
call_code    L
call_descr   Order placed one month ago (6/7) not received.

customer_num 116
call_code    I
call_descr   Second complaint from this customer! Received two cases
              right-handed outfielder gloves (1 HR0) instead of one case
              lefties.
```

The SYSDATE function closely resembles the CURRENT function, but the default precision of its returned value is DATETIME YEAR TO FRACTION(5), rather than the default DATETIME YEAR TO FRACTION(3) precision of CURRENT when no DATETIME qualifier is specified.

## The MONTH function

The following query uses the MONTH function to extract and show what month the customer call was received and resolved, and it uses display labels for the resulting columns. However, it does not make a distinction between years.

Figure 205. Query

```
SELECT customer_num,
       MONTH (call_dtime) call_month,
       MONTH (res_dtime) res_month
FROM cust_calls;
```

Figure 206. Query result

| customer_num | call_month | res_month |
|--------------|------------|-----------|
| 106          | 6          | 6         |
| 110          | 7          | 7         |
| 119          | 7          | 7         |
| 121          | 7          | 7         |
| 127          | 7          |           |
| 116          | 11         | 11        |
| 116          | 12         | 12        |

The following query uses the MONTH function plus DAY and CURRENT to show what month the customer call was received and resolved if DAY is earlier than the current day.

Figure 207. Query

```
SELECT customer_num,
       MONTH (call_dtime) called,
       MONTH (res_dtime) resolved
FROM cust_calls
WHERE DAY (res_dtime) < DAY (CURRENT);
```

Figure 208. Query result

| customer_num | called | resolved |
|--------------|--------|----------|
| 106          | 6      | 6        |
| 119          | 7      | 7        |
| 121          | 7      | 7        |

## The WEEKDAY function

The following query uses the WEEKDAY function to indicate which day of the week calls are received and resolved (0 represents Sunday, 1 is Monday, and so on), and the expression columns are labeled.

Figure 209. Query

```
SELECT customer_num,
       WEEKDAY (call_dtime) called,
       WEEKDAY (res_dtime) resolved
FROM cust_calls
ORDER BY resolved;
```

Figure 210. Query result

| customer_num | called | resolved |
|--------------|--------|----------|
| 127          | 3      |          |
| 110          | 0      | 0        |
| 119          | 1      | 2        |
| 121          | 3      | 3        |
| 116          | 3      | 3        |
| 106          | 3      | 3        |
| 116          | 5      | 4        |

The following query uses the COUNT and WEEKDAY functions to count how many calls were received on a weekend. This kind of statement can give you an idea of customer-call patterns or indicate whether overtime pay might be required.

Figure 211. Query

```
SELECT COUNT(*)
FROM cust_calls
WHERE WEEKDAY (call_dtime) IN (0,6);
```

Figure 212. Query result

```
(count(*))
4
```

## The YEAR function

The following query retrieves rows where the **call\_dtime** is earlier than the beginning of the current year.

Figure 213. Query

```
SELECT customer_num, call_code,
       YEAR (call_dtime) call_year,
       YEAR (res_dtime) res_year
FROM cust_calls
WHERE YEAR (call_dtime) < YEAR (TODAY);
```

Figure 214. Query result

| customer_num | call_code | call_year | res_year |
|--------------|-----------|-----------|----------|
| 116          | I         | 1997      | 1997     |
| 116          | I         | 1997      | 1997     |

## Format DATETIME values

In the following query, the EXTEND function displays only the specified subfields to restrict the two DATETIME values.

Figure 215. Query

```
SELECT customer_num,
       EXTEND (call_dtime, month to minute) call_time,
       EXTEND (res_dtime, month to minute) res_time
FROM cust_calls
ORDER BY res_time;
```

The query returns the month-to-minute range for the columns labeled **call\_time** and **res\_time** and gives an indication of the work load.

Figure 216. Query result

| customer_num | call_time   | res_time    |
|--------------|-------------|-------------|
| 127          | 07-31 14:30 |             |
| 106          | 06-12 08:20 | 06-12 08:25 |
| 119          | 07-01 15:00 | 07-02 08:21 |
| 110          | 07-07 10:24 | 07-07 10:30 |
| 121          | 07-10 14:05 | 07-10 14:06 |
| 116          | 11-28 13:34 | 11-28 16:47 |
| 116          | 12-21 11:24 | 12-27 08:19 |

The TO\_CHAR function can also format DATETIME values. See [The TO\\_CHAR function on page 1843](#) for information about this built-in function, which can also accept DATE values or numeric values as an argument, and returns a formatted character string.

Besides the built-in time functions that these examples illustrate, HCL Informix® also supports the ADD\_MONTHS, LAST\_DAY, MDY, MONTHS\_BETWEEN, NEXT\_DAY, and QUARTER functions. In addition to these functions, the TRUNC and ROUND functions can return values that change the precision of DATE or DATETIME arguments. These additional time functions are described in the *Informix® Guide to SQL: Syntax*.

## Date-conversion functions

You can use a date-conversion function anywhere you use an expression.

The following conversion functions convert between date and character values:

### The DATE function

The DATE function converts a character string to a DATE value. In the following query, the DATE function converts a character string to a DATE value to allow for comparisons with DATETIME values. The query retrieves DATETIME values only when **call\_dtime** is later than the specified DATE.

Figure 217. Query

```
SELECT customer_num, call_dtime, res_dtime
FROM cust_calls
WHERE call_dtime > DATE ('12/31/97');
```

Figure 218. Query result

| customer_num | call_dtime       | res_dtime        |
|--------------|------------------|------------------|
| 106          | 1998-06-12 08:20 | 1998-06-12 08:25 |
| 110          | 1998-07-07 10:24 | 1998-07-07 10:30 |
| 119          | 1998-07-01 15:00 | 1998-07-02 08:21 |
| 121          | 1998-07-10 14:05 | 1998-07-10 14:06 |
| 127          | 1998-07-31 14:30 |                  |

The following query converts DATETIME values to DATE format and displays the values, with labels, only when **call\_dtime** is greater than or equal to the specified date.

Figure 219. Query

```
SELECT customer_num,
DATE (call_dtime) called,
DATE (res_dtime) resolved
FROM cust_calls
WHERE call_dtime >= DATE ('1/1/98');
```

Figure 220. Query result

| customer_num | called     | resolved   |
|--------------|------------|------------|
| 106          | 06/12/1998 | 06/12/1998 |
| 110          | 07/07/1998 | 07/07/1998 |
| 119          | 07/01/1998 | 07/02/1998 |
| 121          | 07/10/1998 | 07/10/1998 |
| 127          | 07/31/1998 |            |

## The TO\_CHAR function

The TO\_CHAR function converts DATETIME or DATE values to character string values. The TO\_CHAR function evaluates a DATETIME value according to the date-formatting directive that you specify and returns an NVARCHAR value. For a complete list of the supported date-formatting directives, see the description of the **GL\_DATETIME** environment variable in the *Informix® GLS User's Guide*.

You can also use the TO\_CHAR function to convert a DATETIME or DATE value to an LVARCHAR value.

The following query uses the TO\_CHAR function to convert a DATETIME value to a more readable character string.

Figure 221. Query

```
SELECT customer_num,
TO_CHAR(call_dtime, "%A %B %d %Y") call_date
FROM cust_calls
WHERE call_code = "B";
```

Figure 222. Query result

```
customer_num 119
call_date    Friday July 01 1998
```

The following query uses the TO\_CHAR function to convert DATE values to more readable character strings.

Figure 223. Query

```
SELECT order_num,
       TO_CHAR(ship_date, "%A %B %d %Y") date_shipped
FROM orders
WHERE paid_date IS NULL;
```

Figure 224. Query result

```
order_num      1004
date_shipped   Monday May 30 1998

order_num      1006
date_shipped

order_num      1007
date_shipped   Sunday June 05 1998

order_num      1012
date_shipped   Wednesday June 29 1998

order_num      1016
date_shipped   Tuesday July 12 1998

order_num      1017
date_shipped   Wednesday July 13 1998
```

The TO\_CHAR function can also format numeric values. For more information about the built-in TO\_CHAR function, see the *Informix® Guide to SQL: Syntax*.

## The TO\_DATE function

The TO\_DATE function accepts an argument of a character data type and converts this value to a DATETIME value. The TO\_DATE function evaluates a character string according to the date-formatting directive that you specify and returns a DATETIME value. For a complete list of the supported date-formatting directives, see the description of the **GL\_DATETIME** environment variable in the *Informix® GLS User's Guide*.

You can also use the TO\_DATE function to convert an LVARCHAR value to a DATETIME value.

The following query uses the TO\_DATE function to convert character string values to DATETIME values whose format you specify.

Figure 225. Query

```
SELECT customer_num, call_descr
FROM cust_calls
WHERE call_dtime = TO_DATE("2008-07-07 10:24",
"%Y-%m-%d %H:%M");
```

Figure 226. Query result

```
customer_num    110
call_descr      Order placed one month ago (6/7) not received.
```

You can use the DATE or TO\_DATE function to convert a character string to a DATE value. One advantage of the TO\_DATE function is that it allows you to specify a format for the value returned. (You can use the TO\_DATE function, which always returns a DATETIME value, to convert a character string to a DATE value because the database server implicitly handles conversions between DATE and DATETIME values.)

## Cardinality function

The CARDINALITY function counts the number of elements that a collection contains. You can use the CARDINALITY function with simple or nested collections. Any duplicates in a collection are counted as individual elements. The following query shows a query that returns, for every row in the **manager** table, **department** values and the number of elements in each **direct\_reports** collection.

Figure 227. Query

```
SELECT department, CARDINALITY(direct_reports) FROM manager;
```

Figure 228. Query result

```
department    marketing 5
department    engineering 7
department    publications 4
department    accounting 3
```

You can also evaluate the number of elements in a collection from within a predicate expression, as the following query shows.

Figure 229. Query

```
SELECT department, CARDINALITY(direct_reports) FROM manager
WHERE CARDINALITY(direct_reports) < 6
GROUP BY department;
```

Figure 230. Query result

```

department  accounting 3
department  marketing 5
department  publications 4

```

## Smart large object functions

The database server provides four SQL functions that you can call from within an SQL statement to import and export smart large objects. The following table shows the smart-large-object functions.

**Table 86. SQL functions for smart large objects**

| Function name | Purpose   |
|---------------|---|
| FILETOBLOB()  | Copies a file into a BLOB column                          |
| FILETOCLOB()  | Copies a file into a CLOB column                          |
| LOCOPY()      | Copies BLOB or CLOB data into another BLOB or CLOB column |
| LOTOFILE()    | Copies a BLOB or CLOB into a file                         |

For detailed information and the syntax of smart-large-object functions, see the Expression segment in the *Informix® Guide to SQL: Syntax*.

You can use any of the functions that the table shows in SELECT, UPDATE, and INSERT statements. For examples of how to use the preceding functions in INSERT and UPDATE statements, see [Modify data on page 1901](#).

Suppose you create the **inmate** and **fbi\_list** tables, as the following figure shows.

Figure 231. Create the inmate and fbi\_list tables.

```

CREATE TABLE inmate
(
  id_num    INT,
  picture   BLOB,
  felony    CLOB
);

CREATE TABLE fbi_list
(
  id        INTEGER,
  mugshot   BLOB
) PUT mugshot IN (sbspace1);

```

The following SELECT statement uses the LOTOFILE() function to copy data from the **felony** column into the `felon_322.txt` file that is located on the client computer:

```
SELECT id_num, LOTOFILE(felony, 'felon_322.txt', 'client')
FROM inmate
WHERE id = 322;
```

The first argument for `LOTOFILE()` specifies the name of the column from which data is to be exported. The second argument specifies the name of the file into which data is to be copied. The third argument specifies whether the target file is located on the client computer ('client') or server computer ('server').

The following rules apply for specifying the path of a file name in a function argument, depending on whether the file resides on the client or server computer:

- If the source file resides on the server computer, you must specify the full path name to the file (not the path name relative to the current working directory).
- If the source file resides on the client computer, you can specify either the full or relative path name to the file.

## String-manipulation functions

String-manipulation functions accept arguments of type `CHAR`, `NCHAR`, `VARCHAR`, `NVARCHAR`, or `LVARCHAR`. You can use a string-manipulation function anywhere you use an expression.

The following functions convert between upper and lowercase letters in a character string:

- `LOWER`
- `UPPER`
- `INITCAP`

The following functions manipulate character strings in various ways:

- `REPLACE`
- `SUBSTR`
- `SUBSTRING`
- `LPAD`
- `RPAD`

**Restriction:** You cannot overload any of the string-manipulation functions to handle extended data types.

## The LOWER function

Use the `LOWER` function to replace every uppercase letter in a character string with a lowercase letter. The `LOWER` function accepts an argument of a character data type and returns a value of the same data type as the argument you specify.

The following query uses the `LOWER` function to convert any uppercase letters in a character string to lowercase letters.

Figure 232. Query

```
SELECT manu_code, LOWER(manu_code)
FROM items
WHERE order_num = 1018
```

Figure 233. Query result

| manu_code | (expression) |
|-----------|--------------|
| PRC       | prc          |
| KAR       | kar          |
| PRC       | prc          |
| SMT       | smt          |
| HRO       | hro          |

## The UPPER function

Use the UPPER function to replace every lowercase letter in a character string with an uppercase letter. The UPPER function accepts an argument of a character data type and returns a value of the same data type as the argument you specify.

The following query uses the UPPER function to convert any lowercase letters in a character string to uppercase letters.

Figure 234. Query

```
SELECT call_code, UPPER(code_descr) FROM call_type
```

Figure 235. Query result

| call_code | (expression)               |
|-----------|----------------------------|
| B         | BILLING ERROR              |
| D         | DAMAGED GOODS              |
| I         | INCORRECT MERCHANDISE SENT |
| L         | LATE SHIPMENT              |
| O         | OTHER                      |

## The INITCAP function

Use the INITCAP function to replace the first letter of every word in a character string with an uppercase letter. The INITCAP function assumes a new word whenever the function encounters a letter that is preceded by any character other than a letter. The INITCAP function accepts an argument of a character data type and returns a value of the same data type as the argument you specify.

The following query uses the INITCAP function to convert the first letter of every word in a character string to an uppercase letter.

Figure 236. Query

```
SELECT INITCAP(description) FROM stock
WHERE manu_code = "ANZ";
```

Figure 237. Query result

```
(expression)
Tennis Racquet
Tennis Ball
Volleyball
Volleyball Net
Helmet
Golf Shoes
3 Golf Balls
Running Shoes
Watch
Kick Board
Swim Cap
```

## The REPLACE function

Use the REPLACE function to replace a certain set of characters in a character string with other characters.

In the following query, the REPLACE function replaces the unit column value `each` with `item` for every row that the query returns. The first argument of the REPLACE function is the expression to be evaluated. The second argument specifies the characters that you want to replace. The third argument specifies a new character string to replace the characters removed.

Figure 238. Query

```
SELECT stock_num, REPLACE(unit,"each", "item") cost_per, unit_price
FROM stock
WHERE manu_code = "HR0";
```

Figure 239. Query result

| stock_num | cost_per | unit_price |
|-----------|----------|------------|
| 1         | case     | \$250.00   |
| 2         | case     | \$126.00   |
| 4         | case     | \$480.00   |
| 7         | case     | \$600.00   |
| 110       | case     | \$260.00   |
| 205       | case     | \$312.00   |
| 301       | item     | \$42.50    |
| 302       | item     | \$4.50     |
| 304       | box      | \$280.00   |
| 305       | case     | \$48.00    |
| 309       | case     | \$40.00    |
| 312       | box      | \$72.00    |

## The SUBSTRING and SUBSTR functions

You can use the SUBSTRING and SUBSTR functions to return a portion of a character string. You specify the *start position* and *length* (optional) to determine which portion of the character string the function returns.

**Restriction:** The units of measurement in the arguments to these two functions are bytes, rather than logical characters. This is of no importance in the default locale, nor in other single-byte locales, but you should not invoke SUBSTRING or SUBSTR in locales in which the logical characters of the code set can differ in their storage lengths.

## The SUBSTRING function

You can use the SUBSTRING function to return some portion of a character string. You specify the *start position* and *length* (optional) to determine which portion of the character string the function returns. You can specify a positive or negative number for the start position. A start position of `1` specifies that the SUBSTRING function begins from the first position in the string. When the start position is zero (0) or a negative number, the SUBSTRING function counts backward from the beginning of the string.

The following query shows an example of the SUBSTRING function, which returns the first four characters for any **sname** column values that the query returns. In this example, the SUBSTRING function starts at the beginning of the string and returns four characters counting forward from the start position.

Figure 240. Query

```
SELECT sname, SUBSTRING(sname FROM 1 FOR 4) FROM state
WHERE code = "AZ";
```

Figure 241. Query result

| sname   | (expression) |
|---------|--------------|
| Arizona | Ariz         |

In the following query, the SUBSTRING function specifies a start position of `6` but does not specify the length. The function returns a character string that extends from the sixth position to the end of the string.

Figure 242. Query

```
SELECT sname, SUBSTRING(sname FROM 6) FROM state
WHERE code = "WV";
```

Figure 243. Query result

| sname         | (expression) |
|---------------|--------------|
| West Virginia | Virginia     |

In the following query, the SUBSTRING function returns only the first character for any **sname** column value that the query returns. For the SUBSTRING function, a start position of `-2` counts backward three positions (`0`, `-1`, `-2`) from the start position of the string (for a start position of `0`, the function counts backward one position from the beginning of the string).

Figure 244. Query

```
SELECT sname, SUBSTRING(sname FROM -2 FOR 4) FROM state
WHERE code = "AZ";
```

Figure 245. Query result

| sname   | (expression) |
|---------|--------------|
| Arizona | A            |

## The SUBSTR function

The SUBSTR function serves the same purpose as the SUBSTRING function, but the syntax of the two functions differs.

To return a portion of a character string, specify the *start position* and *length* (optional) to determine which portion of the character string the SUBSTR function returns. The start position that you specify for the SUBSTR function can be a positive or a negative number. However, the SUBSTR function treats a negative number in the start position differently than does the SUBSTRING function. When the start position is a negative number, the SUBSTR function counts backward from the end of the character string, which depends on the length of the string, not the character length of a word or visible characters that the string contains. The SUBSTR function recognizes zero (0) or 1 in the start position as the first position in the string.

The following query shows an example of the SUBSTR function that includes a negative number for the start position. Given a start position of `-15`, the SUBSTR function counts backward 15 positions from the end of the string to find the start position and then returns the next five characters.

Figure 246. Query

```
SELECT sname, SUBSTR(sname, -15, 5) FROM state
WHERE code = "CA";
```

Figure 247. Query result

| sname      | (expression) |
|------------|--------------|
| California | Calif        |

To use a negative number for the start position, you need to know the length of the value that is evaluated. The **sname** column is defined as CHAR(15), so a SUBSTR function that accepts an argument of type **sname** can use a start position of 0, 1, or `-15` for the function to return a character string that begins from the first position in the string.

The following query returns the same result as [Figure 246: Query on page 1851](#).

Figure 248. Query

```
SELECT sname, SUBSTR(sname, 1, 5) FROM state
WHERE code = "CA";
```

## The LPAD function

Use the LPAD function to return a copy of a string that has been left padded with a sequence of characters that are repeated as many times as necessary or truncated, depending on the specified length of the padded portion of the string. Specify the source string, the length of the string to be returned, and the character string to serve as padding.

The data type of the source string and the character string that serves as padding can be any data type that converts to VARCHAR or NVARCHAR.

The following query shows an example of the LPAD function with a specified length of 21 characters. Because the source string has a length of 15 characters (**sname** is defined as CHAR(15)), the LPAD function pads the first six positions to the left of the source string.

Figure 249. Query

```
SELECT sname, LPAD(sname, 21, "-")
FROM state
WHERE code = "CA" OR code = "AZ";
```

Figure 250. Query result

| sname      | (expression)    |
|------------|-----------------|
| California | -----California |
| Arizona    | -----Arizona    |

## The RPAD function

Use the RPAD function to return a copy of a string that has been right padded with a sequence of characters that are repeated as many times as necessary or truncated, depending on the specified length of the padded portion of the string. Specify the source string, the length of the string to be returned, and the character string to serve as padding.

The data type of the source string and the character string that serves as padding can be any data type that converts to VARCHAR or NVARCHAR.

The following query shows an example of the RPAD function with a specified length of 21 characters. Because the source string has a length of 15 characters (**sname** is defined as CHAR(15)), the RPAD function pads the first six positions to the right of the source string.

Figure 251. Query

```
SELECT sname, RPAD(sname, 21, "-")
FROM state
WHERE code = "WV" OR code = "AZ";
```

Figure 252. Query result

| sname         | (expression)        |
|---------------|---------------------|
| West Virginia | West Virginia ----- |
| Arizona       | Arizona -----       |

In addition to these functions, the LTRIM and RTRIM functions can return a value that drops specified leading or trailing padding characters from their string argument, and the ASCII function can return the numeric value of the codepoint within the ASCII character set of the first character in its string argument. These built-in functions for operations on string values are described in the *Informix® Guide to SQL: Syntax*.

## Other functions

You can also use the LENGTH, USER, CURRENT, SYSDATE, and TODAY functions anywhere in an SQL expression that you would use a constant. In addition, you can include the DBSERVERNAME function in a SELECT statement to display the name of the database server where the current database resides.

You can use these functions to select an expression that consists entirely of constant values or an expression that includes column data. In the first instance, the result is the same for all rows of output.

In addition, you can use the HEX function to return the hexadecimal encoding of an expression, the **ROUND** function to return the rounded value of an expression, and the **TRUNC** function to return the truncated value of an expression. For more information on the preceding functions, see the *Informix® Guide to SQL: Syntax*.

## The LENGTH function

In the following query, the LENGTH function calculates the number of bytes in the combined **fname** and **lname** columns for each row where the length of **company** is greater than 15.

Figure 253. Query

```
SELECT customer_num,
       LENGTH (fname) + LENGTH (lname) namelength
FROM customer
WHERE LENGTH (company) > 15;
```

Figure 254. Query result

| customer_num | namelength |
|--------------|------------|
| 101          | 11         |
| 105          | 13         |
| 107          | 11         |
| 112          | 14         |
| 115          | 11         |
| 118          | 10         |
| 119          | 10         |
| 120          | 10         |
| 122          | 12         |
| 124          | 11         |
| 125          | 10         |
| 126          | 12         |
| 127          | 10         |
| 128          | 11         |

Although the LENGTH function might not be useful when you work with DB-Access, it can be important to determine the string length for programs and reports. The LENGTH function returns the clipped length of a CHARACTER or VARCHAR string and the full number of bytes in a TEXT or BYTE string.

HCL Informix® also supports the CHAR\_LENGTH function, which returns the number of logical characters in its string argument, rather than the number of bytes. This function is useful in locales where a single logical character might require more than a single byte of storage. For more information about the CHAR\_LENGTH function, see the *Informix® Guide to SQL: Syntax* and the *Informix® GLS User's Guide*.

## The USER function

Use the USER function when you want to define a restricted view of a table that contains only rows that include your user ID. For information about how to create views, see the *Informix® Database Design and Implementation Guide* and the GRANT and CREATE VIEW statements in the *Informix® Guide to SQL: Syntax*.

The following query returns the user name (login account name) of the user who executes the query. It is repeated once for each row in the table.

Figure 255. Query

```
SELECT * FROM cust_calls
WHERE user_id = USER;
```

If the user name of the current user is **richc**, the query retrieves only those rows in the **cust\_calls** table where `user_id = richc`.

Figure 256. Query result

```
customer_num  110
call_dtime    1998-07-07 10:24
user_id       richc
call_code     L
call_descr    Order placed one month ago (6/7) not received.
res_dtime     1998-07-07 10:30
res_descr     Checked with shipping (Ed Smith). Order sent yesterday-we
              were waiting for goods from ANZ. Next time will call with
              delay if necessary

customer_num  119
call_dtime    1998-07-01 15:00
user_id       richc
call_code     B
call_descr    Bill does not reflect credit from previous order
res_dtime     1998-07-02 08:21
res_descr     Spoke with Jane Akant in Finance. They found the error and are
              sending new bill to customer
```

## The TODAY function

The TODAY function returns the current system date. If the following query is issued when the current system date is July 10, 1998, it returns this one row.

Figure 257. Query

```
SELECT * FROM orders WHERE order_date = TODAY;
```

Figure 258. Query result

```

order_num      1018
order_date     07/10/1998
customer_num   121
ship_instruct  SW corner of Biltmore Mall
backlog        n
po_num         S22942
ship_date      07/13/1998
ship_weight    70.50
ship_charge    $20.00
paid_date      08/06/1998

```

## The DBSERVERNAME and SITENAME functions

You can include the function `DBSERVERNAME` (or its synonym, `SITENAME`) in a `SELECT` statement to find the name of the database server. You can query the `DBSERVERNAME` for any table that has rows, including system catalog tables.

In the following query, you assign the label **server** to the `DBSERVERNAME` expression and also select the **tabid** column from the **systables** system catalog table. This table describes database tables, and **tabid** is the table identifier.

Figure 259. Query

```

SELECT DBSERVERNAME server, tabid
FROM systables
WHERE tabid <= 4;

```

Figure 260. Query result

| server   | tabid |
|----------|-------|
| montague | 1     |
| montague | 2     |
| montague | 3     |
| montague | 4     |

The `WHERE` clause restricts the numbers of rows displayed. Otherwise, the database server name would be displayed once for each row of the **systables** table.

## The HEX function

In the following query, the `HEX` function returns the hexadecimal format of two columns in the **customer** table, as the result shows.

Figure 261. Query

```

SELECT HEX (customer_num) hexnum, HEX (zipcode) hexzip
FROM customer;

```

Figure 262. Query result

| hexnum     | hexzip     |
|------------|------------|
| 0x00000065 | 0x00016F86 |
| 0x00000066 | 0x00016FA5 |
| 0x00000067 | 0x0001705F |
| 0x00000068 | 0x00016F4A |
| 0x00000069 | 0x00016F46 |
| 0x0000006A | 0x00016F6F |
| ⋮          |            |

## The DBINFO function

You can call the DBINFO function in a SELECT statement to find any of the following information:

- The name of a dbspace corresponding to a tblspace number or expression
- The last SERIAL, SERIAL8 or BIGSERIAL value inserted into a table
- The number of rows processed by the SELECT, INSERT, DELETE, UPDATE, MERGE, EXECUTE FUNCTION, EXECUTE PROCEDURE, or EXECUTE ROUTINE statement
- The session ID of the current session
- The name of the current database to which the session is connected
- Whether an INSERT, UPDATE, or DELETE statement is being performed as part of a replicated transaction.
- The name of the host computer on which the database server runs
- The type of operating system and the word length of the host computer
- The local time zone and the current date and time in Coordinated Universal Time (UTC) format
- The DATETIME value corresponding to a specified integer column or to a specified UTC time value (as an integer number of seconds since 1970-01-01 00:00:00+00:00)
- The exact version of the database server to which a client application is connected, or a specified component of the full version string.

You can use the DBINFO function anywhere within SQL statements and within SPL routines.

The following query shows how you might use the DBINFO function to find out the name of the host computer on which the database server runs.

Figure 263. Query

```
SELECT FIRST 1 DBINFO('dbhostname') FROM systables;
```

Figure 264. Query result

|            |
|------------|
| (constant) |
| lyceum     |

Without the `FIRST 1` clause to restrict the values in the `tabid`, the host name of the computer on which the database server runs would be repeated for each row of the `systables` table. The following query shows how you might use the `DBINFO` function to find out the complete version number and the type of the current database server.

Figure 265. Query

```
SELECT FIRST 1 DBINFO('version','full') FROM systables;
```

For more information about how to use the `DBINFO` function to find information about your current database server, database session, or database, see the *Informix® Guide to SQL: Syntax*.

## The DECODE function

You can use the `DECODE` function to convert an expression of one value to another value. The `DECODE` function has the following form:

```
DECODE(test, a, a_value, b, b_value, ..., n, n_value, exp_m)
```

The `DECODE` function returns `a_value` when `a` equals `test`, and returns `b_value` when `b` equals `test`, and, in general, returns `n_value` when `n` equals `test`.

If several expressions match `test`, `DECODE` returns `n_value` for the first expression found. If no expression matches `test`, `DECODE` returns `exp_m`; if no expression matches `test` and there is no `exp_m`, `DECODE` returns `NULL`.

**Restriction:** The `DECODE` function does not support arguments of type `TEXT` or `BYTE`.

Suppose an `employee` table exists that includes `emp_id` and `evaluation` columns. Suppose also that execution of the following query on the `employee` table returns the rows that the result shows.

Figure 266. Query

```
SELECT emp_id, evaluation FROM employee;
```

Figure 267. Query result

| emp_id | evaluation |
|--------|------------|
| 012233 | great      |
| 012344 | poor       |
| 012677 | NULL       |
| 012288 | good       |
| 012555 | very good  |

In some cases, you might want to convert a set of values. For example, suppose you want to convert the descriptive values of the `evaluation` column in the preceding example to corresponding numeric values. The following query shows how you might use the `DECODE` function to convert values from the `evaluation` column to numeric values for each row in the `employee` table.

Figure 268. Query

```
SELECT emp_id, DECODE(evaluation, "poor", 0, "fair", 25, "good",
50, "very good", 75, "great", 100, -1) AS evaluation
FROM employee;
```

Figure 269. Query result

| emp_id | evaluation |
|--------|------------|
| 012233 | 100        |
| 012344 | 0          |
| 012677 | -1         |
| 012288 | 50         |
| 012555 | 75         |

You can specify any data type for the arguments of the DECODE function provided that the arguments meet the following requirements:

- The arguments *test*, *a*, *b*, ..., *n* all have the same data type or evaluate to a common compatible data type.
- The arguments *a\_value*, *b\_value*, ..., *n\_value* all have the same data type or evaluate to a common compatible data type.

## The NVL function

You can use the NVL function to convert an expression that evaluates to NULL to a value that you specify. The NVL function accepts two arguments: the first argument takes the name of the expression to be evaluated; the second argument specifies the value that the function returns when the first argument evaluates to NULL. If the first argument does not evaluate to NULL, the function returns the value of the first argument. Suppose a **student** table exists that includes **name** and **address** columns. Suppose also that execution of the following query on the **student** table returns the rows that the result shows.

Figure 270. Query

```
SELECT name, address FROM student;
```

Figure 271. Query result

| name           | address                |
|----------------|------------------------|
| John Smith     | 333 Vista Drive        |
| Lauren Collier | 1129 Greenridge Street |
| Fred Frith     | NULL                   |
| Susan Jordan   | NULL                   |

The following query includes the NVL function, which returns a new value for each row in the table where the **address** column contains a NULL value.

Figure 272. Query

```
SELECT name, NVL(address, "address is unknown") AS address
FROM student;
```

Figure 273. Query result

| name           | address                |
|----------------|------------------------|
| John Smith     | 333 Vista Drive        |
| Lauren Collier | 1129 Greenridge Street |
| Fred Frith     | address is unknown     |
| Susan Jordan   | address is unknown     |

You can specify any data type for the arguments of the NVL function provided that the two arguments evaluate to a common compatible data type.

If both arguments of the NVL function evaluate to NULL, the function returns NULL.

HCL Informix® also supports the NULLIF function, which resembles the NVL function, but has different semantics. NULLIF returns NULL if its two arguments are equal, or returns its first argument if its arguments are not equal. For more information about the NULLIF function, see the *Informix® Guide to SQL: Syntax*.

## SPL routines in SELECT statements

Previous examples in this chapter show SELECT statement expressions that consist of column names, operators, and SQL functions. This section shows expressions that contain an SPL routine call.

SPL routines contain special Stored Procedure Language (SPL) statements as well as SQL statements. For more information on SPL routines, see [Create and use SPL routines on page 1998](#).

HCL Informix® allows you to write external routines in C and in Java™. For more information, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

When you include an SPL routine expression in a projection list, the SPL routine must be one that returns a single value (one column of one row). For example, the following statement is valid only if `test_func()` returns a single value:

```
SELECT col_a, test_func(col_b) FROM tab1
WHERE col_c = "Davis";
```

SPL routines that return more than a single value are not supported in the Projection clause of SELECT statements. In the preceding example, if `test_func()` returns more than one value, the database server returns an error message.

SPL routines provide a way to extend the range of functions available by allowing you to perform a subquery on each row you select.

For example, suppose you want a listing of the customer number, the customer's last name, and the number of orders the customer has made. The following query shows one way to retrieve this information. The **customer** table has **customer\_num** and **lname** columns but no record of the number of orders each customer has made. You could write a **get\_orders** routine, which queries the **orders** table for each **customer\_num** and returns the number of corresponding orders (labeled **n\_orders**).

Figure 274. Query

```
SELECT customer_num, lname, get_orders(customer_num) n_orders
FROM customer;
```

The result shows the output from this SPL routine.

Figure 275. Query result

| customer_num | lname   | n_orders |
|--------------|---------|----------|
| 101          | Pauli   | 1        |
| 102          | Sadler  | 9        |
| 103          | Currie  | 9        |
| 104          | Higgins | 4        |
| 123          | Hanlon  | 1        |
| 124          | Putnum  | 1        |
| 125          | Henry   | 0        |
| 126          | Neelie  | 1        |
| 127          | Satifer | 1        |
| 128          | Lessor  | 0        |

Use SPL routines to encapsulate operations that you frequently perform in your queries. For example, the condition in the following query contains a routine, **conv\_price**, that converts the unit price of a stock item to a different currency and adds any import tariffs.

Figure 276. Query

```
SELECT stock_num, manu_code, description FROM stock
WHERE conv_price(unit_price, ex_rate = 1.50,
tariff = 50.00) < 1000;
```

## Data encryption functions

You can use the SET ENCRYPTION PASSWORD statement with built-in SQL encryption functions that use Advanced Encryption Standard (AES) and Triple DES (3DES) encryption to secure your sensitive data. When you use encryption, only those users who have the correct password will be able to read, copy, or modify the data.

Use the SET ENCRYPTION PASSWORD statement with the following built-in encryption and decryption functions:

- ENCRYPT\_AES

```
ENCRYPT_AES(data-string-expression
[, password-string-expression [, hint-string-expression ]])
```

- ENCRYPT\_TDES

```
ENCRYPT_TDES (data-string-expression
[, password-string-expression [, hint-string-expression ]])
```

- DECRYPT\_CHAR

```
DECRYPT_CHAR(EncryptedData [, PasswordOrPhrase])
```

- DECRYPT\_BINARY

```
DECRYPT_BINARY(EncryptedData [, PasswordOrPhrase])
```

- GETHINT

```
GETHINT(EncryptedData)
```

If you have used the SET ENCRYPTION PASSWORD statement to specify a default password, then the database server applies that password in subsequent calls to encryption and decryption functions that you invoke in the same session.

Use ENCRYPT\_AES and ENCRYPT\_TDES to define encrypted data and use DECRYPT\_CHAR and DECRYPT\_BINARY to query encrypted data. Use GETHINT to display the password hint string, if set, on the server.

You can use these SQL built-in functions to implement column-level or cell-level encryption.

- Use column-level encryption to encrypt all values in a given column with the same password.
- Use cell-level encryption to encrypt data within the column with different passwords.

**i Tip:** If you intend to select encrypted data from a large table, specify an unencrypted column on which to select the rows. You can create indexes or foreign-key constraints on columns that contain encrypted data, but to do so is an inefficient use of resources, because such indexes and foreign-key constraints are not used by the query optimizer.

## Using column-level data encryption to secure credit card data

### About this task

The following example uses column-level encryption to secure credit card data.

To use column-level data encryption to secure credit card data:

1. Create the table: `create table customer (id char(30), creditcard lvarchar(67));`
2. Insert the encryption data:

a. Set session password: `SET ENCRYPTION PASSWORD "credit card number is encrypted";`

b. Encrypt data.

```
INSERT INTO customer VALUES
("Alice", encrypt_aes("1234567890123456"));
INSERT INTO customer VALUES
("Bob", encrypt_aes("2345678901234567"));
```

3. Query encryption data with decryption function.

```
SET ENCRYPTION PASSWORD "credit card number is encrypted";
SELECT id FROM customer
WHERE DECRYPT_CHAR(creditcard) = "2345678901234567";
```

### Results

**!** **Important:** Encrypted data values occupy more storage space than the corresponding unencrypted data. A column whose width is sufficient to store plain text might need to be increased before it can support column-level encryption or cell-level encryption. If you attempt to insert an encrypted value into a column whose declared width is shorter than the encrypted string, the column stores a truncated value that cannot be decrypted.

For more information on encryption security, see *Informix® Administrator's Guide*.

For more information on the syntax and storage requirements of built-in encryption and decryption functions, see *Informix® Guide to SQL: Syntax*.

## Summary

This chapter introduced sample syntax and results for functions in basic SELECT statements to query a relational database and to manipulate the returned data. [Functions in SELECT statements on page 1833](#) shows how to perform the following actions:

- Use the aggregate functions in the Projection clause to calculate and retrieve specific data.
- Include the time functions DATE, DAY, MDY, MONTH, WEEKDAY, YEAR, CURRENT, and EXTEND plus the TODAY, LENGTH, and USER functions in your SELECT statements.
- Use conversion functions in the SELECT clause to convert between date and character values.
- Use string-manipulation functions in the SELECT clause to convert between upper and lower case letters or to manipulate character strings in various ways.

[SPL routines in SELECT statements on page 1859](#) shows how to include SPL routines in your SELECT statements.

[Data encryption functions on page 1860](#) shows how the use of the SET ENCRYPTION statement and built-in encryption and decryption functions can prevent users who cannot provide a password from viewing or modifying sensitive data.

## Compose advanced SELECT statements

This section increases the scope of what you can do with the SELECT statement and enables you to perform more complex database queries and data manipulation. [Compose SELECT statements on page 1773](#), focused on five of the clauses in the SELECT statement syntax. This section adds the GROUP BY clause and the HAVING clause. You can use the GROUP BY clause with aggregate functions to organize rows returned by the FROM clause. You can include a HAVING clause to place conditions on the values that the GROUP BY clause returns.

This section also extends the earlier discussion of joins. It illustrates *self-joins*, which enable you to join a table to itself, and four kinds of *outer joins*, in which you apply the keyword OUTER to treat two or more joined tables unequally. It also introduces correlated and uncorrelated subqueries and their operational keywords, shows how to combine queries with the UNION operator, and defines the set operations known as union, intersection, and difference.

Examples in this section show how to use some or all of the SELECT statement clauses in your queries. The clauses must appear in the following order:

1. Projection
2. FROM
3. WHERE
4. GROUP BY
5. HAVING
6. ORDER BY
7. INTO TEMP

For an example of a SELECT statement that uses all these clauses in the correct order, see [Figure 291: Query on page 1867](#).

An additional SELECT statement clause, INTO, which you can use to specify program and host variables in SQL APIs, is described in [SQL programming on page 1944](#), as well as in the publications that come with the product.

This section also describes nested SELECT statements, in which subqueries are specified within the Projection, FROM, or WHERE clauses of the main query. Other sections show how SELECT statements can define and manipulate collections, and how to perform set operations on query results.

## The GROUP BY and HAVING clauses

The optional GROUP BY and HAVING clauses add functionality to your SELECT statement. You can include one or both in a basic SELECT statement to increase your ability to manipulate aggregates.

The GROUP BY clause combines similar rows, producing a single result row for each group of rows that have the same values, for each column listed in the Projection clause. The HAVING clause sets conditions on those groups after you form them. You can use a GROUP BY clause without a HAVING clause, or a HAVING clause without a GROUP BY clause.

## The GROUP BY clause

The GROUP BY clause divides a table into sets. This clause is most often combined with aggregate functions that produce summary values for each of those sets. Some examples in [Compose SELECT statements on page 1773](#) show the use of aggregate functions applied to a whole table. This section illustrates aggregate functions applied to groups of rows.

Using the GROUP BY clause without aggregates is much like using the DISTINCT (or UNIQUE) keyword in the SELECT clause. The following query is described in [Select specific columns on page 1783](#).

Figure 277. Query

```
SELECT DISTINCT customer_num FROM orders;
```

You could also write the statement as the following query shows.

Figure 278. Query

```
SELECT customer_num FROM orders  
GROUP BY customer_num;
```

[Figure 277: Query on page 1863](#) and [Figure 278: Query on page 1863](#) return the following rows.

Figure 279. Query result

```
customer_num
    101
    104
    106
    110

    124
    126
    127
```

The GROUP BY clause collects the rows into sets so that each row in each set has the same customer numbers. With no other columns selected, the result is a list of the unique **customer\_num** values.

The power of the GROUP BY clause is more apparent when you use it with aggregate functions.

The following query retrieves the number of items and the total price of all items for each order.

Figure 280. Query

```
SELECT order_num, COUNT (*) number, SUM (total_price) price
FROM items
GROUP BY order_num;
```

The GROUP BY clause causes the rows of the **items** table to be collected into groups, each group composed of rows that have identical **order\_num** values (that is, the items of each order are grouped together). After the database server forms the groups, the aggregate functions COUNT and SUM are applied within each group.

[Figure 280: Query on page 1864](#) returns one row for each group. It uses labels to give names to the results of the COUNT and SUM expressions, as the result shows.

Figure 281. Query result

| order_num | number | price     |
|-----------|--------|-----------|
| 1001      | 1      | \$250.00  |
| 1002      | 2      | \$1200.00 |
| 1003      | 3      | \$959.00  |
| 1004      | 4      | \$1416.00 |
| 1021      | 4      | \$1614.00 |
| 1022      | 3      | \$232.00  |
| 1023      | 6      | \$824.00  |

The result collects the rows of the **items** table into groups that have identical order numbers and computes the COUNT of rows in each group and the SUM of the prices.

You cannot include a TEXT, BYTE, CLOB, or BLOB column in a GROUP BY clause. To *group*, you must be able to *sort*, and no natural sort order exists for these data types.

Unlike the ORDER BY clause, the GROUP BY clause does not order data. Include an ORDER BY clause *after* your GROUP BY clause if you want to sort data in a particular order or sort on an aggregate in the projection list.

The following query is the same as [Figure 280: Query on page 1864](#) but includes an ORDER BY clause to sort the retrieved rows in ascending order of **price**, as the result shows.

Figure 282. Query

```
SELECT order_num, COUNT(*) number, SUM (total_price) price
FROM items
GROUP BY order_num
ORDER BY price;
```

Figure 283. Query result

| order_num | number | price     |
|-----------|--------|-----------|
| 1010      | 2      | \$84.00   |
| 1011      | 1      | \$99.00   |
| 1013      | 4      | \$143.80  |
| 1022      | 3      | \$232.00  |
| 1001      | 1      | \$250.00  |
| 1020      | 2      | \$438.00  |
| 1006      | 5      | \$448.00  |
| 1002      | 2      | \$1200.00 |
| 1004      | 4      | \$1416.00 |
| 1014      | 2      | \$1440.00 |
| 1019      | 1      | \$1499.97 |
| 1021      | 4      | \$1614.00 |
| 1007      | 5      | \$1696.00 |

The topic [Select specific columns on page 1783](#) describes how to use an integer in an ORDER BY clause to indicate the position of a column in the projection list. You can also use an integer in a GROUP BY clause to indicate the position of column names or display labels in the GROUP BY list.

The following query returns the same rows as [Figure 282: Query on page 1865](#) shows.

Figure 284. Query

```
SELECT order_num, COUNT(*) number, SUM (total_price) price
FROM items
GROUP BY 1
ORDER BY 3;
```

When you build a query, all non-aggregate columns that are in the projection list in the Projection clause must also be included in the GROUP BY clause. A SELECT statement with a GROUP BY clause must return only one row per group. Columns that are listed after GROUP BY are certain to reflect only one distinct value within a group, and that value can be returned. However, a column not listed after GROUP BY might contain different values in the rows that are contained in the group.

The following query shows how to use the GROUP BY clause in a SELECT statement that joins tables.

Figure 285. Query

```
SELECT o.order_num, SUM (i.total_price)
  FROM orders o, items i
 WHERE o.order_date > '01/01/98'
       AND o.customer_num = 110
       AND o.order_num = i.order_num
 GROUP BY o.order_num;
```

The query joins the **orders** and **items** tables, assigns table aliases to them, and returns the rows.

Figure 286. Query result

| order_num | (sum)    |
|-----------|----------|
| 1008      | \$940.00 |
| 1015      | \$450.00 |

## The HAVING clause

To complement a GROUP BY clause, use a HAVING clause to apply one or more qualifying conditions to groups after they are formed. The effect of the HAVING clause on groups is similar to the way the WHERE clause qualifies individual rows. One advantage of using a HAVING clause is that you can include aggregates in the search condition, whereas you cannot include aggregates in the search condition of a WHERE clause.

Each HAVING condition compares one column or aggregate expression of the group with another aggregate expression of the group or with a constant. You can use HAVING to place conditions on both column values and aggregate values in the group list.

The following query returns the average total price per item on all orders that have more than two items. The HAVING clause tests each group as it is formed and selects those that are composed of more than two rows.

Figure 287. Query

```
SELECT order_num, COUNT(*) number, AVG (total_price) average
  FROM items
 GROUP BY order_num
 HAVING COUNT(*) > 2;
```

Figure 288. Query result

| order_num | number | average  |
|-----------|--------|----------|
| 1003      | 3      | \$319.67 |
| 1004      | 4      | \$354.00 |
| 1005      | 4      | \$140.50 |
| 1006      | 5      | \$89.60  |
| 1007      | 5      | \$339.20 |
| 1013      | 4      | \$35.95  |
| 1016      | 4      | \$163.50 |
| 1017      | 3      | \$194.67 |
| 1018      | 5      | \$226.20 |
| 1021      | 4      | \$403.50 |
| 1022      | 3      | \$77.33  |
| 1023      | 6      | \$137.33 |

If you use a HAVING clause without a GROUP BY clause, the HAVING condition applies to all rows that satisfy the search condition. In other words, all rows that satisfy the search condition make up a single group.

The following query, a modified version of [Figure 287: Query on page 1866](#), returns just one row, the average of all **total\_price** values in the table, as the result shows.

Figure 289. Query

```
SELECT AVG (total_price) average
FROM items
HAVING count(*) > 2;
```

Figure 290. Query result

```
average
$270.97
```

If [Figure 289: Query on page 1867](#), like [Figure 287: Query on page 1866](#), had included the non-aggregate column **order\_num** in the Projection clause, you would have to include a GROUP BY clause with that column in the group list. In addition, if the condition in the HAVING clause was not satisfied, the output would show the column heading and a message would indicate that no rows were found.

The following query contains all the SELECT statement clauses that you can use in the Informix® version of interactive SQL (the INTO clause that names host variables is available only in an SQL API).

Figure 291. Query

```
SELECT o.order_num, SUM (i.total_price) price,
       paid_date - order_date span
FROM orders o, items i
WHERE o.order_date > '01/01/98'
      AND o.customer_num > 110
      AND o.order_num = i.order_num
GROUP BY 1, 3
HAVING COUNT (*) < 5
ORDER BY 3
INTO TEMP temptab1;
```

The query joins the **orders** and **items** tables; employs display labels, table aliases, and integers that are used as column indicators; groups and orders the data; and puts the results in a temporary table, as the result shows.

Figure 292. Query result

| order_num | price     | span |
|-----------|-----------|------|
| 1017      | \$584.00  |      |
| 1016      | \$654.00  |      |
| 1012      | \$1040.00 |      |
| 1019      | \$1499.97 | 26   |
| 1005      | \$562.00  | 28   |
| 1021      | \$1614.00 | 30   |
| 1022      | \$232.00  | 40   |
| 1010      | \$84.00   | 66   |
| 1009      | \$450.00  | 68   |
| 1020      | \$438.00  | 71   |

## Create advanced joins

The topic [Create a join on page 1811](#) shows how to include a WHERE clause in a SELECT statement to join two or more tables on one or more columns. It illustrates natural joins and equi-joins.

This section discusses how to use two more complex kinds of joins, self-joins and outer joins. As described for simple joins, you can define aliases for tables and assign display labels to expressions to shorten your multiple-table queries. You can also issue a SELECT statement with an ORDER BY clause that sorts data into a temporary table.

## Self-joins

A join does not always have to involve two different tables. You can join a table to itself, creating a *self-join*. Joining a table to itself can be useful when you want to compare values in a column to other values in the same column.

To create a self-join, list a table twice in the FROM clause, and assign it a different alias each time. Use the aliases to refer to the table in the Projection and WHERE clauses as if it were two separate tables. (Aliases in SELECT statements are discussed in [Aliases on page 1818](#) and in the *Informix® Guide to SQL: Syntax*.)

Just as in joins between tables, you can use arithmetic expressions in self-joins. You can test for null values, and you can use an ORDER BY clause to sort the values in a specified column in ascending or descending order.

The following query finds pairs of orders where the **ship\_weight** differs by a factor of five or more and the **ship\_date** is not null. The query then orders the data by **ship\_date**.

Figure 293. Query

```
SELECT x.order_num, x.ship_weight, x.ship_date,
       y.order_num, y.ship_weight, y.ship_date
FROM orders x, orders y
WHERE x.ship_weight >= 5 * y.ship_weight
      AND x.ship_date IS NOT NULL
      AND y.ship_date IS NOT NULL
ORDER BY x.ship_date;
```

**Table 87. Query result**

| order_num | ship_weight | ship_date  | order_num | ship_weight | ship_date  |
|-----------|-------------|------------|-----------|-------------|------------|
| 1004      | 95.80       | 05/30/1998 | 1011      | 10.40       | 07/03/1998 |
| 1004      | 95.80       | 05/30/1998 | 1020      | 14.00       | 07/16/1998 |
| 1004      | 95.80       | 05/30/1998 | 1022      | 15.00       | 07/30/1998 |
| 1007      | 125.90      | 06/05/1998 | 1015      | 20.60       | 07/16/1998 |
| 1007      | 125.90      | 06/05/1998 | 1020      | 14.00       | 07/16/1998 |

If you want to store the results of a self-join into a temporary table, append an INTO TEMP clause to the SELECT statement and assign display labels to at least one set of columns to rename them. Otherwise, the duplicate column names cause an error and the temporary table is not created.

The following query, which is similar to [Figure 293: Query on page 1868](#), labels all columns selected from the **orders** table and puts them in a temporary table called **shipping**.

Figure 294. Query

```
SELECT x.order_num orders1, x.po_num purch1,
       x.ship_date ship1, y.order_num orders2,
       y.po_num purch2, y.ship_date ship2
FROM orders x, orders y
WHERE x.ship_weight >= 5 * y.ship_weight
      AND x.ship_date IS NOT NULL
      AND y.ship_date IS NOT NULL
ORDER BY orders1, orders2
INTO TEMP shipping;
```

If you query with `SELECT *` from table **shipping**, you see the following rows.

Figure 295. Query result

| orders1 | purch1 | ship1      | orders2 | purch2 | ship2      |
|---------|--------|------------|---------|--------|------------|
| 1004    | 8006   | 05/30/1998 | 1011    | B77897 | 07/03/1998 |
| 1004    | 8006   | 05/30/1998 | 1020    | W2286  | 07/16/1998 |
| 1004    | 8006   | 05/30/1998 | 1022    | W9925  | 07/30/1998 |
| 1005    | 2865   | 06/09/1998 | 1011    | B77897 | 07/03/1998 |
| 1019    | Z55709 | 07/16/1998 | 1020    | W2286  | 07/16/1998 |
| 1019    | Z55709 | 07/16/1998 | 1022    | W9925  | 07/30/1998 |
| 1023    | KF2961 | 07/30/1998 | 1011    | B77897 | 07/03/1998 |

You can join a table to itself more than once. The maximum number of self-joins depends on the resources available to you.

The self-join in the following query creates a list of those items in the **stock** table that are supplied by three manufacturers. The self-join includes the last two conditions in the WHERE clause to eliminate duplicate manufacturer codes in rows that are retrieved.

Figure 296. Query

```

SELECT s1.manu_code, s2.manu_code, s3.manu_code,
       s1.stock_num, s1.description
FROM stock s1, stock s2, stock s3
WHERE s1.stock_num = s2.stock_num
      AND s2.stock_num = s3.stock_num
      AND s1.manu_code < s2.manu_code
      AND s2.manu_code < s3.manu_code
ORDER BY stock_num;

```

Figure 297. Query result

| manu_code | manu_code | manu_code | stock_num | description     |
|-----------|-----------|-----------|-----------|-----------------|
| HRO       | HSK       | SMT       | 1         | baseball gloves |
| ANZ       | NRG       | SMT       | 5         | tennis racquet  |
| ANZ       | HRO       | HSK       | 110       | helmet          |
| ANZ       | HRO       | PRC       | 110       | helmet          |
| ANZ       | HRO       | SHM       | 110       | helmet          |
| ANZ       | HSK       | PRC       | 110       | helmet          |
| ANZ       | HSK       | SHM       | 110       | helmet          |
| ANZ       | PRC       | SHM       | 110       | helmet          |
| HRO       | HSK       | PRC       | 110       | helmet          |
| HRO       | HSK       | SHM       | 110       | helmet          |
| HRO       | PRC       | SHM       | 110       | helmet          |
| KAR       | NKL       | PRC       | 301       | running shoes   |
| KAR       | NKL       | SHM       | 301       | running shoes   |
| KAR       | PRC       | SHM       | 301       | running shoes   |
| NKL       | PRC       | SHM       | 301       | running shoes   |

If you want to select rows from a payroll table to determine which employees earn more than their manager, you might construct the self-join as the following SELECT statement shows:

```

SELECT emp.employee_num, emp.gross_pay, emp.level,
       emp.dept_num, mgr.employee_num, mgr.gross_pay,
       mgr.dept_num, mgr.level
FROM payroll emp, payroll mgr
WHERE emp.gross_pay > mgr.gross_pay
      AND emp.level < mgr.level
      AND emp.dept_num = mgr.dept_num
ORDER BY 4;

```

The following query uses a *correlated subquery* to retrieve and list the 10 highest-priced items ordered.

Figure 298. Query

```

SELECT order_num, total_price
FROM items a
WHERE 10 >
      (SELECT COUNT (*)
       FROM items b
        WHERE b.total_price < a.total_price)
ORDER BY total_price;

```

The query returns the 10 rows.

Figure 299. Query result

| order_num | total_price |
|-----------|-------------|
| 1018      | \$15.00     |
| 1013      | \$19.80     |
| 1003      | \$20.00     |
| 1005      | \$36.00     |
| 1006      | \$36.00     |
| 1013      | \$36.00     |
| 1010      | \$36.00     |
| 1013      | \$40.00     |
| 1022      | \$40.00     |
| 1023      | \$40.00     |

You can create a similar query to find and list the 10 employees in the company who have the most seniority.

For more information about correlated subqueries, refer to [Subqueries in SELECT statements on page 1878](#).

## Outer joins

This section shows how to create and use outer joins in a SELECT statement. The topic [Create a join on page 1811](#) discusses inner joins. Whereas an inner join treats two or more joined tables equally, an outer join treats two or more joined tables asymmetrically. An outer join makes one of the tables dominant (also called the *outer table*) over the other subordinate tables (also called *inner tables*).

In an inner join or in a *simple join*, the result contains only the combinations of rows that satisfy the join conditions. Rows that do not satisfy the join conditions are discarded.

In an outer join, the result contains the combinations of rows that satisfy the join conditions and the rows from the dominant table that would otherwise be discarded because no matching row was found in the subordinate table. The rows from the dominant table that do not have matching rows in the subordinate table contain NULL values in the columns selected from the subordinate table.

An outer join allows you to apply *join filters* to the inner table before the join condition is applied.

The database server supports syntax for outer joins that is an extension to the ANSI standard for the SQL language. Besides outer join syntax based on this Informix® extension, the database server also supports the ANSI standard syntax, which provides more flexibility for creating queries that join a dominant table with one or more subordinate tables. With the exception of joins in view definitions, it is recommended that you use the ANSI standard syntax for creating new outer-join queries.

In view definitions, however, the Informix®-extension syntax does not require materialized views, and so it might offer performance advantages over ISO/ANSI join syntax in those contexts, including business-analytic operations that query complex views joining multiple tables.

Whichever form of outer-join syntax you use, however, a single query cannot mix both syntax modes. All of the outer join operations in the same query block must either use SQL syntax that complies with the ISO/ANSI standard, or else use the Informix® extension syntax.

 **Important:** Before you rely on outer joins, determine whether one or more inner joins can work. You can often use an inner join when you do not need supplemental information from other tables.

 **Restriction:** You cannot combine Informix® and ANSI outer-join syntax in the same query block.

For information on the syntax of outer joins, see the *Informix® Guide to SQL: Syntax*.

## HCL Informix® extension to outer join syntax

The HCL Informix® extension to outer-join syntax begins an outer join with the OUTER keyword. When you use the Informix® syntax, you must include the join condition in the WHERE clause. When you use the Informix® syntax for an outer join, the database server supports the following three basic types of outer joins:

- A simple outer join on two tables
- An outer join for a simple join to a third table
- An outer join of two tables to a third table

An outer join must have a Projection clause, a FROM clause, and a WHERE clause. The join conditions are expressed in a WHERE clause. To transform a simple join into an outer join, insert the keyword OUTER directly before the name of the subordinate tables in the FROM clause. As shown later in this section, you can include the OUTER keyword more than once in your query.

No Informix® extension to outer-join syntax is equivalent to the ANSI right outer join.

## ANSI join syntax

The following ANSI joins are supported:

- Left outer join
- Right outer join

The ANSI outer-join syntax begins an outer join with the LEFT JOIN, LEFT OUTER JOIN, RIGHT JOIN, or RIGHT OUTER JOIN keywords. The OUTER keyword is optional. Queries can specify a join condition and optional join filters in the ON clause. The WHERE clause specifies a post-join filter. In addition, you can explicitly specify the type of join using the LEFT or right clause. ANSI join syntax also allows the dominant or subordinate part of an outer join to be the result set of another join, when you begin the join with a left parenthesis.

If you use ANSI syntax for an outer join, you must use the ANSI syntax for all outer joins in a single query block.

 **Tip:** The examples in this section use table aliases for brevity. [Aliases on page 1818](#) discusses table aliases.

## Left outer join

In the syntax of a left outer join, the dominant table of the outer join appears to the left of the keyword that begins the outer join. A left outer join returns all of the rows for which the join condition is true and, in addition, returns all other rows from the dominant table and displays the corresponding values from the subservient table as NULL.

The following query uses ANSI syntax for a LEFT OUTER JOIN to join the **customer** and **cust\_calls** tables, with **customer** the dominant table:

Figure 300. Query 1

```
SELECT c.customer_num, c.lname, c.company, c.phone,
       u.call_dtime, u.call_descr
FROM customer c LEFT OUTER JOIN cust_calls u
ON c.customer_num = u.customer_num;
```

The next query similarly uses the ON clause to specify the join condition, and adds an additional filter in the WHERE clause to limit your result set; such a filter is a post-join filter.

The query returns only rows in which customers have not made any calls to customer service. In this query, the database server applies the filter in the WHERE clause after it performs the outer join on the **customer\_num** column of the **customer** and **cust\_calls** tables.

Figure 301. Query 2

```
SELECT c.customer_num, c.lname, c.company, c.phone,
       u.call_dtime, u.call_descr
FROM customer c LEFT OUTER JOIN cust_calls u
ON c.customer_num = u.customer_num
WHERE u.customer_num IS NULL;
```

The next example shows the Informix®-extension syntax that is equivalent to the previous ANSI-compliant left outer join:

Figure 302. Query 3

```
SELECT c.customer_num, c.lname, c.company, c.phone,
       u.call_dtime, u.call_descr
FROM customer c OUTER cust_calls u
WHERE c.customer_num = u.customer_num
AND u.customer_num IS NULL;
```

Here the WHERE clause defines the join condition, and excludes rows with non-NULL **cust\_calls** values.

## Examples of ISO/ANSI LEFT OUTER JOIN queries

The following examples illustrate various query constructions that ANSI join syntax can support:

```
SELECT *
FROM (t1 LEFT OUTER JOIN (t2 LEFT OUTER JOIN t3 ON t2.c1=t3.c1)
    ON t1.c1=t3.c1) JOIN (t4 LEFT OUTER JOIN t5 ON t4.c1=t5.c1)
    ON t1.c1=t4.c1;

SELECT *
```

```

FROM (t1 LEFT OUTER JOIN (t2 LEFT OUTER JOIN t3 ON t2.c1=t3.c1)
     ON t1.c1=t3.c1),
     (t4 LEFT OUTER JOIN t5 ON t4.c1=t5.c1)
WHERE t1.c1 = t4.c1;

SELECT *
FROM (t1 LEFT OUTER JOIN (t2 LEFT OUTER JOIN t3 ON t2.c1=t3.c1)
     ON t1.c1=t3.c1) LEFT OUTER JOIN (t4 JOIN t5 ON t4.c1=t5.c1)
     ON t1.c1=t4.c1;

SELECT *
FROM t1 LEFT OUTER JOIN (t2 LEFT OUTER JOIN t3 ON t2.c1=t3.c1)
     ON t1.c1=t2.c1;

SELECT *
FROM t1 LEFT OUTER JOIN (t2 LEFT OUTER JOIN t3 ON t2.c1=t3.c1)
     ON t1.c1=t3.c1;

SELECT *
FROM (t1 LEFT OUTER JOIN t2 ON t1.c1=t2.c1)
     LEFT OUTER JOIN t3 ON t2.c1=t3.c1;

SELECT *
FROM (t1 LEFT OUTER JOIN t2 ON t1.c1=t2.c1)
     LEFT OUTER JOIN t3 ON t1.c1=t3.c1;

SELECT *
FROM t9, (t1 LEFT JOIN t2 ON t1.c1=t2.c1),
     (t3 LEFT JOIN t4 ON t3.c1=10), t10, t11,
     (t12 LEFT JOIN t14 ON t12.c1=100);

SELECT * FROM
  ((SELECT c1,c2 FROM t3) AS vt3(v31,v32)
   LEFT OUTER JOIN
    ( (SELECT c1,c2 FROM t1) AS vt1(vc1,vc2)
      LEFT OUTER JOIN
        (SELECT c1,c2 FROM t2) AS vt2(vc3,vc4)
          ON vt1.vc1 = vt2.vc3)
   ON vt3.v31 = vt2.vc3);

```

The last example above includes ANSI-compliant joins on derived tables. It specifies a left outer join on the results of a subquery in the FROM clause of the outer query with the results of another left outer join on two other subquery results. See the section [Subqueries in the FROM clause on page 1880](#) for less complex examples of the ANSI-compliant syntax for subqueries.

## Right outer join

In the syntax of a right outer join, the dominant table of the outer join appears to the right of the keyword that begins the outer join. A right outer join returns all of the rows for which the join condition is true and, in addition, returns all other rows from the dominant table and displays the corresponding values from the subservient table as NULL.

The following query is an example of a right outer join on the **customer** and **orders** tables.

Figure 303. Query

```
SELECT c.customer_num, c.fname, c.lname, o.order_num,
o.order_date, o.customer_num
FROM customer c RIGHT OUTER JOIN orders o
ON (c.customer_num = o.customer_num);
```

The query returns all rows from the dominant table **orders** and, as necessary, displays the corresponding values from the subservient table **customer** as NULL.

Figure 304. Query result

| customer_num | fname   | lname   | order_num | order_date | customer_num |
|--------------|---------|---------|-----------|------------|--------------|
| 104          | Anthony | Wiggins | 1001      | 05/30/1998 | 104          |
| 101          | Ludwig  | Pauli   | 1002      | 05/30/1998 | 101          |
| 104          | Anthony | Wiggins | 1003      | 05/30/1998 | 104          |
| <NULL>       | <NULL>  | <NULL>  | 1004      | 06/05/1998 | 106          |

## Simple join

The following query is an example of a simple join on the **customer** and **cust\_calls** tables.

Figure 305. Query

```
SELECT c.customer_num, c.lname, c.company,
c.phone, u.call_dtime, u.call_descr
FROM customer c, cust_calls u
WHERE c.customer_num = u.customer_num;
```

The query returns only those rows in which the customer has made a call to customer service, as the result shows.

Figure 306. Query result

|              |   |
|--------------|---|
| customer_num | 106   |
| lname        | Watson  |
| company      | Watson & Son  |
| phone        | 415-389-8789  |
| call_dtime   | 1998-06-12 08:20  |
| call_descr   | Order was received, but two of the cans of ANZ tennis balls within the case were empty                                      |
| customer_num | 116   |
| lname        | Parmelee  |
| company      | Olympic City  |
| phone        | 415-534-8822  |
| call_dtime   | 1997-12-21 11:24  |
| call_descr   | Second complaint from this customer! Received two cases right-handed outfielder gloves (1 HRO) instead of one case lefties. |

## Simple outer join on two tables

The following query uses the same Projection clause, tables, and comparison condition as the preceding example, but this time it creates a simple outer join in Informix® extension syntax.

Figure 307. Query

```
SELECT c.customer_num, c.lname, c.company,
       c.phone, u.call_dtime, u.call_descr
FROM customer c, OUTER cust_calls u
WHERE c.customer_num = u.customer_num;
```

The addition of the keyword `OUTER` before the `cust_calls` table makes it the subservient table. An outer join causes the query to return information on all customers, whether or not they have made calls to customer service. All rows from the dominant `customer` table are retrieved, and NULL values are assigned to columns of the subservient `cust_calls` table, as the result shows.

Figure 308. Query result

```
customer_num 101
lname        Pauli
company       All Sports Supplies
phone         408-789-8075
call_dtime
call_descr

customer_num 102
lname        Sadler
company       Sports Spot
phone         415-822-1289
call_dtime
call_descr

customer_num 107
lname        Ream
company       Athletic Supplies
phone         415-356-9876
call_dtime
call_descr

customer_num 108
lname        Quinn
company       Quinn's Sports
phone         415-544-8729
call_dtime
call_descr
```

## Outer join for a simple join to a third table

Using the Informix® syntax, the following query shows an outer join that is the result of a simple join to a third table. This second type of outer join is known as a *nested simple join*.

Figure 309. Query

```
SELECT c.customer_num, c.lname, o.order_num,
       i.stock_num, i.manu_code, i.quantity
FROM customer c, OUTER (orders o, items i)
WHERE c.customer_num = o.customer_num
      AND o.order_num = i.order_num
      AND manu_code IN ('KAR', 'SHM')
ORDER BY lname;
```

The query first performs a simple join on the **orders** and **items** tables, retrieving information on all orders for items with a **manu\_code** of KAR or SHM. It then performs an outer join to combine this information with data from the dominant **customer** table. An optional ORDER BY clause reorganizes the data into the following form.

Figure 310. Query result

| customer_num | lname     | order_num | stock_num | manu_code | quantity |
|--------------|-----------|-----------|-----------|-----------|----------|
| 114          | Albertson |           |           |           |          |
| 118          | Baxter    |           |           |           |          |
| 113          | Beatty    |           |           |           |          |
| 105          | Vector    |           |           |           |          |
| 121          | Wallack   | 1018      | 302       | KAR       | 3        |
| 106          | Watson    |           |           |           |          |

## Outer join of two tables to a third table

Using the Informix® extension syntax, the following query shows an outer join that is the result of an outer join of each of two tables to a third table. In this third type of outer join, join relationships are possible only between the dominant table and the subservient tables.

Figure 311. Query

```
SELECT c.customer_num, c.lname, o.order_num,
       order_date, call_dtime
FROM customer c, OUTER orders o, OUTER cust_calls x
WHERE c.customer_num = o.customer_num
      AND c.customer_num = x.customer_num
ORDER BY lname
INTO TEMP service;
```

The query individually joins the subservient tables **orders** and **cust\_calls** to the dominant **customer** table; it does not join the two subservient tables. An INTO TEMP clause selects the results into a temporary table for further manipulation or queries, as the result shows.

Figure 312. Query result

| customer_num | lname     | order_num | order_date | call_dtime       |
|--------------|-----------|-----------|------------|------------------|
| 114          | Albertson |           |            |                  |
| 118          | Baxter    |           |            |                  |
| 113          | Beatty    |           |            |                  |
| 103          | Currie    |           |            |                  |
| 115          | Grant     | 1010      | 06/17/1998 |                  |
| 117          | Sipes     | 1012      | 06/18/1998 |                  |
| 105          | Vector    |           |            |                  |
| 121          | Wallack   | 1018      | 07/10/1998 | 1998-07-10 14:05 |
| 106          | Watson    | 1004      | 05/22/1998 | 1998-06-12 08:20 |
| 106          | Watson    | 1014      | 06/25/1998 | 1998-06-12 08:20 |

If [Figure 311: Query on page 1877](#) had tried to create a join condition between the two subservient tables **o** and **x**, as the following query shows, an error message would indicate the creation of a two-sided outer join.

Figure 313. Query

```
WHERE o.customer_num = x.customer_num
```

## Joins that combine outer joins

To achieve multiple levels of nesting, you can create a join that employs any combination of the three types of outer joins. Using the ANSI syntax, the following query creates a join that is the result of a combination of a simple outer join on two tables and a second outer join.

Figure 314. Query

```
SELECT c.customer_num, c.lname, o.order_num,
       stock_num, manu_code, quantity
FROM customer c, OUTER (orders o, OUTER items i)
WHERE c.customer_num = o.customer_num
      AND o.order_num = i.order_num
      AND manu_code IN ('KAR', 'SHM')
ORDER BY lname;
```

The query first performs an outer join on the **orders** and **items** tables, retrieving information on all orders for items with a **manu\_code** of KAR or SHM. It then performs a second outer join that combines this information with data from the dominant **customer** table.

Figure 315. Query result

| customer_num | lname     | order_num | stock_num | manu_code | quantity |
|--------------|-----------|-----------|-----------|-----------|----------|
| 114          | Albertson |           |           |           |          |
| 118          | Baxter    |           |           |           |          |
| 113          | Beatty    |           |           |           |          |
| 103          | Currie    |           |           |           |          |
| 115          | Grant     | 1010      |           |           |          |
| 117          | Sipes     | 1012      |           |           |          |
| 117          | Sipes     | 1007      |           |           |          |
| 105          | Vector    |           |           |           |          |
| 121          | Wallack   | 1018      | 302       | KAR       | 3        |
| 106          | Watson    | 1014      |           |           |          |
| 106          | Watson    | 1004      |           |           |          |

You can specify the join conditions in two ways when you apply an outer join to the result of an outer join to a third table. The two subservient tables are joined, but you can join the dominant table to either subservient table without affecting the results if the dominant table and the subservient table share a common column.

## Subqueries in SELECT statements

A *subquery* (the inner SELECT statement, where one SELECT statement is nested within another) can return zero or more rows or expressions. Each subquery must be delimited by parentheses, and must contain a Projection clause and a FROM clause. A subquery can itself contain other subqueries.

The database server supports subqueries in the following contexts:

- A SELECT statement nested in the Projection clause of another SELECT statement
- a SELECT statement nested in the WHERE clause of another SELECT statement
- a SELECT statement nested in the FROM clause of another SELECT statement.

You can also specify a subquery in various clauses of the INSERT, DELETE, MERGE, or UPDATE statements where a subquery is valid.

Subqueries in the Projection clause or in the WHERE clause can be *correlated* or *uncorrelated*. A subquery is correlated when the value that it produces depends on a value produced by the outer SELECT statement that contains it. For more information, see [Correlated subqueries on page 1879](#).

Any other kind of subquery is considered uncorrelated. Only uncorrelated subqueries are valid in the FROM clause of the SELECT statement.

## Correlated subqueries

A *correlated subquery* is a subquery that refers to a column of a table that is not listed in its FROM clause. The column can be in the Projection clause or in the WHERE clause. To find the table to which the correlated subquery refers, search the columns until a correlation is found.

In general, correlated subqueries diminish performance. Use the table name or alias in the subquery so that there is no doubt as to which table the column is in.

The database server will use the outer query to get values. For example, if the table **taba** has the column **col1** and table **tabb** has the column **col2** and they contain the following:

```
taba.col1    aa,bb,null
tabb.col2    bb, null
```

And the query is:

```
select * from taba where col1 in (select col1 from tabb);
```

Then the results might be meaningless. The database server will provide all values in **taba.col1** and then compare them to **taba.col1** (outer query WHERE clause). This will return all rows. You usually use the subquery to return column values from the inner table. Had the query been written as:

```
select * from taba where col1 in (select tabb.col1 from tabb);
```

Then the `error -217 column not found` would have resulted.

The important feature of a correlated subquery is that, because it depends on a value from the outer SELECT, it must be executed repeatedly, once for every value that the outer SELECT produces. An uncorrelated subquery is executed only once.

## Using subqueries to combine SELECT statements

You can construct a SELECT statement with a subquery to replace two separate SELECT statements.

Subqueries in SELECT statements allow you to perform various tasks, including the following actions:

- Compare an expression to the result of another SELECT statement
- Determine whether the results of another SELECT statement include a specific expression
- Determine whether another SELECT statement returns any rows

An optional WHERE clause in a subquery is often used to narrow the search condition.

A subquery selects and returns values to the first or outer SELECT statement. A subquery can return no value, a single value, or a set of values, as follows:

- If a subquery returns no value, the query does not return any rows. Such a subquery is equivalent to a NULL value.
- If a subquery returns one value, the value is in the form of either one aggregate expression or exactly one row and one column. Such a subquery is equivalent to a single number or character value.
- If a subquery returns a list or set of values, the values can represent one row or one column.
- In the FROM clause of the outer query, a subquery can represent a set of rows (sometimes called a *derived table* or a *table expression*).

## Subqueries in a Projection clause

A subquery can occur in the Projection clause of another SELECT statement. The following query shows how you might use a subquery in a Projection clause to return the total shipping charges (from the **orders** table) for each customer in the **customer** table. You could also write this query as a join between two tables.

Figure 316. Query

```
SELECT customer.customer_num,
       (SELECT SUM(ship_charge)
        FROM orders
        WHERE customer.customer_num = orders.customer_num)
       AS total_ship_chg
FROM customer;
```

Figure 317. Query result

| customer_num | total_ship_chg |
|--------------|----------------|
| 101          | \$15.30        |
| 102          |                |
| 103          |                |
| 104          | \$38.00        |
| 105          |                |
| :            |                |
| 123          | \$8.50         |
| 124          | \$12.00        |
| 125          |                |
| 126          | \$13.00        |
| 127          | \$18.00        |
| 128          |                |

## Subqueries in the FROM clause

This topic describes subqueries that occur as nested SELECT statements in the FROM clause of an outer SELECT statement. Such subqueries are sometimes called *derived tables* or *table expressions* because the outer query uses the results of the subquery as a data source.

The following query uses asterisk notation in the outer query to return the results of a subquery that retrieves all fields of the **address** column in the **employee** table.

Figure 318. Query

```
SELECT * FROM (SELECT address.* FROM employee);
```

Figure 319. Query result

```
address  ROW(102 Ruby, Belmont, CA, 49932, 1000)
address  ROW(133 First, San Jose, CA, 85744, 4900)
address  ROW(152 Topaz, Willits, CA, 69445, 1000)
```

This illustrates how to specify a derived table, but it is a trivial example of this syntax, because the outer query does not manipulate any values in the table expression that the subquery in the FROM clause returns. (See [Figure 158: Query on page 1827](#) for a simple query that returns the same results.)

The following query is a more complex example in which the outer query selects only the first qualifying row of a derived table that a subquery in the FROM clause specifies as a simple join on the **customer** and **cust\_calls** tables.

Figure 320. Query

```
SELECT LIMIT 1 * FROM
  (SELECT c.customer_num, c.lname, c.company,
         c.phone, u.call_dtime, u.call_descr
   FROM customer c, cust_calls u
   WHERE c.customer_num = u.customer_num
  ORDER BY u.call_dtime DESC);
```

The query returns only those rows in which the customer has made a call to customer service, as the result shows.

Figure 321. Query result

```
customer_num  106
lname         Watson
company       Watson & Son
phone         415-389-8789
call_dtime    1998-06-12 08:20
call_descr    Order was received, but two of the cans of
              ANZ tennis balls within the case were empty
```

In the preceding example, the subquery includes an ORDER BY clause that specifies a column that appears in Projection list of the subquery, but the query would also be valid if the Projection list had omitted the **u.call\_dtime** column. The FROM clause is the only context in which a subquery can specify the ORDER BY clause.

## Subqueries in WHERE clauses

This section describes subqueries that occur as a SELECT statement that is nested in the WHERE clause of another SELECT statement.

You can use any relational operator with ALL and ANY to compare something to every one of (ALL) or to any one of (ANY) the values that the subquery produces. You can use the keyword SOME in place of ANY. The operator IN is equivalent to = ANY. To create the opposite search condition, use the keyword NOT or a different relational operator.

The EXISTS operator tests a subquery to see if it found any values; that is, it asks if the result of the subquery is not null. You cannot use the EXISTS keyword in a subquery that contains a column with a TEXT or BYTE data type.

For the syntax that you use to create a condition with a subquery, see the *Informix® Guide to SQL: Syntax*.

The following keywords introduce a subquery in the WHERE clause of a SELECT statement.

### The ALL keyword

Use the keyword ALL preceding a subquery to determine whether a comparison is true for every value returned. If the subquery returns no values, the search condition is *true*. (If it returns no values, the condition is true of all the zero values.)

The following query lists the following information for all orders that contain an item for which the total price is less than the total price on every item in order number 1023.

Figure 322. Query

```
SELECT order_num, stock_num, manu_code, total_price
FROM items
WHERE total_price < ALL
  (SELECT total_price FROM items
   WHERE order_num = 1023);
```

Figure 323. Query result

| order_num | stock_num | manu_code | total_price |
|-----------|-----------|-----------|-------------|
| 1003      | 9         | ANZ       | \$20.00     |
| 1005      | 6         | SMT       | \$36.00     |
| 1006      | 6         | SMT       | \$36.00     |
| 1010      | 6         | SMT       | \$36.00     |
| 1013      | 5         | ANZ       | \$19.80     |
| 1013      | 6         | SMT       | \$36.00     |
| 1018      | 302       | KAR       | \$15.00     |

### The ANY keyword

Use the keyword ANY (or its synonym SOME) before a subquery to determine whether a comparison is true for at least one of the values returned. If the subquery returns no values, the search condition is *false*. (Because no values exist, the condition cannot be true for one of them.)

The following query finds the order number of all orders that contain an item for which the total price is greater than the total price of any one of the items in order number 1005.

Figure 324. Query

```
SELECT DISTINCT order_num
  FROM items
 WHERE total_price > ANY
   (SELECT total_price
     FROM items
    WHERE order_num = 1005);
```

Figure 325. Query result

```
order_num
1001
1002
1003
1004

1020
1021
1022
1023
```

## Single-valued subqueries

You do not need to include the keyword ALL or ANY if you know the subquery can return exactly one value to the outer-level query. A subquery that returns exactly one value can be treated like a function. This kind of subquery often uses an aggregate function because aggregate functions always return single values.

The following query uses the aggregate function MAX in a subquery to find the **order\_num** for orders that include the maximum number of volleyball nets.

Figure 326. Query

```
SELECT order_num FROM items
 WHERE stock_num = 9
    AND quantity =
      (SELECT MAX (quantity)
       FROM items
      WHERE stock_num = 9);
```

Figure 327. Query result

```
order_num
1012
```

The following query uses the aggregate function MIN in the subquery to select items for which the total price is higher than 10 times the minimum price.

Figure 328. Query

```

SELECT order_num, stock_num, manu_code, total_price
  FROM items x
 WHERE total_price >
       (SELECT 10 * MIN (total_price)
        FROM items
        WHERE order_num = x.order_num);

```

Figure 329. Query result

| order_num | stock_num | manu_code | total_price |
|-----------|-----------|-----------|-------------|
| 1003      | 8         | ANZ       | \$840.00    |
| 1018      | 307       | PRC       | \$500.00    |
| 1018      | 110       | PRC       | \$236.00    |
| 1018      | 304       | HRO       | \$280.00    |

## Correlated subqueries

A *correlated subquery* is a subquery that refers to a column of a table that is not in its FROM clause. The column can be in the Projection clause or in the WHERE clause.

In general, correlated subqueries diminish performance. It is recommended that you qualify the column name in subqueries with the name or alias of the table, in order to remove any doubt regarding in which table the column resides.

The following query is an example of a correlated subquery that returns a list of the 10 latest shipping dates in the **orders** table. It includes an ORDER BY clause after the subquery to order the results because (except in the FROM clause) you cannot include ORDER BY within a subquery.

Figure 330. Query

```

SELECT po_num, ship_date FROM orders main
 WHERE 10 >
       (SELECT COUNT (DISTINCT ship_date)
        FROM orders sub
        WHERE sub.ship_date < main.ship_date)
 AND ship_date IS NOT NULL
 ORDER BY ship_date, po_num;

```

The subquery is correlated because the number that it produces depends on **main.ship\_date**, a value that the outer SELECT produces. Thus, the subquery must be re-executed for every row that the outer query considers.

The query uses the COUNT function to return a value to the main query. The ORDER BY clause then orders the data. The query locates and returns the 16 rows that have the 10 latest shipping dates, as the result shows.

Figure 331. Query result

| po_num   | ship_date  |
|----------|------------|
| 4745     | 06/21/1998 |
| 278701   | 06/29/1998 |
| 429Q     | 06/29/1998 |
| 8052     | 07/03/1998 |
| B77897   | 07/03/1998 |
| LZ230    | 07/06/1998 |
| B77930   | 07/10/1998 |
| PC6782   | 07/12/1998 |
| DM354331 | 07/13/1998 |
| S22942   | 07/13/1998 |
| MA003    | 07/16/1998 |
| W2286    | 07/16/1998 |
| Z55709   | 07/16/1998 |
| C3288    | 07/25/1998 |
| KF2961   | 07/30/1998 |
| W9925    | 07/30/1998 |

If you use a correlated subquery, such as [Figure 330: Query on page 1884](#), on a large table, you should index the **ship\_date** column to improve performance. Otherwise, this SELECT statement is inefficient, because it executes the subquery once for every row of the table. For information about indexing and performance issues, see the *Informix® Administrator's Guide* and your *Informix® Performance Guide*.

You cannot use a correlated subquery in the FROM clause, however, as the following invalid example illustrates:

```
SELECT item_num, stock_num FROM items,
  (SELECT stock_num FROM catalog
   WHERE stock_num = items.item_num) AS vtab;
```

The subquery in this example fails with error -24138:

```
ALL COLUMN REFERENCES IN A TABLE EXPRESSION MUST REFER
TO TABLES IN THE FROM CLAUSE OF THE TABLE EXPRESSION.
```

The database server issues this error because the **items.item\_num** column in the subquery also appears in the Projection clause of the outer query, but the FROM clause of the inner query specifies only the **catalog** table. The term *table expression* in the error message text refers to the set of column values or expressions that are returned by a subquery in the FROM clause, where only uncorrelated subqueries are valid.

## The EXISTS keyword

The keyword EXISTS is known as an *existential qualifier* because the subquery is true only if the outer SELECT, as the following query shows, finds at least one row.

Figure 332. Query

```
SELECT UNIQUE manu_name, lead_time
  FROM manufact
 WHERE EXISTS
   (SELECT * FROM stock
    WHERE description MATCHES '*shoe*'
     AND manufact.manu_code = stock.manu_code);
```

You can often construct a query with EXISTS that is equivalent to one that uses IN. The following query uses an IN predicate to construct a query that returns the same result as the query above.

Figure 333. Query

```
SELECT UNIQUE manu_name, lead_time
  FROM stock, manufact
 WHERE manufact.manu_code IN
   (SELECT manu_code FROM stock
    WHERE description MATCHES '*shoe*')
   AND stock.manu_code = manufact.manu_code;
```

Figure 332: Query on page 1886 and Figure 333: Query on page 1886 return rows for the manufacturers that produce a kind of shoe, as well as the lead time for ordering the product. The result shows the return values.

Figure 334. Query result

| manu_name | lead_time |
|-----------|-----------|
| Anza      | 5         |
| Hero      | 4         |
| Karsten   | 21        |
| Nikolus   | 8         |
| ProCycle  | 9         |
| Shimara   | 30        |

Add the keyword NOT to IN or to EXISTS to create a search condition that is the opposite of the condition in the preceding queries. You can also substitute !=ALL for NOT IN.

The following query shows two ways to do the same thing. One way might allow the database server to do less work than the other, depending on the design of the database and the size of the tables. To find out which query might be better, use the SET EXPLAIN command to get a listing of the query plan. SET EXPLAIN is discussed in your *Informix® Performance Guide* and *Informix® Guide to SQL: Syntax*.

Figure 335. Query

```
SELECT customer_num, company FROM customer
 WHERE customer_num NOT IN
   (SELECT customer_num FROM orders
    WHERE customer.customer_num = orders.customer_num);

SELECT customer_num, company FROM customer
 WHERE NOT EXISTS
   (SELECT * FROM orders
    WHERE customer.customer_num = orders.customer_num);
```

Each statement in the query above returns the following rows, which identify customers who have not placed orders.

Figure 336. Query result

```
customer_num company
102 Sports Spot
103 Phil's Sports
105 Los Altos Sports
107 Athletic Supplies
108 Quinn's Sports
109 Sport Stuff
113 Sportstown
114 Sporting Place
118 Blue Ribbon Sports
125 Total Fitness Sports
128 Phoenix University
```

The keywords EXISTS and IN are used for the set operation known as *intersection*, and the keywords NOT EXISTS and NOT IN are used for the set operation known as *difference*. These concepts are discussed in [Set operations on page 1893](#).

The following query performs a subquery on the **items** table to identify all the items in the **stock** table that have not yet been ordered.

Figure 337. Query

```
SELECT * FROM stock
WHERE NOT EXISTS
  (SELECT * FROM items
   WHERE stock.stock_num = items.stock_num
        AND stock.manu_code = items.manu_code);
```

The query returns the following rows.

Figure 338. Query result

```
stock_num manu_code description unit_price unit unit_descr
101 PRC bicycle tires $88.00 box 4/box
102 SHM bicycle brakes $220.00 case 4 sets/case
102 PRC bicycle brakes $480.00 case 4 sets/case
105 PRC bicycle wheels $53.00 pair pair
312 HRO racer goggles $72.00 box 12/box
313 SHM swim cap $72.00 box 12/box
313 ANZ swim cap $60.00 box 12/box
```

No logical limit exists to the number of subqueries a SELECT statement can have.

Perhaps you want to check whether information has been entered correctly in the database. One way to find errors in a database is to write a query that returns output only when errors exist. A subquery of this type serves as a kind of *audit query*, as the following query shows.

Figure 339. Query

```
SELECT * FROM items
WHERE total_price != quantity *
  (SELECT unit_price FROM stock
   WHERE stock.stock_num = items.stock_num
        AND stock.manu_code = items.manu_code);
```

The query returns only those rows for which the total price of an item on an order is not equal to the stock unit price times the order quantity. If no discount has been applied, such rows were probably entered incorrectly in the database. The query returns rows only when errors occur. If information is correctly inserted into the database, no rows are returned.

Figure 340. Query result

| item_num | order_num | stock_num | manu_code | quantity | total_price |
|----------|-----------|-----------|-----------|----------|-------------|
| 1        | 1004      | 1         | HRO       | 1        | \$960.00    |
| 2        | 1006      | 5         | NRG       | 5        | \$190.00    |

## Subqueries in DELETE and UPDATE statements

Besides subqueries within the WHERE clause of a SELECT statement, you can use subqueries within other data manipulation language (DML) statements, including the WHERE clause of DELETE and UPDATE statements.

Certain restrictions apply. If the FROM clause of a subquery returns more than one row, and the clause specifies the same table or view that the outer DML statement is modifying, the DML operation will succeed under these circumstances:

- The DML statement is not an INSERT statement.
- No SPL routine within the subquery references the table that is being modified.
- The subquery does not include a correlated column name.
- The subquery is specified using the Condition with Subquery syntax in the WHERE clause of the DELETE or UPDATE statement.

If any of these conditions are not met, the DML operation fails with error -360.

The following example updates the **stock** table by increasing the **unit\_price** value by 10% for a subset of prices. The WHERE clause specifies which prices to increase by applying the IN operator to the rows returned by a subquery that selects only the rows of the **stock** table where the **unit\_price** value is less than 75.

```
UPDATE stock SET unit_price = unit_price * 1.1
WHERE unit_price IN
(SELECT unit_price FROM stock WHERE unit_price < 75);
```

## Handle collections in SELECT statements

The database server provides the following SQL features to handle collection expressions:

### Collection subquery

A collection subquery takes a virtual table (the result of a subquery) and converts it into a collection.

A collection subquery always returns a collection of type MULTISSET. You can use a collection subquery to convert a Query result of relational data into a MULTISSET collection. For information about the collection data types, see the *Informix® Database Design and Implementation Guide*.

### Collection-derived table

A collection-derived table takes a collection and converts it into a virtual table.

Each element of the collection is constructed as a row in the collection-derived table. You can use a collection-derived table to access the individual elements of a collection.

The collection subquery and collection-derived table features represent inverse operations: the collection subquery converts row values from a relational table into a collection whereas the collection-derived table converts the elements of a collection into rows of a relational table.

## Collection subqueries

A collection subquery enables users to construct a collection expression from a subquery expression. A collection subquery uses the `MULTISET` keyword immediately before the subquery to convert the values returned into a `MULTISET` collection. When you use the `MULTISET` keyword before a subquery expression, however, the database server does not change the rows of the underlying table but only modifies a copy of those rows. For example, if a collection subquery is passed to a user-defined routine that modifies the collection, then a copy of the collection is modified but not the underlying table.

A collection subquery is an expression that can take either of the following forms:

```
MULTISET(SELECT expression1, expression2... FROM tab_name...)
MULTISET(SELECT ITEM expression FROM tab_name...)
```

## Omit the ITEM keyword in a collection subquery

If you omit the `ITEM` keyword in the collection subquery expression, the collection subquery is a `MULTISET` whose element type is always an unnamed `ROW` type. The fields of the unnamed `ROW` type match the data types of the expressions specified in the Projection clause of the subquery.

Suppose you create the following table that contains a column of type `MULTISET`:

```
CREATE TABLE tab2
(
  id_num INT,
  ms_col MULTISET(ROW(a INT) NOT NULL)
);
```

The following query shows how you might use a collection subquery in a `WHERE` clause to convert the rows of `INT` values that the subquery returns to a collection of type `MULTISET`. In this example, the database server returns rows when the `ms_col` column of `tab2` is equal to the result of the collection subquery expression

Figure 341. Query

```
SELECT id_num FROM tab2
WHERE ms_col = (MULTISET(SELECT int_col FROM tab1));
```

The query omits the `ITEM` keyword in the collection subquery, so the `INT` values the subquery returns are of type `MULTISET (ROW(a INT) NOT NULL)` that matches the data type of the `ms_col` column of `tab2`.

## Specify the ITEM keyword in a collection subquery

When the projection list of the subquery contains a single expression, you can preface the projection list of the subquery with the ITEM keyword to specify that the element type of the MULTISSET matches the data type of the subquery result. In other words, when you include the ITEM keyword, the database server does not put a row wrapper around the projection list. For example, if the subquery (that immediately follows the MULTISSET keyword) returns INT values, the collection subquery is of type MULTISSET(INT NOT NULL).

Suppose you create a function `int_func()` that accepts an argument of type MULTISSET(INT NOT NULL). The following query shows a collection subquery that converts rows of INT values to a MULTISSET and uses the collection subquery as an argument in the function `int_func()`.

Figure 342. Query

```
EXECUTE FUNCTION int_func(MULTISSET(SELECT ITEM int_col
FROM tab1
WHERE int_col BETWEEN 1 AND 10));
```

The query includes the ITEM keyword in the subquery, so the `int_col` values that the query returns are converted to a collection of type MULTISSET (INT NOT NULL). Without the ITEM keyword, the collection subquery would return a collection of type MULTISSET (ROW(a INT) NOT NULL).

## Collection subqueries in the FROM clause

Collection subqueries are valid in the FROM clause of SELECT statements, where the outer query can use the values returned by the subquery as a source of data.

The query examples in the section [Collection subqueries on page 1889](#) specify collection subqueries by using the TABLE keyword followed (within parentheses) by the MULTISSET keyword, followed by a subquery. This syntax is the Informix® extension to the ANSI/ISO standard for the SQL language.

In the FROM clause of the SELECT statement, and only in that context, you can substitute syntax that complies with the ANSI/ISO standard for SQL by specifying a subquery, omitting the TABLE and MULTISSET keywords and the nested parentheses, to specify a collection subquery.

The following query uses the Informix® extension syntax to join two collection subqueries in the FROM clause of the outer query:

Figure 343. Query

```
SELECT * FROM TABLE(MULTISSET(SELECT SUM(C1) FROM T1 GROUP BY C1)),
TABLE(MULTISSET(SELECT SUM(C1) FROM T2 GROUP BY C2));
```

The following logically equivalent query returns the same results as the query above by using ANSI/ISO-compliant syntax to join two derived tables in the FROM clause of the outer query:

Figure 344. Query

```
SELECT * FROM (SELECT SUM(C1) FROM T1 GROUP BY C1),
(SELECT SUM(C1) FROM T2 GROUP BY C2);
```

An advantage of this query over the TABLE(MULTISSET(SELECT ...)) Informix® extension version is that it can also be executed by any database server that supports the ANSI/ISO-compliant syntax in the FROM clause. For more information about syntax and restrictions for collection subqueries, see the *Informix® Guide to SQL: Syntax*.

## Collection-derived tables

A *collection-derived table* enables you to handle the elements of a collection expression as rows in a virtual table. Use the TABLE keyword in the FROM clause of a SELECT statement to create a collection-derived table. The database server supports collection-derived tables in SELECT, INSERT, UPDATE, and DELETE statements.

The following query uses a collection-derived table named **c\_table** to access elements from the **sales** column of the **sales\_rep** table in the **superstores\_demo** database. The **sales** column is a collection of an unnamed row type whose two fields, **month** and **amount**, store sales data. The query returns an element for **sales.amount** when **sales.month** equals 98-03. Because the inner select is itself an expression, it cannot return more than one column value per iteration of the outer query. The outer query specifies how many rows of the **sales\_rep** table are evaluated.

Figure 345. Query

```
SELECT (SELECT c_table.amount FROM TABLE (sales_rep.sales) c_table
WHERE c_table.month = '98-03')
FROM sales_rep;
```

Figure 346. Query result

```
(expression)
$47.22
$53.22
```

The following query uses a collection-derived table to access elements from the **sales** collection column where the **rep\_num** column equals 102. With a collection-derived table, you can specify aliases for the table and columns. If no table name is specified for a collection-derived table, the database server creates one automatically. This example specifies the derived column list **s\_month** and **s\_amount** for the collection-derived table **c\_table**.

Figure 347. Query

```
SELECT * FROM TABLE((SELECT sales FROM sales_rep
WHERE sales_rep.rep_num = 102)) c_table(s_month, s_amount);
```

Figure 348. Query result

| s_month | s_amount |
|---------|----------|
| 1998-03 | \$53.22  |
| 1998-04 | \$18.22  |

The following query creates a collection-derived table but does not specify a derived table or derived column names. The query returns the same result as [Figure 347: Query on page 1891](#) except the derived columns assume the default field names of the **sales** column in the **sales\_rep** table.

Figure 349. Query

```
SELECT * FROM TABLE((SELECT sales FROM sales_rep
WHERE sales_rep.rep_num = 102));
```

Figure 350. Query result

| month   | amount  |
|---------|---------|
| 1998-03 | \$53.22 |
| 1998-04 | \$18.22 |

**Restriction:** A collection-derived table is read-only, so it cannot be the target table of INSERT, UPDATE, or DELETE statements or the underlying table of an updatable cursor or view.

For a complete description of the syntax and restrictions on collection-derived tables, see the *Informix® Guide to SQL: Syntax*.

## ISO-compliant syntax for collection derived tables

The query examples in the topic [Collection-derived tables on page 1891](#) specify collection-derived tables by using the TABLE keyword followed by a SELECT statement enclosed within double parentheses. This syntax is the Informix® extension to the ANSI/ISO standard for the SQL language.

In the FROM clause of the SELECT statement, however, and only in that context, you can instead use syntax that complies with the ANSI/ISO standard for SQL by specifying a subquery, without the TABLE keyword or the nested parentheses, to define a collection-derived table.

The following example is logically equivalent to [Figure 347: Query on page 1891](#), and specifies the derived column list **s\_month** and **s\_amount** for the collection-derived table **c\_table**.

Figure 351. Query

```
SELECT * FROM (SELECT sales FROM sales_rep
WHERE sales_rep.rep_num = 102) c_table(s_month, s_amount);
```

Figure 352. Query result

| s_month | s_amount |
|---------|----------|
| 1998-03 | \$53.22  |
| 1998-04 | \$18.22  |

As in the Informix® extension syntax, declaring names for the derived table or for its columns is optional, rather than required. The following query uses ANSI/ISO-compliant syntax for a derived table in the FROM clause of the outer query, and produces the same results as [Figure 349: Query on page 1891](#):

Figure 353. Query

```
SELECT * FROM (SELECT sales FROM sales_rep
WHERE sales_rep.rep_num = 102);
```

Figure 354. Query result

| month   | amount  |
|---------|---------|
| 1998-03 | \$53.22 |
| 1998-04 | \$18.22 |

## Set operations

The standard set operations *union*, *intersection*, and *difference* let you manipulate database information. These three operations let you use SELECT statements to check the integrity of your database after you perform an update, insert, or delete. They can be useful when you transfer data to a history table, for example, and want to verify that the correct data is in the history table before you delete the data from the original table.

## Union

A union operation uses the UNION operator to combine two queries into a single *compound query*. You can use the UNION operator between two or more SELECT statements to produce a temporary table that contains rows that exist in any or all of the original tables. You can also use the UNION operator in the definition of a view.

You cannot use the UNION operator inside a subquery in the following contexts

- in the Projection clause of the SELECT statement
- in the WHERE clause of the SELECT, INSERT, DELETE, or UPDATE statement.

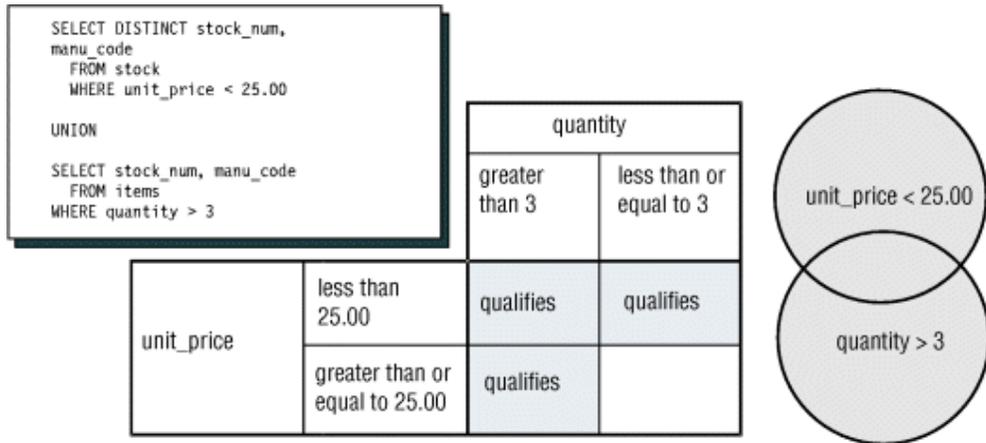

The UNION operator is valid, however, in a subquery in the FROM clause of the SELECT statement, as in the following example:

```
SELECT * FROM (SELECT col1 FROM tab1 WHERE col1 = 100) AS vtab1(c1),
              (SELECT col1 FROM tab2 WHERE col1 = 10
               UNION ALL
               SELECT col1 FROM tab1 WHERE col1 < 50 ) AS vtab2(vc1);
```

HCL Informix® does not support ordering on ROW types. Because a UNION operation requires a sort to remove duplicate values, you cannot use a UNION operator when either query in the union operation includes ROW type data. However, the database server does support UNION ALL with ROW type data, because this type of operation does not require a sort.

The following figure illustrates the UNION set operation.

Figure 355. The Union set operation

The UNION keyword selects all rows from the two queries, removes duplicates, and returns what is left. Because the results of the queries are combined into a single result, the projection list in each query must have the same number of columns. Also, the corresponding columns that are selected from each table must contain compatible data types (CHARACTER data type columns must be the same length), and these corresponding columns must all allow or all disallow NULL values.

For the complete syntax of the SELECT statement and the UNION operator, see the *Informix® Guide to SQL: Syntax*. For information specific to the Informix® ESQL/C product and any limitations that involve the INTO clause and compound queries, see the *Informix® ESQL/C Programmer's Manual*.

The following query performs a union on the **stock\_num** and **manu\_code** columns in the **stock** and **items** tables.

Figure 356. Query

```
SELECT DISTINCT stock_num, manu_code FROM stock
WHERE unit_price < 25.00
UNION
SELECT stock_num, manu_code FROM items
WHERE quantity > 3;
```

The query selects those items that have a unit price of less than \$25.00 or that have been ordered in quantities greater than three and lists their **stock\_num** and **manu\_code**, as the result shows.

Figure 357. Query result

```
stock_num manu_code

5 ANZ
5 NRG
5 SMT
9 ANZ
103 PRC
106 PRC
201 NKL
301 KAR
302 HRO
302 KAR
```

## ORDER BY clause with UNION

As the following query shows, when you include an ORDER BY clause, it must follow the final SELECT statement and use an integer, not an identifier, to refer to the ordering column. Ordering takes place after the set operation is complete.

Figure 358. Query

```
SELECT DISTINCT stock_num, manu_code FROM stock
  WHERE unit_price < 25.00
UNION
SELECT stock_num, manu_code FROM items
  WHERE quantity > 3
  ORDER BY 2;
```

The compound query above selects the same rows as [Figure 356: Query on page 1894](#) but displays them in order of the manufacturer code, as the result shows.

Figure 359. Query result

```
stock_num manu_code
      5 ANZ
      9 ANZ
     302 HRO
     301 KAR
     302 KAR
     201 NKL
      5 NRG
     103 PRC
     106 PRC
      5 SMT
```

## The UNION ALL keywords

By default, the UNION keyword excludes duplicate rows. To retain the duplicate values, add the optional keyword ALL, as the following query shows.

Figure 360. Query

```
SELECT stock_num, manu_code FROM stock
  WHERE unit_price < 25.00
UNION ALL
SELECT stock_num, manu_code FROM items
  WHERE quantity > 3
  ORDER BY 2
  INTO TEMP stock item;
```

The query uses the UNION ALL keywords to unite two SELECT statements and adds an INTO TEMP clause after the final SELECT to put the results into a temporary table. It returns the same rows as [Figure 358: Query on page 1895](#) but also includes duplicate values.

Figure 361. Query result

```

stock_num manu_code
          9 ANZ
          5 ANZ
          9 ANZ
          5 ANZ
          9 ANZ
          :
          5 NRG
          5 NRG
         103 PRC
         106 PRC
          5 SMT
          5 SMT

```

## Different column names

Corresponding columns in the Projection clauses for the combined queries must have compatible data types, but the columns do not need to use the same column names.

The following query selects the **state** column from the **customer** table and the corresponding **code** column from the **state** table.

Figure 362. Query

```

SELECT DISTINCT state FROM customer
   WHERE customer_num BETWEEN 120 AND 125
UNION
SELECT DISTINCT code FROM state
   WHERE sname MATCHES '*a';

```

The query returns state code abbreviations for customer numbers 120 through 125 and for states whose **sname** ends in **a**.

Figure 363. Query result

```

state
AK
AL
AZ
CA
DE

SD
VA
WV

```

In compound queries, the column names or display labels in the first SELECT statement are the ones that appear in the results. Thus, in the query, the column name **state** from the first SELECT statement is used instead of the column name **code** from the second.

## UNION with multiple tables

The following query performs a union on three tables. The maximum number of unions depends on the practicality of the application and any memory limitations.

Figure 364. Query

```
SELECT stock_num, manu_code FROM stock
  WHERE unit_price > 600.00
UNION ALL
SELECT stock_num, manu_code FROM catalog
  WHERE catalog_num = 10025
UNION ALL
SELECT stock_num, manu_code FROM items
  WHERE quantity = 10
  ORDER BY 2;
```

The query selects items where the **unit\_price** in the **stock** table is greater than \$600, the **catalog\_num** in the **catalog** table is 10025, or the **quantity** in the **items** table is 10; and the query orders the data by **manu\_code**. The result shows the return values.

Figure 365. Query result

```
stock_num manu_code
      5 ANZ
      9 ANZ
      8 ANZ
      4 HSK
      1 HSK
     203 NKL
      5 NRG
     106 PRC
     113 SHM
```

## A literal in the Projection clause

The following query uses a literal in the projection list to tag the output of part of a union so it can be distinguished later. The tag is given the label **sortkey**. The query uses **sortkey** to order the retrieved rows.

Figure 366. Query

```
SELECT '1' sortkey, lname, fname, company,
  city, state, phone
  FROM customer x
  WHERE state = 'CA'
UNION
SELECT '2' sortkey, lname, fname, company,
  city, state, phone
  FROM customer y
  WHERE state <> 'CA'
  INTO TEMP calcust;
SELECT * FROM calcust
  ORDER BY 1;
```

The query creates a list in which the customers from California appear first.

Figure 367. Query result

```
sortkey 1
lname   Baxter
fname   Dick
company Blue Ribbon Sports
city    Oakland
state   CA
phone   415-655-0011

sortkey 1
lname   Beatty
fname   Lana
company Sportstown
city    Menlo Park
state   CA
phone   415-356-9982
:
sortkey 2
lname   Wallack
fname   Jason
company City Sports
city    Wilmington
state   DE
phone   302-366-7511
```

## A FIRST clause

You can use the FIRST clause to select the first rows that result from a union query. The following query uses a FIRST clause to return the first five rows of a union between the **stock** and **items** tables.

Figure 368. Query

```
SELECT FIRST 5 DISTINCT stock_num, manu_code
  FROM stock
 WHERE unit_price < 55.00
UNION
SELECT stock_num, manu_code
  FROM items
 WHERE quantity > 3;
```

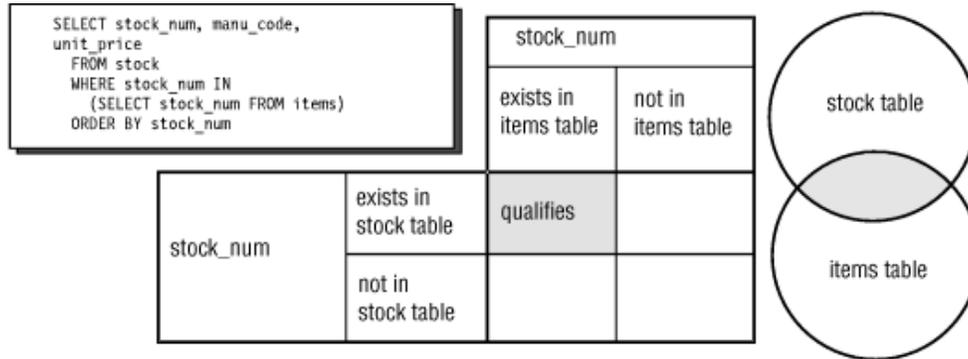

Figure 369. Query result

```
stock_num manu_code
         5 NRG
         5 ANZ
         6 SMT
         6 ANZ
         9 ANZ
```

## Intersection

The *intersection* of two sets of rows produces a table that contains rows that exist in both the original tables. Use the keyword EXISTS or IN to introduce subqueries that show the intersection of two sets. The following figure illustrates the intersection set operation.

Figure 370. The intersection set operation

The following query is an example of a nested SELECT statement that shows the intersection of the **stock** and **items** tables. The result contains all the elements that appear in both sets and returns the following rows.

Figure 371. Query

```
SELECT stock_num, manu_code, unit_price FROM stock
WHERE stock_num IN
(SELECT stock_num FROM items)
ORDER BY stock_num;
```

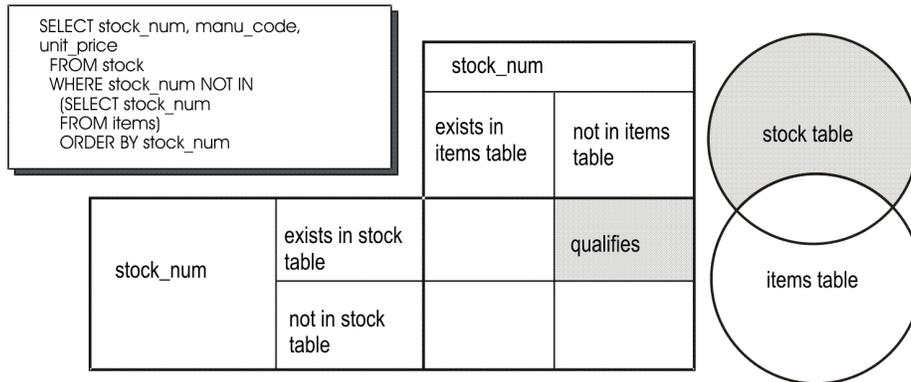

Figure 372. Query result

```
stock_num manu_code unit_price
1 HRO $250.00
1 HSK $800.00
1 SMT $450.00
2 HRO $126.00
3 HSK $240.00
3 SHM $280.00
:
306 SHM $190.00
307 PRC $250.00
309 HRO $40.00
309 SHM $40.00
```

## Difference

The *difference* between two sets of rows produces a table that contains rows in the first set that are not also in the second set. Use the keywords NOT EXISTS or NOT IN to introduce subqueries that show the difference between two sets. The following figure illustrates the difference set operation.

Figure 373. The difference set operation

The following query is an example of a nested SELECT statement that shows the difference between the **stock** and **items** tables.

Figure 374. Query

```
SELECT stock_num, manu_code, unit_price FROM stock
WHERE stock_num NOT IN
(SELECT stock_num FROM items)
ORDER BY stock_num;
```

The result contains all the elements from only the first set, which returns 17 rows.

Figure 375. Query result

| stock_num | manu_code | unit_price |
|-----------|-----------|------------|
| 102       | PRC       | \$480.00   |
| 102       | SHM       | \$220.00   |
| 106       | PRC       | \$23.00    |
| :         |           |            |
| 312       | HRO       | \$72.00    |
| 312       | SHM       | \$96.00    |
| 313       | ANZ       | \$60.00    |
| 313       | SHM       | \$72.00    |

## Summary

This chapter builds on concepts introduced in [Compose SELECT statements on page 1773](#). It provides sample syntax and results for more advanced kinds of SELECT statements, which are used to query a relational database. This chapter presents the following material:

- Introduces the GROUP BY and HAVING clauses, which you can use with aggregates to return groups of rows and apply conditions to those groups
- Shows how to join a table to itself with a self-join to compare values in a column with other values in the same column and to identify duplicates
- Explains how an outer join treats two or more tables asymmetrically, and provides examples of the four kinds of outer join using both the Informix® extension and ANSI join syntax.

- Describes how to nest a SELECT statement in the WHERE clause of another SELECT statement to create correlated and uncorrelated subqueries and shows how to use aggregate functions in subqueries
- Describes how to nest SELECT statements in the FROM clause of another SELECT statement to specify uncorrelated subqueries whose results are a data source for the outer SELECT statement
- Demonstrates how to use the keywords ALL, ANY, EXISTS, IN, and SOME to create subqueries, and the effect of adding the keyword NOT or a relational operator
- Describes how to use collection subqueries to convert relational data to a collection of type MULTISSET and how to use collection-derived tables to access elements within a collection
- Discusses the union, intersection, and difference set operations
- Shows how to use the UNION and UNION ALL keywords to create compound queries that consist of two or more SELECT statements

## Modify data

This section describes how to modify the data in your databases. Modifying data is fundamentally different from querying data. Querying data involves examining the contents of tables. To modify data involves changing the contents of tables.

### Modify data in your database

The following statements modify data:

- DELETE
- INSERT
- MERGE
- UPDATE

Although these SQL statements are relatively simple when compared with the more advanced SELECT statements, use them carefully because they change the contents of the database.

Think about what happens if the system hardware or software fails during a query. Even if the effect on the application is severe, the database itself is unharmed. However, if the system fails while a modification is under way, the state of the database is in doubt. Obviously, a database in an uncertain state has far-reaching implications. Before you delete, insert, or update rows in a database, ask yourself the following questions:

- Is user access to the database and its tables secure; that is, are specific users given limited database and table-level privileges?
- Does the modified data preserve the existing integrity of the database?
- Are systems in place that make the database relatively immune to external events that might cause system or hardware failures?

If you cannot answer yes to each of these questions, do not panic. Solutions to all these problems are built into the Informix® database servers. After a description of the statements that modify data, this section discusses these solutions. The *Informix® Database Design and Implementation Guide* covers these topics in greater detail.

## Delete rows

The DELETE statement removes any row or combination of rows from a table. You cannot recover a deleted row after the transaction is committed. (Transactions are discussed under [Interrupted modifications on page 1935](#). For now, think of a transaction and a statement as the same thing.)

When you delete a row, you must also be careful to delete any rows of other tables whose values depend on the deleted row. If your database enforces referential constraints, you can use the ON DELETE CASCADE option of the CREATE TABLE or ALTER TABLE statements to allow deletes to cascade from one table in a relationship to another. For more information on referential constraints and the ON DELETE CASCADE option, refer to [Referential integrity on page 1926](#).

## Delete all rows of a table

The DELETE statement specifies a table and usually contains a WHERE clause that designates the row or rows that are to be removed from the table. If the WHERE clause is left out, all rows are deleted.

**Important:** Do not execute the following statement.

```
DELETE FROM customer;
```

You can write DELETE statements with or without the FROM keyword.

```
DELETE customer;
```

Because these DELETE statements do not contain a WHERE clause, all rows from the **customer** table are deleted. If you attempt an unconditional delete using the DB-Access menu options, the program warns you and asks for confirmation. However, an unconditional DELETE from within a program can occur without warning.

If you want to delete rows from a table named **from**, you must first set the **DELIMIDENT** environment variable, or qualify the name of the table with the name of its owner:

```
DELETE legree.from;
```

For more information about delimited identifiers and **DELIMIDENT** environment variable, see the descriptions of the Quoted String expression and of the Identifier segment in the *Informix® Guide to SQL: Syntax*.

## Delete all rows using TRUNCATE

You can use the TRUNCATE statement to quickly remove all rows from a table and also remove all corresponding index data. You cannot recover deleted rows after the transaction is committed. You can use the TRUNCATE statement on tables that contain any type of columns, including smart large objects.

Removing rows with the TRUNCATE statement is faster than removing them with the DELETE statement. It is not necessary to run the UPDATE STATISTICS statement immediately after the TRUNCATE statement. After TRUNCATE executes successfully, HCL Informix® automatically updates the statistics and distributions for the table and for its indexes in the system catalog to show no rows in the table or in its dbspace partitions.

For a description of logging, see [Transaction logging on page 1936](#).

TRUNCATE is a data-definition language statement that does not activate DELETE triggers, if any are defined on the table. For an explanation on using triggers, see [Create and use triggers on page 2068](#).

If the table that the TRUNCATE statement specifies is a typed table, a successful TRUNCATE operation removes all the rows and B-tree structures from that table and from all its subtables within the table hierarchy. TRUNCATE has no equivalent to the ONLY keyword of the DELETE statement to restricts the operation to a single table within the typed table hierarchy.

always logs the TRUNCATE operation, even for a non-logging table. In databases that support transaction logging, only the COMMIT WORK or ROLLBACK WORK statement of SQL is valid after TRUNCATE within the same transaction. For information on the performance impact of using the TRUNCATE statement, see your *Informix® Performance Guide*. For the complete syntax, see the *Informix® Guide to SQL: Syntax*.

## Delete specified rows

The WHERE clause in a DELETE statement has the same form as the WHERE clause in a SELECT statement. You can use it to designate exactly which row or rows should be deleted. You can delete a customer with a specific customer number, as the following example shows:

```
DELETE FROM customer WHERE customer_num = 175;
```

In this example, because the **customer\_num** column has a unique constraint, you can ensure that no more than one row is deleted.

## Delete selected rows

You can also choose rows that are based on nonindexed columns, as the following example shows:

```
DELETE FROM customer WHERE company = 'Druid Cyclery';
```

Because the column that is tested does not have a unique constraint, this statement might delete more than one row. (Druid Cyclery might have two stores, both with the same name but different customer numbers.)

To find out how many rows a DELETE statement affects, select the count of qualifying rows from the **customer** table for Druid Cyclery.

```
SELECT COUNT(*) FROM customer WHERE company = 'Druid Cyclery';
```

You can also select the rows and display them to ensure that they are the ones you want to delete.

Using a SELECT statement as a test is only an approximation, however, when the database is available to multiple users concurrently. Between the time you execute the SELECT statement and the subsequent DELETE statement, other users could have modified the table and changed the result. In this example, another user might perform the following actions:

- Insert a new row for another customer named Druid Cyclery
- Delete one or more of the Druid Cyclery rows before you insert the new row
- Update a Druid Cyclery row to have a new company name, or update some other customer to have the name Druid Cyclery.

Although it is not likely that other users would do these things in that brief interval, the possibility does exist. This same problem affects the UPDATE statement. Ways of addressing this problem are discussed under [Concurrency and locks on page 1938](#), and in greater detail in [Programming for a multiuser environment on page 1978](#).

Another problem you might encounter is a hardware or software failure before the statement finishes. In this case, the database might have deleted no rows, some rows, or all specified rows. The state of the database is unknown, which is undesirable. To prevent this situation, use transaction logging, as [Interrupted modifications on page 1935](#) discusses.

## Delete rows that contain row types

When a row contains a column that is defined on a ROW type, you can use dot notation to specify that the only rows deleted are those that contain a specific field value. For example, the following statement deletes only those rows from the **employee** table in which the value of the **city** field in the **address** column is `San Jose`:

```
DELETE FROM employee
WHERE address.city = 'San Jose';
```

In the preceding statement, the **address** column might be a named ROW type or an unnamed ROW type. The syntax you use to specify field values of a ROW type is the same.

## Delete rows that contain collection types

When a row contains a column that is defined on a collection type, you can search for a particular element in a collection and delete the row or rows in which that element is found. For example, the following statement deletes rows in which the **direct\_reports** column contains a collection with the element `Baker`:

```
DELETE FROM manager
WHERE 'Baker' IN direct_reports;
```

## Delete rows from a supertable

When you delete the rows of a supertable, the scope of the delete is a supertable and its subtables. Suppose you create a supertable **person** that has two subtables **employee** and **sales\_rep** defined under it. The following DELETE statement on the **person** table can delete rows from all the tables **person**, **employee**, and **sales\_rep**:

```
DELETE FROM person
WHERE name = 'Walker';
```

To limit a delete to rows of the supertable only, you must use the **ONLY** keyword in the **DELETE** statement. For example, the following statement deletes rows of the **person** table only:

```
DELETE FROM ONLY(person)
WHERE name = 'Walker';
```

**Important:** Use caution when you delete rows from a supertable because the scope of a delete on a supertable includes the supertable and all its subtables.

## Complicated delete conditions

The **WHERE** clause in a **DELETE** statement can be almost as complicated as the one in a **SELECT** statement. It can contain multiple conditions that are connected by **AND** and **OR**, and it might contain subqueries.

Suppose you discover that some rows of the **stock** table contain incorrect manufacturer codes. Rather than update them, you want to delete them so that they can be re-entered. You know that these rows, unlike the correct ones, have no matching rows in the **manufact** table. The fact that these incorrect rows have no matching rows in the **manufact** table allows you to write a **DELETE** statement such as the one in the following example:

```
DELETE FROM stock
WHERE 0 = (SELECT COUNT(*) FROM manufact
WHERE manufact.manu_code = stock.manu_code);
```

The subquery counts the number of rows of **manufact** that match; the count is 1 for a correct row of **stock** and 0 for an incorrect one. The latter rows are chosen for deletion.

**Tip:** One way to develop a **DELETE** statement with a complicated condition is to first develop a **SELECT** statement that returns precisely the rows to be deleted. Write it as `SELECT *`; when it returns the desired set of rows, change `SELECT *` to read `DELETE` and execute it once more.

The **WHERE** clause of a **DELETE** statement cannot use a subquery that tests the same table. That is, when you delete from **stock**, you cannot use a subquery in the **WHERE** clause that also selects from **stock**.

The key to this rule is in the **FROM** clause. If a table is named in the **FROM** clause of a **DELETE** statement, it cannot also appear in the **FROM** clause of a subquery of the **DELETE** statement.

## The Delete clause of MERGE

Instead of writing a subquery in the **WHERE** clause, you can use the **MERGE** statement to join rows from a source tables and a target table, and then delete from the target the rows that match the join condition. (The source table in a Delete **MERGE** can also be a collection-derived table whose rows are the result of a query that joins other tables and views, but in the example that follows, the source is a single table.)

As in the previous example, suppose you discover that some rows of the **stock** table contain incorrect manufacturer codes. Rather than update them, you want to delete them so that they can be re-entered. You can use the MERGE statement that specifies **stock** as the target table, **manufact** as the source table, a join condition in the ON clause, and with the Delete clause for the **stock** rows with incorrect manufacturer codes, as in the following example:

```
MERGE INTO stock USING manufact
  ON stock.manu_code != manufact.manu_code
 WHEN MATCHED THEN DELETE;
```

In this example, all the rows of the **stock** table for which the join condition in the ON clause is satisfied will be deleted. Here the inequality predicate in the join condition (`stock.manu_code != manufact.manu_code`) evaluates to true for the rows of **stock** in which the **manu\_code** column value is not equal to any **manu\_code** value in the **manufact** table.

The **source** table that is being joined to the *target* table must be listed in the USING clause.

The MERGE statement can also update rows of the target table, or insert data from the source table into the target table, according to whether or not the row satisfies the condition that the ON clause specifies for joining the target and source tables. A single MERGE statement can also combine both DELETE and INSERT operations, or can combine both UPDATE and INSERT operations without deleting any rows. The source table is unchanged by the MERGE statement. For more information on the syntax and restrictions for Delete merges, Insert merges, and Update merges, see the description of the MERGE statement in the *Informix® Guide to SQL: Syntax*.

## Insert rows

The INSERT statement adds a new row, or rows, to a table. The statement has two basic functions. It can create a single new row using column values you supply, or it can create a group of new rows using data selected from other tables.

## Single rows

In its simplest form, the INSERT statement creates one new row from a list of column values and puts that row in the table.

The following statement shows how to add a row to the **stock** table:

```
INSERT INTO stock
  VALUES (115, 'PRC', 'tire pump', 108, 'box', '6/box');
```

The **stock** table has the following columns:

### **stock\_num**

A number that identifies the type of merchandise.

### **manu\_code**

A foreign key to the **manufact** table.

### **description**

A description of the merchandise.

**unit\_price**

The unit price of the merchandise.

**unit**

The unit of measure

**unit\_descr**

Characterizes the unit of measure.

The values that are listed in the VALUES clause in the preceding example have a one-to-one correspondence with the columns of the **stock** table. To write a VALUES clause, you must know the columns of the tables as well as their sequence from first to last.

## Possible column values

The VALUES clause accepts only constant values, not general SQL expressions. You can supply the following values:

- Literal numbers
- Literal DATETIME values
- Literal INTERVAL values
- Quoted strings of characters
- The word NULL for a NULL value
- The word TODAY for the current date
- The word CURRENT (or SYSDATE) for the current date and time
- The word USER for your authorization identifier
- The word DBSERVERNAME (or SITENAME) for the name of the computer where the database server is running

**Note:** An alternative to the INSERT statement is the MERGE statement, which can use the same VALUES clause syntax as the INSERT statement to insert rows into a table. The MERGE statement performs an outer join of a source table and a target table, and then inserts into the target table any rows in the result set of the join for which the join predicate evaluates to FALSE. The source table is unchanged by the MERGE statement. Besides inserting rows, the MERGE statement can optionally combine both DELETE and INSERT operations, or combine both UPDATE and INSERT operations. For more information about the syntax and the restrictions on Insert merges, Delete merges, and Update merges, see the description of the MERGE statement in the *Informix® Guide to SQL: Syntax*.

## Restrictions on column values

Some columns of a table might not allow null values. If you attempt to insert NULL in such a column, the statement is rejected. Other columns in the table might not permit duplicate values. If you specify a value that is a duplicate of one that is

already in such a column, the statement is rejected. Some columns might even restrict the possible column values allowed. Use data integrity constraints to restrict columns. For more information, see [Data integrity on page 1924](#).

 **Restriction:** Do not specify the currency symbols for columns that contain money values. Just specify the numeric value of the amount.

The database server can convert between numeric and character data types. You can give a string of numeric characters (for example, '10075.6') as the value of a numeric column. The database server converts the numeric string to a number. An error occurs only if the string does not represent a number.

You can specify a number or a date as the value for a character column. The database server converts that value to a character string. For example, if you specify TODAY as the value for a character column, a character string that represents the current date is used. (The **DBDATE** environment variable specifies the format that is used.)

## Serial data types

A table can have only one column of the SERIAL data type. It can also have either a SERIAL8 column or a BIGSERIAL column.

When you insert values, specify the value zero for the serial column. The database server generates the next actual value in sequence. Serial columns do not allow NULL values.

You can specify a nonzero value for a serial column (as long as it does not duplicate any existing value in that column), and the database server uses the value. That nonzero value might set a new starting point for values that the database server generates. (The next value the database server generates for you is one greater than the maximum value in the column.)

## List specific column names

You do not have to specify values for every column. Instead, you can list the column names after the table name and then supply values for only those columns that you named. The following example shows a statement that inserts a new row into the **stock** table:

```
INSERT INTO stock (stock_num, description, unit_price, manu_code)
VALUES (115, 'tyre pump ', 114, 'SHM');
```

Only the data for the stock number, description, unit price, and manufacturer code is provided. The database server supplies the following values for the remaining columns:

- It generates a serial number for an unlisted serial column.
- It generates a default value for a column with a specific default associated with it.
- It generates a NULL value for any column that allows nulls but it does not specify a default value for any column that specifies NULL as the default value.

You must list and supply values for all columns that do not specify a default value or do not permit NULL values.

You can list the columns in any order, as long as the values for those columns are listed in the same order. For information about how to designate null or default values for a column, see the *Informix® Database Design and Implementation Guide*.

After the INSERT statement in the preceding example is executed, the following new row is inserted into the **stock** table:

```
stock_num manu_code  description  unit_price unit  unit_descr
      115      SHM  tyre pump           114
```

Both **unit** and **unit\_descr** are blank, which indicates that NULL values exist in those two columns. Because the **unit** column permits NULL values, the number of tire pumps that can be purchased for \$114 is not known. Of course, if a default value of `box` were specified for this column, then `box` would be the unit of measure. In any case, when you insert values into specific columns of a table, pay attention to what data is needed for that row.

## Insert rows into typed tables

You can insert rows into a typed table in the same way you insert rows into a table not based on a ROW type.

When a typed table contains a row-type column (the named ROW type that defines the typed table contains a nested ROW type), you insert into the row-type column in the same way you insert into a row-type column for a table not based on a ROW type. The following section, [Syntax rules for inserts on columns on page 1909](#), describes how to perform inserts into row-type columns.

This section uses row types **zip\_t**, **address\_t**, and **employee\_t** and typed table **employee** for examples. The following figure shows the SQL syntax that creates the row types and table.

Figure 376. SQL syntax that creates the row types and table.

```
CREATE ROW TYPE zip_t
(
  z_code   CHAR(5),
  z_suffix CHAR(4)
);

CREATE ROW TYPE address_t
(
  street  VARCHAR(20),
  city    VARCHAR(20),
  state   CHAR(2),
  zip     zip_t
);

CREATE ROW TYPE employee_t
(
  name     VARCHAR(30),
  address  address_t,
  salary   INTEGER
);

CREATE TABLE employee OF TYPE employee_t;
```

## Syntax rules for inserts on columns

The following syntax rules apply for inserts on columns that are defined on named ROW types or unnamed ROW types:

- Specify the ROW constructor before the field values to be inserted.
- Enclose the field values of the ROW type in parentheses.
- Cast the ROW expression to the appropriate named ROW type (for named ROW types).

## Rows that contain named row types

The following statement shows you how to insert a row into the **employee** table in [Figure 377: Create the student table. on page 1910](#):

```
INSERT INTO employee
VALUES ('Poole, John',
ROW('402 High St', 'Willits', 'CA',
ROW(69055,1450))::address_t, 35000 );
```

Because the **address** column of the **employee** table is a named ROW type, you must use a cast operator and the name of the ROW type (**address\_t**) to insert a value of type **address\_t**.

## Rows that contain unnamed row types

Suppose you create the table that the following figure shows. The **student** table defines the **s\_address** column as an unnamed row type.

Figure 377. Create the student table.

```
CREATE TABLE student
(
s_name      VARCHAR(30),
s_address   ROW(street VARCHAR (20), city VARCHAR(20),
                state CHAR(2), zip VARCHAR(9)),
                grade_point_avg DECIMAL(3,2)
);
```

The following statement shows you how to add a row to the **student** table. To insert into the unnamed row-type column **s\_address**, use the ROW constructor but do not cast the row-type value.

```
INSERT INTO student
VALUES ('Keene, Terry',
ROW('53 Terra Villa', 'Wheeling', 'IL', '45052'),
3.75);
```

## Specify NULL values for row types

The fields of a row-type column can contain NULL values. You can specify NULL values either at the level of the column or the field.

The following statement specifies a NULL value at the column level to insert NULL values for all fields of the **s\_address** column. When you insert a NULL value at the column level, do not include the ROW constructor.

```
INSERT INTO student VALUES ('Brauer, Howie', NULL, 3.75);
```

When you insert a NULL value for particular fields of a ROW type, you must include the ROW constructor. The following INSERT statement shows how you might insert NULL values into particular fields of the **address** column of the **employee** table. (The **address** column is defined as a named ROW type.)

```
INSERT INTO employee
VALUES (
  'Singer, John',
  ROW(NULL, 'Davis', 'CA',
  ROW(97000, 2000))::address_t, 67000
);
```

When you specify a NULL value for the field of a ROW type, you do not need to explicitly cast the NULL value when the ROW type occurs in an INSERT statement, an UPDATE statement, or a program variable assignment.

The following INSERT statement shows how you insert NULL values for the **street** and **zip** fields of the **s\_address** column for the **student** table:

```
INSERT INTO student
VALUES(
  'Henry, John',
  ROW(NULL, 'Seattle', 'WA', NULL), 3.82
);
```

## Insert rows into supertables

No special considerations exist when you insert a row into a supertable. An INSERT statement applies only to the table that is specified in the statement. For example, the following statement inserts values into the supertable but does not insert values into any subtables:

```
INSERT INTO person
VALUES (
  'Poole, John',
  ROW('402 Sapphire St.', 'Elmondo', 'CA', '69055'),
  345605900
);
```

## Insert collection values into columns

This section describes how to insert a collection value into a column with DB-Access. It does not discuss how to insert individual elements into a collection column. To access or modify the individual elements of a collection, use an SPL routine

or Informix® ESQL/C program. For information about how to create Informix® ESQL/C programs to insert into a collection, see the *Informix® ESQL/C Programmer's Manual*. For information about how to create an SPL routine to insert into a collection, see [Create and use SPL routines on page 1998](#).

The examples that this section provides are based on the **manager** table in the following figure. The **manager** table contains both simple and nested collection types.

Figure 378. Create the manager table.

```
CREATE TABLE manager
(
  mgr_name      VARCHAR(30),
  department    VARCHAR(12),
  direct_reports SET(VARCHAR(30) NOT NULL),
  projects      LIST(ROW(pro_name VARCHAR(15),
                        pro_members SET(VARCHAR(20) NOT NULL))
                    NOT NULL)
);
```

## Insert values into simple collections and nested collections

When you insert values into a row that contains a collection column, you insert the values of all the elements that the collection contains as well as values for the other columns. For example, the following statement inserts a single row into the **manager** table, which includes columns for both simple collections and nested collections:

```
INSERT INTO manager(mgr_name, department,
  direct_reports, projects)
VALUES
(
  'Sayles', 'marketing',
  "SET{'Simonian', 'Waters', 'Adams', 'Davis', 'Jones'}",
  LIST{
    ROW('voyager_project', SET{'Simonian', 'Waters',
      'Adams', 'Davis'}),
    ROW('horizon_project', SET{'Freeman', 'Jacobs',
      'Walker', 'Smith', 'Cannan'}),
    ROW('sapphire_project', SET{'Villers', 'Reeves',
      'Doyle', 'Strongin'})
  }
);
```

## Insert NULL values into a collection that contains a row type

To insert values into a collection that is a ROW type, you must specify a value for each field in the ROW type.

In general, NULL values are not allowed in a collection. However, if the element type of the collection is a ROW type, you can insert NULL values into individual fields of the row type.

You can also specify an *empty collection*. An empty collection is a collection that contains no elements. To specify an empty collection, use the braces ({}). For example, the following statement inserts data into a row in the **manager** table but specifies that the **direct\_reports** and **projects** columns are empty collections:

```
INSERT INTO manager
VALUES ('Sayles', 'marketing', "SET{}",
"LIST{ROW(NULL, SET{})}"
);
```

A collection column cannot contain NULL elements. The following statement returns an error because NULL values are specified as elements of collections:

```
INSERT INTO manager
VALUES ('Cole', 'accounting', "SET{NULL}",
"LIST{ROW(NULL, ""SET{NULL}""}")"
```

The following syntax rules apply for performing inserts and updates on collection types:

- Use braces ({} ) to demarcate the elements that each collection contains.
- If the collection is a nested collection, use braces ({} ) to demarcate the elements of both the inner and outer collections.

## Insert smart large objects

When you use the INSERT statement to insert an object into a **BLOB** or **CLOB** column, the database server stores the object in an sbospace, rather than the table. The database server provides SQL functions that you can call from within an INSERT statement to import and export BLOB or CLOB data, otherwise known as smart large objects. For a description of these functions, see [Smart large object functions on page 1846](#).

The following INSERT statement uses the filetoblob() and filetoclob() functions to insert a row of the **inmate** table. ([Figure 231: Create the inmate and fbi\\_list tables. on page 1846](#) defines the **inmate** table.)

```
INSERT INTO inmate
VALUES (437, FILETOBLOB('datafile', 'client'),
FILETOCLOB('tmp/text', 'server'));
```

In the preceding example, the first argument for the FILETOBLOB() and FILETOCLOB() functions specifies the path of the source file to be copied into the **BLOB** and **CLOB** columns of the **inmate** table, respectively. The second argument for each function specifies whether the source file is located on the client computer ('client') or server computer ('server'). To specify the path of a file name in the function argument, apply the following rules:

- If the source file resides on the server computer, you must specify the full path name to the file (not the path name relative to the current working directory).
- If the source file resides on the client computer, you can specify either the full or relative path name to the file.

**Note:** For CLOB columns, direct strings can also be used in place of FILETOCLOB() function.

## Multiple rows and expressions

The other major form of the INSERT statement replaces the VALUES clause with a SELECT statement. This feature allows you to insert the following data:

- Multiple rows with only one statement (each time the SELECT statement returns a row, a row is inserted)
- Calculated values (the VALUES clause permits only constants) because the projection list can contain expressions

For example, suppose a follow-up call is required for every order that has been paid for but not shipped. The INSERT statement in the following example finds those orders and inserts a row in **cust\_calls** for each order:

```
INSERT INTO cust_calls (customer_num, call_descr)
SELECT customer_num, order_num FROM orders
WHERE paid_date IS NOT NULL
AND ship_date IS NULL;
```

This SELECT statement returns two columns. The data from these columns (in each selected row) is inserted into the named columns of the **cust\_calls** table. Then an order number (from **order\_num**, a SERIAL column) is inserted into the call description, which is a character column. Remember that the database server allows you to insert integer values into a character column. It automatically converts the serial number to a character string of decimal digits.

## Restrictions on the insert selection

The following list contains the restrictions on the SELECT statement for inserting rows:

- It cannot contain an INTO clause.
- It cannot contain an INTO TEMP clause.
- It cannot contain an ORDER BY clause.
- It cannot refer to the table into which you are inserting rows.

The INTO, INTO TEMP, and ORDER BY clause restrictions are minor. The INTO clause is not useful in this context. (For more information, see [SQL programming on page 1944](#).) To work around the INTO TEMP clause restriction, first select the data you want to insert into a temporary table and then insert the data from the temporary table with the INSERT statement. Likewise, the lack of an ORDER BY clause is not important. If you need to ensure that the new rows are physically ordered in the table, you can first select them into a temporary table and order it, and then insert from the temporary table. You can also apply a physical order to the table using a clustered index after all insertions are done.

**Important:** The last restriction is more serious because it prevents you from naming the same table in both the INTO clause of the INSERT statement and the FROM clause of the SELECT statement. Naming the same table in both the INTO clause of the INSERT statement and the FROM clause of the SELECT statement causes the database server to enter an endless loop in which each inserted row is reselected and reinserted.

In some cases, however, you might want to select from the same table into which you must insert data. For example, suppose that you have learned that the Nikolus company supplies the same products as the Anza company, but at half the

price. You want to add rows to the **stock** table to reflect the difference between the two companies. Optimally, you want to select data from all the Anza stock rows and reinsert it with the Nikolus manufacturer code. However, you cannot select from the same table into which you are inserting.

To get around this restriction, select the data you want to insert into a temporary table. Then select from that temporary table in the INSERT statement, as the following example shows:

```
SELECT stock_num, 'NIK' temp_manu, description, unit_price/2
      half_price, unit, unit_descr FROM stock
WHERE manu_code = 'ANZ'
      AND stock_num < 110
INTO TEMP anzrows;

INSERT INTO stock SELECT * FROM anzrows;

DROP TABLE anzrows;
```

This SELECT statement takes existing rows from **stock** and substitutes a literal value for the manufacturer code and a computed value for the unit price. These rows are then saved in a temporary table, **anzrows**, which is immediately inserted into the **stock** table.

When you insert multiple rows, a risk exists that one of the rows contains invalid data that might cause the database server to report an error. When such an error occurs, the statement terminates early. Even if no error occurs, a small risk exists that a hardware or software failure might occur while the statement is executing (for example, the disk might fill up).

In either event, you cannot easily tell how many new rows were inserted. If you repeat the statement in its entirety, you might create duplicate rows, or you might not. Because the database is in an unknown state, you cannot know what to do. The solution lies in using transactions, as [Interrupted modifications on page 1935](#) discusses.

## Update rows

Use the UPDATE statement to change the contents of one or more existing rows of a table, according to the specifications of the SET clause. This statement takes two fundamentally different forms. One lets you assign specific values to columns by name; the other lets you assign a list of values (that might be returned by a SELECT statement) to a list of columns. In either case, if you are updating rows, and some of the columns have data integrity constraints, the data that you change must conform to the constraints placed on those columns. For more information, refer to [Data integrity on page 1924](#).

**Note:** An alternative to the UPDATE statement is the MERGE statement, which can use the same SET clause syntax as the UPDATE statement to modify one or more values in existing rows of a table. The MERGE statement performs an outer join of a source table and a target table, and then updates rows in the target table with values from the result set of the join for which the join predicate evaluates to TRUE. Values in the source table are unchanged by the MERGE statement. Besides updating rows, the MERGE statement can optionally combine both UPDATE and INSERT operations, or can combine both DELETE and INSERT operations without updating any rows. For more information

about the syntax and the restrictions on Update merges, Delete merges, and Insert merges, see the description of the MERGE statement in the *Informix® Guide to SQL: Syntax*.

## Select rows to update

Either form of the UPDATE statement can end with a WHERE clause that determines which rows are modified. If you omit the WHERE clause, all rows are modified. To select the precise set of rows that need changing in the WHERE clause can be quite complicated. The only restriction on the WHERE clause is that the table that you update cannot be named in the FROM clause of a subquery.

The first form of an UPDATE statement uses a series of assignment clauses to specify new column values, as the following example shows:

```
UPDATE customer
  SET fname = 'Barnaby', lname = 'Dorfler'
  WHERE customer_num = 103;
```

The WHERE clause selects the row you want to update. In the demonstration database, the **customer.customer\_num** column is the primary key for that table, so this statement can update no more than one row.

You can also use subqueries in the WHERE clause. Suppose that the Anza Corporation issues a safety recall of their tennis balls. As a result, any unshipped orders that include stock number 6 from manufacturer ANZ must be put on back order, as the following example shows:

```
UPDATE orders
  SET backlog = 'y'
  WHERE ship_date IS NULL
  AND order_num IN
    (SELECT DISTINCT items.order_num FROM items
     WHERE items.stock_num = 6
     AND items.manu_code = 'ANZ');
```

This subquery returns a column of order numbers (zero or more). The UPDATE operation then tests each row of **orders** against the list and performs the update if that row matches.

## Update with uniform values

Each assignment after the keyword SET specifies a new value for a column. That value is applied uniformly to every row that you update. In the examples in the previous section, the new values were constants, but you can assign any expression, including one based on the column value itself. Suppose the manufacturer code HRO has raised all prices by five percent, and you must update the **stock** table to reflect this increase. Use the following statement:

```
UPDATE stock
  SET unit_price = unit_price * 1.05
  WHERE manu_code = 'HRO';
```

You can also use a subquery as part of the assigned value. When a subquery is used as an element of an expression, it must return exactly one value (one column and one row). Perhaps you decide that for any stock number, you must charge a higher

price than any manufacturer of that product. You need to update the prices of all unshipped orders. The SELECT statements in the following example specify the criteria:

```
UPDATE items
  SET total_price = quantity *
    (SELECT MAX (unit_price) FROM stock
     WHERE stock.stock_num = items.stock_num)
  WHERE items.order_num IN
    (SELECT order_num FROM orders
     WHERE ship_date IS NULL);
```

The first SELECT statement returns a single value: the highest price in the **stock** table for a particular product. The first SELECT statement is a correlated subquery because, when a value from **items** appears in the WHERE clause for the first SELECT statement, you must execute the query for every row that you update.

The second SELECT statement produces a list of the order numbers of unshipped orders. It is an uncorrelated subquery that is executed once.

## Restrictions on updates

Restrictions exist on the use of subqueries when you modify data. In particular, you cannot query the table that is being modified. You can refer to the present value of a column in an expression, as in the example that increments the **unit\_price** column by 5 percent. You can also refer to a value of a column in a WHERE clause in a subquery, as in the example that updated the **stock** table, in which the **items** table is updated and **items.stock\_num** is used in a join expression.

The need to update and query a table at the same time does not occur often in a well-designed database. (For more information about database design, see the *Informix® Database Design and Implementation Guide*.) However, you might want to update and query at the same time when a database is first being developed, before its design has been carefully thought through. A typical problem arises when a table inadvertently and incorrectly contains a few rows with duplicate values in a column that should be unique. You might want to delete the duplicate rows or update only the duplicate rows. Either way, a test for duplicate rows inevitably requires a subquery on the same table that you want to modify, which is not allowed in an UPDATE statement or DELETE statement. [Modify data through SQL programs on page 1968](#) discusses how to use an *update cursor* to perform this kind of modification.

## Update with selected values

The second form of UPDATE statement replaces the list of assignments with a single bulk assignment, in which a list of columns is set equal to a list of values. When the values are simple constants, this form is nothing more than the form of the previous example with its parts rearranged, as the following example shows:

```
UPDATE customer
  SET (fname, lname) = ('Barnaby', 'Dorfler')
  WHERE customer_num = 103;
```

No advantage exists to writing the statement this way. In fact, it is harder to read because it is not obvious which values are assigned to which columns.

However, when the values to be assigned come from a single SELECT statement, this form makes sense. Suppose that changes of address are to be applied to several customers. Instead of updating the **customer** table each time a change is reported, the new addresses are collected in a single temporary table named **newaddr**. It contains columns for the customer number and the address-related fields of the **customer** table. Now the time comes to apply all the new addresses at once.

```
UPDATE customer
SET (address1, address2, city, state, zipcode) =
  ((SELECT address1, address2, city, state, zipcode
    FROM newaddr
    WHERE newaddr.customer_num=customer.customer_num))
WHERE customer_num IN (SELECT customer_num FROM newaddr);
```

A single SELECT statement produces the values for multiple columns. If you rewrite this example in the other form, with an assignment for each updated column, you must write five SELECT statements, one for each column to be updated. Not only is such a statement harder to write, but it also takes much longer to execute.

**Tip:** In SQL API programs, you can use record or host variables to update values. For more information, refer to [SQL programming on page 1944](#).

## Update row types

The syntax you use to update a row-type value differs somewhat depending on whether the column is a named ROW type or unnamed ROW type. This section describes those differences and also describes how to specify NULL values for the fields of a ROW type.

### Update rows that contain named row types

To update a column that is defined on a named ROW type, you must specify all fields of the ROW type. For example, the following statement updates only the **street** and **city** fields of the **address** column in the **employee** table, but each field of the ROW type must contain a value (NULL values are allowed):

```
UPDATE employee
SET address = ROW('103 California St',
  San Francisco', address.state, address.zip)::address_t
WHERE name = 'zawinul, joe';
```

In this example, the values of the **state** and **zip** fields are read from and then immediately reinserted into the row. Only the **street** and **city** fields of the **address** column are updated.

When you update the fields of a column that are defined on a named ROW type, you must use a ROW constructor and cast the row value to the appropriate named ROW type.

### Update rows that contain unnamed row types

To update a column that is defined on an unnamed ROW type, you must specify all fields of the ROW type. For example, the following statement updates only the **street** and **city** fields of the **address** column in the **student** table, but each field of the ROW type must contain a value (NULL values are allowed):

```
UPDATE student
  SET s_address = ROW('13 Sunset', 'Fresno',
    s_address.state, s_address.zip)
  WHERE s_name = 'henry, john';
```

To update the fields of a column that are defined on an unnamed ROW type, always specify the ROW constructor before the field values to be inserted.

## Specify Null values for the fields of a row type

The fields of a row-type column can contain NULL values. When you insert into or update a row-type field with a NULL value, you must cast the value to the data type of that field.

The following UPDATE statement shows how you might specify NULL values for particular fields of a named row-type column:

```
UPDATE employee
  SET address = ROW(NULL::VARCHAR(20), 'Davis', 'CA',
    ROW(NULL::CHAR(5), NULL::CHAR(4))::address_t)
  WHERE name = 'henry, john';
```

The following UPDATE statement shows how you specify NULL values for the **street** and **zip** fields of the **address** column for the **student** table.

```
UPDATE student
  SET address = ROW(NULL::VARCHAR(20), address.city,
    address.state, NULL::VARCHAR(9))
  WHERE s_name = 'henry, john';
```

**Important:** You cannot specify NULL values for a row-type column. You can only specify NULL values for the individual fields of the row type.

## Update collection types

When you use DB-Access to update a collection type, you must update the entire collection. The following statement shows how to update the **projects** column. To locate the row that needs to be updated, use the IN keyword to perform a search on the **direct\_reports** column.

```
UPDATE manager
  SET projects = "LIST
  {
    ROW('brazil_project', SET{'Pryor', 'Murphy', 'Kinsley',
      'Bryant'}),
    ROW ('cuba_project', SET{'Forester', 'Barth', 'Lewis',
      'Leonard'})
  }"
  WHERE 'Williams' IN direct_reports;
```

The first occurrence of the SET keyword in the preceding statement is part of the UPDATE statement syntax.

**Important:** Do not confuse the SET keyword of an UPDATE statement with the SET constructor that indicates that a collection is a SET data type.

Although you can use the IN keyword to locate specific elements of a simple collection, you cannot update individual elements of a collection column from DB-Access. However, you can create Informix® ESQL/C programs and SPL routines to update elements within a collection. For information about how to create Informix® ESQL/C programs to update a collection, see the *Informix® ESQL/C Programmer's Manual*. For information about how to create SPL routines to update a collection, see the section [Handle collections on page 2032](#).

## Update rows of a supertable

When you update the rows of a supertable, the scope of the update is a supertable and its subtables.

When you construct an UPDATE statement on a supertable, you can update all columns in the supertable and columns of subtables that are inherited from the supertable. For example, the following statement updates rows from the **employee** and **sales\_rep** tables, which are subtables of the supertable **person**:

```
UPDATE person
  SET salary=65000
 WHERE address.state = 'CA';
```

However, an update on a supertable does not allow you to update columns from subtables that are not in the supertable. For example, in the previous update statement, you cannot update the **region\_num** column of the **sales\_rep** table because the **region\_num** column does not occur in the **employee** table.

When you perform updates on supertables, be aware of the scope of the update. For example, an UPDATE statement on the **person** table that does not include a WHERE clause to restrict which rows to update, modifies all rows of the **person**, **employee**, and **sales\_rep** table.

To limit an update to rows of the supertable only, you must use the ONLY keyword in the UPDATE statement. For example, the following statement updates rows of the **person** table only:

```
UPDATE ONLY(person)
  SET address = ROW('14 Jackson St', 'Berkeley',
  address.state, address.zip)
 WHERE name = 'Sallie, A.';
```

**Important:** Use caution when you update rows of a supertable because the scope of an update on a supertable includes the supertable and all its subtables.

## CASE expression to update a column

The CASE expression allows a statement to return one of several possible results, depending on which of several condition tests evaluates to TRUE.

The following example shows how to use a CASE expression in an UPDATE statement to increase the unit price of certain items in the **stock** table:

```
UPDATE stock
  SET unit_price = CASE
    WHEN stock_num = 1
      AND manu_code = "HRO"
    THEN unit_price * 1.2
    WHEN stock_num = 1
      AND manu_code = "SMT"
    THEN unit_price * 1.1
    ELSE 0
  END
```

You must include at least one WHEN clause within the CASE expression; subsequent WHEN clauses and the ELSE clause are optional. If no WHEN condition evaluates to true, the resulting value is null.

## SQL functions to update smart large objects

You can use an SQL function that you can call from within an UPDATE statement to import and export smart large objects. For a description of these functions, see page [Smart large object functions on page 1846](#).

The following UPDATE statement uses the LOCOPY() function to copy BLOB data from the **mugshot** column of the **fbi\_list** table into the **picture** column of the **inmate** table. (Figure 231: [Create the inmate and fbi\\_list tables. on page 1846](#) defines the **inmate** and **fbi\_list** tables.)

```
UPDATE inmate (picture)
  SET picture = (SELECT LOCOPY(mugshot, 'inmate', 'picture')
                FROM fbi_list WHERE fbi_list.id = 669)
 WHERE inmate.id_num = 437;
```

The first argument for LOCOPY() specifies the column (**mugshot**) from which the object is exported. The second and third arguments specify the name of the table (**inmate**) and column (**picture**) whose storage characteristics the newly created object will use. After execution of the UPDATE statement, the **picture** column contains data from the **mugshot** column.

When you specify the path of a file name in the function argument, apply the following rules:

- If the source file resides on the server computer, you must specify the full path name to the file (not the path name relative to the current working directory).
- If the source file resides on the client computer, you can specify either the full or relative path name to the file.

## The MERGE statement to update a table

The MERGE statement allows you to apply a Boolean condition to the result of an outer join of a source table and a target table. If the MERGE statement includes the Update clause, rows that satisfy the join condition that you specify after the ON keyword are used in UPDATE operations on the target. The SET clause of the MERGE statement supports the same syntax as the SET clause of the UPDATE statement, and specifies which columns of the target table to update.

The following example illustrates how you can use the Update clause of the MERGE statement to update a target table:

```
MERGE INTO t_target AS t USING t_source AS s ON t.col_a = s.col_a
WHEN MATCHED THEN UPDATE
SET t.col_b = t.col_b + s.col_b ;
```

In the preceding example, the name of the target table is **t\_target** and the name of the source table is **t\_source**. For rows of the join result where **col\_a** has the same value in both the source and the target tables, the MERGE statement updates the **t\_target** table by adding the value of column **col\_b** in the source table to the current value of the **col\_b** column in the **t\_target** table.

An UPDATE operation of the MERGE statement does not modify the source table, and cannot update any row in the target table more than once.

A single MERGE statement can combine both UPDATE and INSERT operations, or can combine both DELETE and INSERT operations but the delete clause is not required. For a different example of MERGE that includes no Update clause, see the topic [The Delete clause of MERGE on page 1905](#)

## Privileges on a database and on its objects

You can use the following database privileges to control who accesses a database:

- Database-level privileges
- Table-level privileges
- Routine-level privileges
- Language-level privileges
- Type-level privileges
- Sequence-level privileges
- Fragment-level privileges

This section briefly describes database- and table-level privileges. For more information about database privileges, see the *Informix® Database Design and Implementation Guide*. For a list of privileges and a description of the GRANT and REVOKE statements, see the *Informix® Guide to SQL: Syntax*.

## Database-level privileges

When you create a database, you are the only one who can access it until you, as the owner or database administrator (DBA) of the database, grant database-level privileges to others. The following table shows database-level privileges.

| Privilege | Effect  |
|-----------|---|
| Connect   | Allows you to open a database, issue queries, and create and place indexes on temporary tables. |
| Resource  | Allows you to create permanent tables.  |

e

| Privilege | Effect   |
|-----------|--|
| DBA       | Allows you to perform several additional functions as the DBA. |

## Table-level privileges

When you create a table in a database that is not ANSI compliant, all users have access privileges to the table until you, as the owner of the table, revoke table-level privileges from specific users. The following table introduces the four privileges that govern how users can access a table.

| Privilege | Purpose   |
|-----------|---|
| Select    | Granted on a table-by-table basis and allows you to select rows from a table. (This privilege can be limited to specific columns in a table.) |
| Delete    | Allows you to delete rows.  |
| Insert    | Allows you to insert rows.  |
| Update    | Allows you to update existing rows (that is, to change their content).  |

The people who create databases and tables often grant the Connect and Select privileges to **public** so that all users have them. If you can query a table, you have at least the Connect and Select privileges for that database and table.

You need the other table-level privileges to modify data. The owners of tables often withhold these privileges or grant them only to specific users. As a result, you might not be able to modify some tables that you can query freely.

Because these privileges are granted on a table-by-table basis, you can have only Insert privileges on one table and only Update privileges on another, for example. The Update privileges can be restricted even further to specific columns in a table.

For more information on these and other table-level privileges, see the *Informix® Database Design and Implementation Guide*.

## Display table privileges

If you are the owner of a table (that is, if you created it), you have all privileges on that table. Otherwise, you can determine the privileges you have for a certain table by querying the system catalog. The system catalog consists of system tables that describe the database structure. The privileges granted on each table are recorded in the **systabauth** system table. To display these privileges, you must also know the unique identifier number of the table. This number is specified in the **systables** system table. To display privileges granted on the **orders** table, you might enter the following SELECT statement:

```
SELECT * FROM systabauth
WHERE tabid = (SELECT tabid FROM systables
              WHERE tablename = 'orders');
```

The output of the query resembles the following example:

| grantor          | grantee | tabid    | tabauth |
|------------------|---------|----------|---------|
| tfecitmutator    | 101     | su-i-x-- |         |
| tfecitprocrustes | 101     | s--idx-- |         |
| tfecitpublic     | 101     | s--i-x-- |         |

The grantor is the user who grants the privilege. The grantor is usually the owner of the table but the owner can be another user that the grantor empowered. The grantee is the user to whom the privilege is granted, and the grantee **public** means any user with Connect privilege. If your user name does not appear, you have only those privileges granted to **public**.

The **tabauth** column specifies the privileges granted. The letters in each row of this column are the initial letters of the privilege names, except that **i** means Insert and **x** means Index. In this example, **public** has Select, Insert, and Index privileges. Only the user **mutator** has Update privileges, and only the user **procrustes** has Delete privileges.

Before the database server performs any action for you (for example, execution of a DELETE statement), it performs a query similar to the preceding one. If you are not the owner of the table, and if the database server cannot find the necessary privilege on the table for your user name or for **public**, it refuses to perform the operation.

## Grant privileges to roles

As DBA, you can create roles to standardize the privileges given to a class of users. When you assign privileges to that role, every user of that role has those access privileges. The SQL statements used for defining and manipulating roles include: CREATE ROLE, DROP ROLE, GRANT, REVOKE, and SET ROLE. For more information on the SQL syntax statements for defining and manipulating roles, see the *Informix® Guide to SQL: Syntax*.

Default roles automatically apply upon connection to the database for particular users and groups, without requiring the user to issue a SET ROLE statement. For example:

```
GRANT DEFAULT ROLE manager TO larry;
```

For more information on roles and default roles, see [Control database use on page 1765](#) or see the *Informix® Administrator's Guide*.

For more information on granting and revoking privileges, see [Grant and revoke privileges in applications on page 1965](#). Also see *Informix® Database Design and Implementation Guide*.

## Data integrity

The INSERT, UPDATE, and DELETE statements modify data in an existing database. Whenever you modify existing data, the *integrity* of the data can be affected. For example, an order for a nonexistent product could be entered into the **orders** table, a customer with outstanding orders could be deleted from the **customer** table, or the order number could be updated in the **orders** table and not in the **items** table. In each of these cases, the integrity of the stored data is lost.

Data integrity is actually made up of the following parts:

### Entity integrity

Each row of a table has a unique identifier.

**Semantic integrity**

The data in the columns properly reflects the types of information the column was designed to hold.

**Referential integrity**

The relationships between tables are enforced.

Well-designed databases incorporate these principles so that when you modify data, the database itself prevents you from doing anything that might harm the integrity of the data.

**Entity integrity**

An entity is any person, place, or thing to be recorded in a database. Each table represents an entity, and each row of a table represents an instance of that entity. For example, if *order* is an entity, the **orders** table represents the idea of an order and each row in the table represents a specific order.

To identify each row in a table, the table must have a primary key. The primary key is a unique value that identifies each row. This requirement is called the *entity integrity constraint*.

For example, the **orders** table primary key is **order\_num**. The **order\_num** column holds a unique system-generated order number for each row in the table. To access a row of data in the **orders** table, use the following SELECT statement:

```
SELECT * FROM orders WHERE order_num = 1001;
```

Using the order number in the WHERE clause of this statement enables you to access a row easily because the order number uniquely identifies that row. If the table allowed duplicate order numbers, it would be almost impossible to access one single row because all other columns of this table allow duplicate values.

For more information on primary keys and entity integrity, see the *Informix® Database Design and Implementation Guide*.

**Semantic integrity**

Semantic integrity ensures that data entered into a row reflects an allowable value for that row. The value must be within the *domain*, or allowable set of values, for that column. For example, the **quantity** column of the **items** table permits only numbers. If a value outside the domain can be entered into a column, the semantic integrity of the data is violated.

The following constraints enforce semantic integrity:

**Data type**

The data type defines the types of values that you can store in a column. For example, the data type SMALLINT allows you to enter values from -32,767 to 32,767 into a column.

**Default value**

The default value is the value inserted into the column when an explicit value is not specified. For example, the **user\_id** column of the **cust\_calls** table defaults to the login name of the user if no name is entered.

### Check constraint

The check constraint specifies conditions on data inserted into a column. Each row inserted into a table must meet these conditions. For example, the **quantity** column of the **items** table might check for quantities greater than or equal to one.

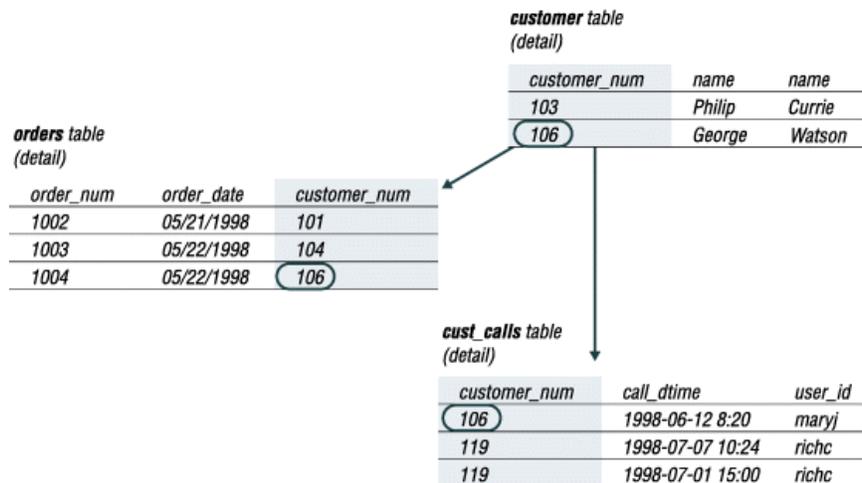

For more information on how to use semantic integrity constraints in database design, see the *Informix® Database Design and Implementation Guide*.

## Referential integrity

Referential integrity refers to the relationship between tables. Because each table in a database must have a primary key, this primary key can appear in other tables because of its relationship to data within those tables. When a primary key from one table appears in another table, it is called a *foreign key*.

Foreign keys join tables and establish dependencies between tables. Tables can form a hierarchy of dependencies in such a way that if you change or delete a row in one table, you destroy the meaning of rows in other tables. For example, the following figure shows that the **customer\_num** column of the **customer** table is a primary key for that table and a foreign key in the **orders** and **cust\_call** tables. Customer number 106, George Watson™, is *referenced* in both the **orders** and **cust\_calls** tables. If customer 106 is deleted from the **customer** table, the link between the three tables and this particular customer is destroyed.

Figure 379. Referential integrity in the demonstration database

When you delete a row that contains a primary key or update it with a different primary key, you destroy the meaning of any rows that contain that value as a foreign key. Referential integrity is the logical dependency of a foreign key on a primary key. The integrity of a row that contains a foreign key depends on the integrity of the row that it references—the row that contains the matching primary key.

By default, the database server does not allow you to violate referential integrity and gives you an error message if you attempt to delete rows from the parent table before you delete rows from the child table. You can, however, use the ON

DELETE CASCADE option to cause deletes from a parent table to trip deletes on child tables. See [The ON DELETE CASCADE option on page 1927](#).

To define primary and foreign keys, and the relationship between them, use the CREATE TABLE and ALTER TABLE statements. For more information on these statements, see the *Informix® Guide to SQL: Syntax*. For information about how to build a data model with primary and foreign keys, see the *Informix® Database Design and Implementation Guide*.

## The ON DELETE CASCADE option

To maintain referential integrity when you delete rows from a primary key for a table, use the ON DELETE CASCADE option in the REFERENCES clause of the CREATE TABLE and ALTER TABLE statements. This option allows you to delete a row from a parent table and its corresponding rows in matching child tables with a single delete command.

### Lock during cascading deletes

During deletes, locks are held on all qualifying rows of the parent and child tables. When you specify a delete, the delete that is requested from the parent table occurs before any referential actions are performed.

### What happens to multiple children tables

If you have a parent table with two child constraints, one child with cascading deletes specified and one child without cascading deletes, and you attempt to delete a row from the parent table that applies to both child tables, the DELETE statement fails, and no rows are deleted from either the parent or child tables.

### Logging must be turned on

You must turn on logging in your current database for cascading deletes to work. Logging and cascading deletes are discussed in [Transaction logging on page 1936](#).

## Example of cascading deletes

Suppose you have two tables with referential integrity rules applied, a parent table, **accounts**, and a child table, **sub\_accounts**. The following CREATE TABLE statements define the referential constraints:

```
CREATE TABLE accounts (
  acc_num SERIAL primary key,
  acc_type INT,
  acc_descr CHAR(20));

CREATE TABLE sub_accounts (
  sub_acc INTEGER primary key,
  ref_num INTEGER REFERENCES accounts (acc_num)
  ON DELETE CASCADE,
  sub_descr CHAR(20));
```

The primary key of the accounts table, the **acc\_num** column, uses a SERIAL data type, and the foreign key of the **sub\_accounts** table, the **ref\_num** column, uses an INTEGER data type. Combining the SERIAL data type on the primary key and the INTEGER data type on the foreign key is allowed. Only in this condition can you mix and match data types. The

SERIAL data type is an INTEGER, and the database automatically generates the values for the column. All other primary and foreign key combinations must match explicitly. For example, a primary key that is defined as CHAR must match a foreign key that is defined as CHAR.

The definition of the foreign key of the **sub\_accounts** table, the **ref\_num** column, includes the ON DELETE CASCADE option. This option specifies that a delete of any row in the parent table **accounts** will automatically cause the corresponding rows of the child table **sub\_accounts** to be deleted.

To delete a row from the accounts table that will cascade a delete to the **sub\_accounts** table, you must turn on logging. After logging is turned on, you can delete the account number 2 from both tables, as the following example shows:

```
DELETE FROM accounts WHERE acc_num = 2;
```

## Restrictions on cascading deletes

You can use cascading deletes for most deletes, including deletes on self-referencing and cyclic queries. The only exception is correlated subqueries, which are nested SELECT statements in which the value that the subquery (or inner SELECT) produces depends on a value produced by the outer SELECT statement that contains it. If you have implemented cascading deletes, you cannot write deletes that use a child table in the correlated subquery. You receive an error when you attempt to delete from a correlated subquery.

**Restriction:** You cannot define a DELETE trigger event on a table if the table defines a referential constraint with ON DELETE CASCADE.

## Object modes and violation detection

The object modes and violation detection features of the database can help you monitor data integrity. These features are particularly powerful when they are combined during schema changes or when insert, delete, and update operations are performed on large volumes of data over short periods.

Database objects, within the context of a discussion of the object modes feature, are constraints, indexes, and triggers, and each of them have different modes. Do not confuse database objects that are relevant to the object modes feature with generic database objects. Generic database objects are things like tables and synonyms.

## Definitions of object modes

You can set disabled, enabled, or filtering modes for a constraint or a unique index. You can set disabled or enabled modes for a trigger or a duplicate index. You can use database object modes to control the effects of INSERT, DELETE, and UPDATE statements.

## Enabled mode

Constraints, indexes, and triggers are enabled by default.

When a database object is enabled, the database server recognizes the existence of the database object and takes the database object into consideration while it executes an INSERT, DELETE, or UPDATE statement. Thus, an enabled constraint is enforced, an enabled index updated, and an enabled trigger is executed when the trigger event takes place.

When you enable constraints and unique indexes, if a violating row exists, the data manipulation statement fails (that is no rows change) and the database server returns an error message.

You can identify the reason for the failure when you analyze the information in the violations and diagnostic tables. You can then take corrective action or roll back the operation.

## Disabled mode

When a database object is disabled, the database server does not take it into consideration during the execution of an INSERT, DELETE, or UPDATE statement. A disabled constraint is not enforced, a disabled index is not updated, and a disabled trigger is not executed when the trigger event takes place. When you disable constraints and unique indexes, any data manipulation statement that violates the restriction of the constraint or unique index succeed, (that is, the target row is changed), and the database server does not return an error message.

## Filtering mode

When a constraint or unique index is in filtering mode, the statement succeeds and the database server enforces the constraint or the unique index requirement during an INSERT, DELETE, or UPDATE statement by writing the failed rows to the violations table associated with the target table. Diagnostic information about the constraint violation is written to the diagnostics table associated with the target table.

## Example of modes with data manipulation statements

An example with the INSERT statement can illustrate the differences between the enabled, disabled, and filtering modes. Consider an INSERT statement in which a user tries to add a row that does not satisfy an integrity constraint on a table. For example, assume that user **joe** created a table named **cust\_subset**, and this table consists of the following columns: **ssn** (customer's social security number), **fname** (customer's first name), **lname** (customer's last name), and **city** (city in which the customer lives). The **ssn** column has the INT data type. The other three columns have the CHAR data type.

Assume that user **joe** defined the **lname** column as not null but has not assigned a name to the not null constraint, so the database server has implicitly assigned the name **n104\_7** to this constraint. Finally, assume that user **joe** created a unique index named **unq\_ssn** on the **ssn** column.

Now user **linda** who has the Insert privilege on the **cust\_subset** table enters the following INSERT statement on this table:

```
INSERT INTO cust_subset (ssn, fname, city)
VALUES (973824499, "jane", "los altos");
```

To better understand the distinctions among enabled, disabled, and filtering modes, you can view the results of the preceding INSERT statement in the following three sections.

## Results of the insert operation when the constraint is enabled

If the NOT NULL constraint on the **cust\_subset** table is enabled, the INSERT statement fails to insert the new row in this table. Instead user **linda** receives the following error message when they enter the INSERT statement:

```
-292 An implied insert column lname does not accept NULLs.
```

## Results of the insert operation when the constraint is disabled

If the NOT NULL constraint on the **cust\_subset** table is disabled, the INSERT statement that user **linda** issues successfully inserts the new row in this table. The new row of the **cust\_subset** table has the following column values.

| ssn       | fname | lname | city      |
|-----------|-------|-------|-----------|
| 973824499 | jane  | NULL  | los altos |

## Results of the insert when constraint is in filtering mode

If the NOT NULL constraint on the **cust\_subset** table is set to the filtering mode, the INSERT statement that user **linda** issues fails to insert the new row in this table. Instead the new row is inserted into the violations table, and a diagnostic row that describes the integrity violation is added to the diagnostics table.

Assume that user **joe** has started a violations and diagnostics table for the **cust\_subset** table. The violations table is named **cust\_subset\_vio**, and the diagnostics table is named **cust\_subset\_dia**. The new row added to the **cust\_subset\_vio** violations table when user **linda** issues the INSERT statement on the **cust\_subset** target table has the following column values.

| ssn       | fname | lname | city      | informix_tupleid | informix_optype | informix_reowner |
|-----------|-------|-------|-----------|------------------|-----------------|------------------|
| 973824499 | jane  | NULL  | los altos | 1                | I               | linda            |

This new row in the **cust\_subset\_vio** violations table has the following characteristics:

- The first four columns of the violations table exactly match the columns of the target table. These four columns have the same names and the same data types as the corresponding columns of the target table, and they have the column values that were supplied by the INSERT statement that user **linda** entered.
- The value **1** in the **informix\_tupleid** column is a unique serial identifier that is assigned to the nonconforming row.
- The value **I** in the **informix\_optype** column is a code that identifies the type of operation that has caused this nonconforming row to be created. Specifically, **I** stands for an INSERT operation.
- The value **linda** in the **informix\_reowner** column identifies the user who issued the statement that caused this nonconforming row to be created.

The INSERT statement that user **linda** issued on the **cust\_subset** target table also causes a diagnostic row to be added to the **cust\_subset\_dia** diagnostics table. The new diagnostic row added to the diagnostics table has the following column values.

| <b>informix_tupleid</b> | <b>objtype</b> | <b>objowner</b> | <b>objname</b> |
|-------------------------|----------------|-----------------|----------------|
| 1                       | C              | joe             | n104_7         |

This new diagnostic row in the **cust\_subset\_dia** diagnostics table has the following characteristics:

- This row of the diagnostics table is linked to the corresponding row of the violations table by means of the **informix\_tupleid** column that appears in both tables. The value **1** appears in this column in both tables.
- The value **c** in the **objtype** column identifies the type of integrity violation that the corresponding row in the violations table caused. Specifically, the value **c** stands for a constraint violation.
- The value **joe** in the **objowner** column identifies the owner of the constraint for which an integrity violation was detected.
- The value **n104\_7** in the **objname** column gives the name of the constraint for which an integrity violation was detected.

By joining the violations and diagnostics tables, user **joe** (who owns the **cust\_subset** target table and its associated special tables) or the DBA can find out that the row in the violations table whose **informix\_tupleid** value is **1** was created after an INSERT statement and that this row is violating a constraint. The table owner or DBA can query the **sysconstraints** system catalog table to determine that this constraint is a NOT NULL constraint. Now that the reason for the failure of the INSERT statement is known, user **joe** or the DBA can take corrective action.

## Multiple diagnostic rows for one violations row

In the preceding example, only one row in the diagnostics table corresponds to the new row in the violations table. However, more than one diagnostic row can be added to the diagnostics table when a single new row is added to the violations table. For example, if the **ssn** value (973824499) that user **linda** entered in the INSERT statement had been the same as an existing value in the **ssn** column of the **cust\_subset** target table, only one new row would appear in the violations table, but the following two diagnostic rows would be present in the **cust\_subset\_dia** diagnostics table.

| <b>informix_tupleid</b> | <b>objtype</b> | <b>objowner</b> | <b>objname</b> |
|-------------------------|----------------|-----------------|----------------|
| 1                       | C              | joe             | n104_7         |
| 1                       | I              | joe             | unq_ssn        |

Both rows in the diagnostics table correspond to the same row of the violations table because both of these rows have the value **1** in the **informix\_tupleid** column. The first diagnostic row, however, identifies the constraint violation caused by the INSERT statement that user **linda** issued, while the second diagnostic row identifies the unique-index violation that the same INSERT statement caused. In this second diagnostic row, the value **I** in the **objtype** column stands for a unique-index violation, and the value **unq\_ssn** in the **objname** column gives the name of the index for which the integrity violation was detected.

For more information about how to set database object modes, see the SET Database Object Mode statement in the *Informix® Guide to SQL: Syntax*.

## Violations and diagnostics tables

When you start a violations table for a target table, any rows that violate constraints and unique indexes during INSERT, UPDATE, and DELETE operations on the target table do not cause the entire operation to fail, but are filtered out to the violations table. The diagnostics table contains information about the integrity violations caused by each row in the violations table. By examining these tables, you can identify the cause of failure and take corrective action by either fixing the violation or rolling back the operation.

After you create a violations table for a target table, you cannot alter the columns or the fragmentation of the base table or the violations table. If you alter the constraints on a target table after you have started the violations table, nonconforming rows will be filtered to the violations table.

For information about how to start and stop the violations tables, see the START VIOLATIONS TABLE and STOP VIOLATIONS TABLE statements in the *Informix® Guide to SQL: Syntax*.

## Relationship of violations tables and database object modes

If you set the constraints or unique indexes defined on a table to the filtering mode, but you do not create the violations and diagnostics tables for this target table, any rows that violate a constraint or unique-index requirement during an insert, update, or delete operation are not filtered to a violations table. Instead, you receive an error message that indicates that you must start a violations table for the target table.

Similarly, if you set a disabled constraint or disabled unique index to the enabled or filtering mode and you want the ability to identify existing rows that do not satisfy the constraint or unique-index requirement, you must create the violations tables before you issue the SET Database Object Mode statement.

## Examples of START VIOLATIONS TABLE statements

The examples that follow show different ways to execute the START VIOLATIONS TABLE statement.

### Start violations and diagnostics tables without specifying their names

To start a violations and diagnostics table for the target table named **customer** in the demonstration database, enter the following statement:

```
START VIOLATIONS TABLE FOR customer;
```

Because your START VIOLATIONS TABLE statement does not include a USING clause, the violations table is named **customer\_vio** by default, and the diagnostics table is named **customer\_dia** by default. The **customer\_vio** table includes the following columns:

```
customer_num
fname
lname
company
address1
address2
city
state
```

```

zipcode
phone
informix_tupleid
informix_optype
informix_reowner

```

The **customer\_vio** table has the same table definition as the **customer** table except that the **customer\_vio** table has three additional columns that contain information about the operation that caused the bad row.

The **customer\_dia** table includes the following columns:

```

informix_tupleid
objtype
objowner
objname

```

This list of columns shows an important difference between the diagnostics table and violations table for a target table. Whereas the violations table has a matching column for every column in the target table, the columns of the diagnostics table are independent of the schema of the target table. The diagnostics table created by any START VIOLATIONS TABLE statement always has the four columns in the list above, with the same column names and data types.

### Start violations and diagnostics tables and specify their names

The following statement starts a violations and diagnostics table for the target table named **items**. The USING clause declares explicit names for the violations and diagnostics tables. The violations table is to be named **exceptions**, and the diagnostics table is to be named **reasons**.

```

START VIOLATIONS TABLE FOR items
  USING exceptions, reasons;

```

### Specify the maximum number of rows in the diagnostics table

The following statement starts violations and diagnostics tables for the target table named **orders**. The MAX ROWS clause specifies the maximum number of rows that can be inserted into the **orders\_dia** diagnostics table when a single statement, such as an INSERT, MERGE, or SET Database Object Mode, is executed on the target table.

```

START VIOLATIONS TABLE FOR orders MAX ROWS 50000;

```

If you do not specify a value for MAX ROWS in the START VIOLATIONS TABLE statement, there is no default limit on the number of rows in the diagnostics table, apart from the available disk space.

The MAX ROWS clause limits the number of rows only for operations in which the table functions as a diagnostics table.

## Example of privileges on the violations table

The following example illustrates how the initial set of privileges on a violations table is derived from the current set of privileges on the target table.

For example, assume that we created a table named **cust\_subset** and that this table consists of the following columns: **ssn** (customer's social security number), **fname** (customer's first name), **lname** (customer's last name), and **city** (city in which the customer lives).

The following set of privileges exists on the **cust\_subset** table:

- User **alvin** is the owner of the table.
- User **barbara** has the Insert and Index privileges on the table. She also has the Select privilege on the **ssn** and **lname** columns.
- User **carrie** has the Update privilege on the **city** column. She also has the Select privilege on the **ssn** column.
- User **danny** has the Alter privilege on the table.

Now user **alvin** starts a violations table named **cust\_subset\_viol**s and a diagnostics table named **cust\_subset\_diag**s for the **cust\_subset** table, as follows:

```
START VIOLATIONS TABLE FOR cust_subset
  USING cust_subset_viol, cust_subset_diag;
```

The database server grants the following set of initial privileges on the **cust\_subset\_viol**s violations table:

- User **alvin** is the owner of the violations table, so he has all table-level privileges on the table.
- User **barbara** has the Insert, Delete, and Index privileges on the violations table. She also has the Select privilege on the following columns of the violations table: the **ssn** column, the **lname** column, the **informix\_tupleid** column, the **informix\_optype** column, and the **informix\_reowner** column.
- User **carrie** has the Insert and Delete privileges on the violations table. She has the Update privilege on the following columns of the violations table: the **city** column, the **informix\_tupleid** column, the **informix\_optype** column, and the **informix\_reowner** column. She has the Select privilege on the following columns of the violations table: the **ssn** column, the **informix\_tupleid** column, the **informix\_optype** column, and the **informix\_reowner** column.
- User **danny** has no privileges on the violations table.

## Example of privileges on the diagnostics table

The following example illustrates how the initial set of privileges on a diagnostics table is derived from the current set of privileges on the target table.

For example, assume that a table called **cust\_subset** consists of the following columns: **ssn** (customer's social security number), **fname** (customer's first name), **lname** (customer's last name), and **city** (city in which the customer lives).

The following set of privileges exists on the **cust\_subset** table:

- User **alvin** is the owner of the table.
- User **barbara** has the Insert and Index privileges on the table. They also have the Select privilege on the **ssn** and **lname** columns.
- User **carrie** has the Update privilege on the **city** column. They also have the Select privilege on the **ssn** column.
- User **danny** has the Alter privilege on the table.

Now user **alvin** starts a violations table named **cust\_subset\_viol**s and a diagnostics table named **cust\_subset\_diag**s for the **cust\_subset** table, as follows:

```
START VIOLATIONS TABLE FOR cust_subset
  USING cust_subset_viol, cust_subset_diag;
```

The database server grants the following set of initial privileges on the **cust\_subset\_diags** diagnostics table:

- User **alvin** is the owner of the diagnostics table, so he has all table-level privileges on the table.
- User **barbara** has the Insert, Delete, Select, and Index privileges on the diagnostics table.
- User **carrie** has the Insert, Delete, Select, and Update privileges on the diagnostics table.
- User **danny** has no privileges on the diagnostics table.

## Interrupted modifications

Even if all the software is error-free and all the hardware is utterly reliable, the world outside the computer can interfere. Lightning might strike the building, interrupting the electrical supply and stopping the computer in the middle of your UPDATE statement. A more likely scenario occurs when a disk fills up or a user supplies incorrect data, causing your multirow insert to stop early with an error. In any case, whenever you modify data, you must assume that some unforeseen event can interrupt the modification.

When an external cause interrupts a modification, you cannot be sure how much of the operation was completed. Even in a single-row operation, you cannot know whether the data reached the disk or the indexes were properly updated.

If multirow modifications are a problem, multistatement modifications are worse. They are usually embedded in programs so you do not see the individual SQL statements being executed. For example, to enter a new order in the demonstration database, perform the following steps:

1. Insert a row in the **orders** table. (This insert generates an order number.)
2. For each item ordered, insert a row in the **items** table.

Two ways to program an order-entry application exist. One way is to make it completely interactive so that the program inserts the first row immediately and then inserts each item as the user enters data. But this approach exposes the operation to the possibility of many more unforeseen events: the customer's telephone disconnecting, the user pressing the wrong key, the user's terminal or computer losing power, and so on.

The following list describes the correct way to build an order-entry application:

- Accept all the data interactively.
- Validate the data, and expand it (look up codes in **stock** and **manufact**, for example).
- Display the information on the screen for inspection.
- Wait for the operator to make a final commitment.
- Perform the insertions quickly.

Even with these steps, an unforeseen circumstance can halt the program after it inserts the order but before it finishes inserting the items. If that happens, the database is in an unpredictable condition: its data integrity is compromised.

## Transactions

The solution to all these potential problems is called the *transaction*. A transaction is a sequence of modifications that must be accomplished either completely or not at all. The database server guarantees that operations performed within the bounds of a transaction are either completely and perfectly committed to disk, or the database is restored to the same state as before the transaction started.

The transaction is not merely protection against unforeseen failures; it also offers a program a way to escape when the program detects a logical error.

## Transaction logging

The database server can keep a record of each change that it makes to the database during a transaction. If something happens to cancel the transaction, the database server automatically uses the records to reverse the changes. Many things can make a transaction fail. For example, the program that issues the SQL statements can fail or be terminated. As soon as the database server discovers that the transaction failed, which might be only after the computer and the database server are restarted, it uses the records from the transaction to return the database to the same state as before.

The process of keeping records of transactions is called *transaction logging* or simply *logging*. The records of the transactions, called *log records*, are stored in a portion of disk space separate from the database. This space is called the *logical log* because the log records represent logical units of the transactions.

HCL Informix® provides support to:

- Create nonlogging (raw) or logging (standard) tables in a logging database.
- Alter a table from nonlogging to logging and vice-versa using the ALTER TABLE statement.

supports nonlogging tables for fast loads of very large tables. It is recommended that you do not use nonlogging tables within a transaction. To avoid concurrency problems, use the ALTER TABLE statement to make the table standard (that is, logging) before you use the table in a transaction.

For more information about nonlogging tables for , see the *Informix® Administrator's Guide*. For the performance advantages of nonlogging tables, see the *Informix® Performance Guide*. For information about the ALTER TABLE statement, see the *Informix® Guide to SQL: Syntax*.

Most Informix® databases do not generate transaction records automatically. The DBA decides whether to make a database use transaction logging. Without transaction logging, you cannot roll back transactions.

## Logging and cascading deletes

Logging must be turned on in your database for cascading deletes to work because, when you specify a cascading delete, the delete is first performed on the primary key of the parent table. If the system fails after the rows of the primary key of the parent table are performed but before the rows of the foreign key of the child table are deleted, referential integrity is violated. If logging is turned off, even temporarily, deletes do not cascade. After logging is turned back on, however, deletes can cascade again.

HCL Informix® allows you to turn on logging with the WITH LOG clause in the CREATE DATABASE statement.

## Specify transactions

You can use two methods to specify the boundaries of transactions with SQL statements. In the most common method, you specify the start of a multistatement transaction by executing the BEGIN WORK statement. In databases that are created with the MODE ANSI option, no need exists to mark the beginning of a transaction. One is always in effect; you indicate only the end of each transaction.

In both methods, to specify the end of a successful transaction, execute the COMMIT WORK statement. This statement tells the database server that you reached the end of a series of statements that must succeed together. The database server does whatever is necessary to make sure that all modifications are properly completed and committed to disk.

A program can also cancel a transaction deliberately by executing the ROLLBACK WORK statement. This statement asks the database server to cancel the current transaction and undo any changes.

An order-entry application can use a transaction in the following ways when it creates a new order:

- Accept all data interactively
- Validate and expand it
- Wait for the operator to make a final commitment
- Execute BEGIN WORK
- Insert rows in the **orders** and **items** tables, checking the error code that the database server returns
- If no errors occurred, execute COMMIT WORK; otherwise execute ROLLBACK WORK

If any external failure prevents the transaction from being completed, the partial transaction rolls back when the system restarts. In all cases, the database is in a predictable state. Either the new order is completely entered, or it is not entered at all.

## Backups and logs with HCL Informix® database servers

By using transactions, you can ensure that the database is always in a consistent state and that your modifications are properly recorded on disk. But the disk itself is not perfectly safe. It is vulnerable to mechanical failures and to flood, fire, and earthquake. The only safeguard is to keep multiple copies of the data. These redundant copies are called *backup copies*.

The *transaction log* (also called the *logical log*) complements the backup copy of a database. Its contents are a history of all modifications that occurred since the last time the database was backed up. If you ever need to restore the database from the backup copy, you can use the transaction log to roll the database forward to its most recent state.

The database server contains elaborate features to support backups and logging. Your database server archive and backup guide describes these features.

The database server has stringent requirements for performance and reliability (for example, it supports making backup copies while databases are in use).

The database server manages its own disk space, which is devoted to logging.

The database server performs logging concurrently for all databases using a limited set of log files. The log files can be copied to another medium (backed up) while transactions are active.

Database users never have to be concerned with these facilities because the DBA usually manages them from a central location.

HCL Informix® supports the onload and onunload utilities. Use the onunload utility to make a personal backup copy of a single database or table. This program copies a table or a database to tape. Its output consists of binary images of the disk pages as they were stored in the database server. As a result, the copy can be made quickly, and the corresponding onload program can restore the file quickly. However, the data format is not meaningful to any other programs. For information about how to use the onload and onunload utilities, see the *Informix® Migration Guide*.

If your DBA uses ON-Bar to create backups and back up logical logs, you might also be able to create your own backup copies using ON-Bar. For more information, see your *Informix® Backup and Restore Guide*.

## Concurrency and locks

If your database is contained in a single-user workstation, without a network connecting it to other computers, concurrency is unimportant. In all other cases, you must allow for the possibility that, while your program is modifying data, another program is also reading or modifying the same data. *Concurrency* involves two or more independent uses of the same data at the same time.

A high level of concurrency is crucial to good performance in a multiuser database system. Unless controls exist on the use of data, however, concurrency can lead to a variety of negative effects. Programs could read obsolete data; modifications could be lost even though it seems they were entered successfully.

To prevent errors of this kind, the database server imposes a system of *locks*. A lock is a claim, or reservation, that a program can place on a piece of data. The database server guarantees that, as long as the data is locked, no other program can modify it. When another program requests the data, the database server either makes the program wait or turns it back with an error.

To control the effect that locks have on your data access, use a combination of SQL statements: SET LOCK MODE and either SET ISOLATION or SET TRANSACTION. You can understand the details of these statements after reading a discussion on the use of *cursors* from within programs. Cursors are covered in [SQL programming on page 1944](#), and [Modify data through SQL programs on page 1968](#). For more information about locking and concurrency, see [Programming for a multiuser environment on page 1978](#).

## HCL Informix® data replication

*Data replication*, in the broadest sense of the term, means that database objects have more than one representation at more than one distinct site. For example, one way to replicate data, so that reports can be run against the data without disturbing client applications that are using the original database, is to copy the database to a database server on a different computer.

The following list describes the advantages of data replication:

- Clients who access replicated data locally, as opposed to remote data that is not replicated, experience improved performance because they do not have to use network services.
- Clients at all sites experience improved availability with replicated data, because if local replicated data is unavailable, a copy of the data is still available, albeit remotely.

These advantages do not come without a cost. Data replication obviously requires more storage for replicated data than for unreplicated data, and updating replicated data can take more processing time than updating a single object.

Data replication can actually be implemented in the logic of client applications, by explicitly specifying where data should be found or updated. However, this method of achieving data replication is costly, error-prone, and difficult to maintain. Instead, the concept of data replication is often coupled with *replication transparency*. Replication transparency is functionality built into a database server (instead of client applications) to handle the details of locating and maintaining data replicas automatically.

Within the broad framework of data replication, a database server implements nearly transparent data replication of entire database servers. All the data that one database server manages is replicated and dynamically updated on another database server, usually at a remote site. Data replication of the HCL Informix® database server is sometimes called *hot-site backup*, because it provides a means of maintaining a backup copy of the entire database server that can be used quickly in the event of a catastrophic failure.

Because the database server provides replication transparency, you generally do not need to be concerned with or aware of data replication; the DBA takes care of it. However, if your organization decides to use data replication, you should be aware that special connectivity considerations exist for client applications in a data replication environment. These considerations are described in the *Informix® Administrator's Guide*.

The HCL Informix® Enterprise Replication feature provides a different method of data replication. For information on this feature, see the HCL Informix® Enterprise Replication Guide.

## Summary

Database access is regulated by the privileges that the database owner grants to you. The privileges that let you query data are often granted automatically, but the ability to modify data is regulated by specific Insert, Delete, and Update privileges that are granted on a table-by-table basis.

If data integrity constraints are imposed on the database, your ability to modify data is restricted by those constraints. Your database- and table-level privileges and any data constraints control how and when you can modify data. In addition, the object modes and violation detection features of the database affect how you can modify data and help to preserve the integrity of your data.

You can delete one or more rows from a table with the DELETE statement. Its WHERE clause selects the rows; use a SELECT statement with the same clause to preview the deletes.

The TRUNCATE statement deletes all the rows of a table.

Rows are added to a table with the INSERT statement. You can insert a single row that contains specified column values, or you can insert a block of rows that a SELECT statement generates.

Use the UPDATE statement to modify the contents of existing rows. You specify the new contents with expressions that can include subqueries, so that you can use data that is based on other tables or the updated table itself. The statement has

two forms. In the first form, you specify new values column by column. In the second form, a SELECT statement or a record variable generates a set of new values.

Use the REFERENCES clause of the CREATE TABLE and ALTER TABLE statements to create relationships between tables. The ON DELETE CASCADE option of the REFERENCES clause allows you to delete rows from parent and associated child tables with one DELETE statement.

Use transactions to prevent unforeseen interruptions in a modification from leaving the database in an indeterminate state. When modifications are performed within a transaction, they are rolled back after an error occurs. The transaction log also extends the periodically made backup copy of the database. If the database must be restored, it can be brought back to its most recent state.

Data replication, which is transparent to users, offers another type of protection from catastrophic failures.

## Access and modify data in an external database

This section summarizes accessing tables and routines that are not in the current database.

### Access other database servers

You can access any table or routine in an *external* database by qualifying the name of the database object (table, view, synonym, or routine).

When the external database is on the same database server as the current database, you must qualify the object name with the database name and a colon. For example, to refer to a table in a database other than the local database, the following SELECT statement accesses information from an external database:

```
SELECT name, number FROM salesdb:contacts
```

In this example, the query returns data from the table, **contacts**, that is in the database, **salesdb**.

A *remote* database server is any database server that is not the current database server. When the external database is on a remote database server, you must qualify the name of the database object with the database server name and the database name, as the following example illustrates:

```
SELECT name, number FROM salesdb@distantserver:contacts
```

In this example, the query returns data from the table, **contacts**, that is in the database, **salesdb** on the remote database server, **distantserver**.

For the syntax and rules on how to specify database object names in an external database, see the *Informix® Guide to SQL: Syntax*.

### Access ANSI databases

In ANSI databases, the owner of the object is part of the object name: **ownername.objectname**. When both the current and external databases are ANSI databases, unless you are the owner of the object, you must include the owner name. The following SELECT statement shows a fully-qualified table name:

```
SELECT name, number FROM salesdb@aserver:ownername.contacts
```

 **Tip:** You can always over-qualify an object name. That is, you can specify the full object name, `database@servername:ownername.objectname`, even in situations that do not require the full object name.

For more information about ANSI-compliant databases, refer to the *Informix® Database Design and Implementation Guide*.

## Create joins between external database servers

You can use the same notation in a join. When you specify the database name explicitly, the long table names can become cumbersome unless you use aliases to shorten them, as the following example shows:

```
SELECT O.order_num, C.fname, C.lname
FROM masterdb@central:customer C, sales@boston:orders O
WHERE C.customer_num = O.Customer_num
```

## Access external routines

To refer to a routine on a database server other than the current database server, qualify the routine name with the database server name and database name (and the owner name if the remote database is ANSI compliant), as the following SELECT statement illustrates:

```
SELECT name, salesdb@boston:how_long()
FROM salesdb@boston:contacts
```

## Restrictions for remote database access

This section summarizes the restrictions for remote database access.

## SQL statements that access more than one database

Only the data manipulation language (DML) statements of SQL, and a subset of the data definition language (DDL) statements of SQL can reference database objects outside the local database from which the statement is issued, or in databases of server instances that are not the local HCL Informix® server instance.

You can run the following SQL statements across databases and across database server instances:

- CREATE DATABASE
- CREATE SYNONYM
- CREATE VIEW
- DATABASE
- DELETE
- DROP DATABASE
- EXECUTE FUNCTION
- EXECUTE PROCEDURE
- INFO
- INSERT

- LOAD
- LOCK TABLE
- MERGE
- SELECT
- UNLOAD
- UNLOCK TABLE
- UPDATE

**Restriction:**

To run each of these SQL statements successfully across databases or across database servers, the local database and the external databases must all have the same logging mode. For example, if the local database from which you issue a distributed query was created as MODE ANSI, any other database that the query accesses cannot be unlogged, and cannot use explicit transactions.

**Return data types in cross-database operations**

Distributed operations that use SQL statements or UDRs to access other databases of the local HCL Informix® database server instance can return values of these data types:

- Any built-in atomic data type that is not opaque
- The built-in opaque types BLOB, BOOLEAN, BSON, CLOB, JSON, and LVARCHAR
- DISTINCT types based on a non-opaque built-in atomic type, or on a built-in opaque type listed above
- User-defined data types (UDTs) that can be cast to built-in types.

The DISTINCT or UDT values above must all be explicitly cast to built-in data types, and all the DISTINCT types, UDTs, and casts must be defined identically in each of the participating databases.

These data types can be returned by SPL, C, and Java-language UDRs as parameters or as return values, if the UDRs are defined in all of the participating databases. The DISTINCT data types must have exactly the same data type hierarchy defined in all databases that participate in the distributed query.

A cross-database distributed query or other cross-database DML operation that accesses another database of the local Informix® database server will fail with an error if it references a table, view, or synonym that includes a column of any of the following data types:

- IMPEXP
- IMPEXPBIN
- LOLIST
- SENDRECV
- DISTINCT of any of the built-in opaque data types in this list
- Complex types, including COLLECTION, LIST, MULTISSET, or SET, and named or unnamed ROW types.

This restriction against cross-database distributed operations that access tables with these built-in opaque or complex data types also applies to operations that access databases of two or more database server instances, which the next section describes.

### Return data types in cross-server operations

A distributed query (or any other distributed DML operation or function call) across databases of two or more Informix® instances cannot return complex or large-object data types, nor most UDTs or opaque data types. Cross-server distributed queries, DML operations, and function calls can return only the following data types:

- Any non-opaque built-in data type
- BOOLEAN
- BSON
- JSON
- LVARCHAR
- DISTINCT of non-opaque built-in types
- DISTINCT of BOOLEAN or LVARCHAR
- DISTINCT of BSON or JSON
- DISTINCT of any of the DISTINCT types in this list.

The same cross-database DDL requirements, that all UDRs, casts, and DISTINCT data types have identical definitions in every participating database, also apply to distributed SQL operations across the databases of two or more Informix® database-server instances.

A cross-server DML operation that accesses a database of another Informix® instance will fail with an error. However, if it references a table object that includes a column of any of the following data types:

- BLOB
- BYTE
- CLIENTBINVAL
- CLOB
- IFX\_LO\_SPEC
- IFX\_LO\_STAT
- IMPEXP
- IMPEXPBIN
- INDEXKEYARRAY
- LOLIST
- POINTER
- RTNPARAMTYPES
- SELFUNCARGS
- SENDRECV
- STAT
- TEXT
- XID
- User-defined OPAQUE type

- Complex types, including COLLECTION, LIST, MULTISSET, or SET, and named or unnamed ROW types.
- DISTINCT of any of the opaque or complex data types in this list.

## Access external database objects

To access external database objects:

- You must hold appropriate access permissions on these objects.
- Both databases must be set to the same locale.

**Important:** Distributed transactions cannot access objects in a database of another Informix® server instance unless both server instances support either a TCP/IP or an IPCSTR connection, as defined in their DBSERVERNAME or DBSERVERALIASES configuration parameters and in the sqlhosts information. This connection-type requirement applies to any communication between Informix® database server instances, even if both database servers reside on the same computer.

## SQL programming

The previous examples treat SQL as if it were an interactive computer language; that is, as if you could type a SELECT statement directly into the database server and see rows of data rolling back to you.

Of course, that is not the case. Many layers of software stand between you and the database server. The database server retains data in a binary form that must be formatted before it can be displayed. It does not return a mass of data at once; it returns one row at a time, as a program requests it.

You can access information in your database through interactive access with DB-Access, through application programs written with an SQL API such as Informix® ESQL/C, or through an application language such as SPL.

Almost any program can contain SQL statements, execute them, and retrieve data from a database server. This chapter explains how these activities are performed and indicates how you can write programs that perform them.

This chapter introduces concepts that are common to SQL programming in any language. Before you can write a successful program in a particular programming language, you must first become fluent in that language. Then, because the details of the process are different in every language, you must become familiar with the publication for the Informix® SQL API specific to that language.

## SQL in programs

You can write a program in any of several languages and mix SQL statements among the other statements of the program, just as if they were ordinary statements of that programming language. These SQL statements are embedded in the program, and the program contains *embedded SQL*, which is often abbreviated as ESQL.

## SQL in SQL APIs

ESQL products are Informix® SQL APIs (application programming interfaces). produces an SQL API for the C programming language.

The following figure shows how an SQL API product works. You write a source program in which you treat SQL statements as executable code. Your source program is processed by an embedded SQL *preprocessor*, a program that locates the embedded SQL statements and converts them into a series of procedure calls and special data structures.

Figure 380. Overview of processing a program with embedded SQL statements

The converted source program then passes through the programming language compiler. The compiler output becomes an executable program after it is linked with a static or *dynamic* library of SQL API procedures. When the program runs, the SQL API library procedures are called; they set up communication with the database server to carry out the SQL operations.

If you link your executable program to a threading library package, you can develop Informix® ESQL/C *multithreaded applications*. A multithreaded application can have many threads of control. It separates a process into multiple execution threads, each of which runs independently. The major advantage of a multithreaded Informix® ESQL/C application is that each thread can have many active connections to a database server simultaneously. While a nonthreaded Informix® ESQL/C application can establish many connections to one or more databases, it can have only one connection active at a time. A multithreaded Informix® ESQL/C application can have one active connection per thread and many threads per application.

For more information on multithreaded applications, see the *Informix® ESQL/C Programmer's Manual*.

## SQL in application languages

Whereas Informix® SQL API products allow you to embed SQL in the host language, some languages include SQL as a natural part of their statement set. Informix® Stored Procedure Language (SPL) uses SQL as a natural part of its statement set. You use an SQL API product to write application programs. You use SPL to write routines that are stored with a database and called from an application program.

## Static embedding

You can introduce SQL statements into a program through *static embedding* or *dynamic statements*. The simpler and more common way is by static embedding, which means that the SQL statements are written as part of the code. The statements

are *static* because they are a fixed part of the source text. For more information on static embedding, see [Retrieve single rows on page 1951](#) and [Retrieve multiple rows on page 1955](#).

## Dynamic statements

Some applications require the ability to compose SQL statements *dynamically*, in response to user input. For example, a program might have to select different columns or apply different criteria to rows, depending on what the user wants.

With dynamic SQL, the program composes an SQL statement as a string of characters in memory and passes it to the database server to be executed. Dynamic statements are not part of the code; they are constructed in memory during execution. For more information, see [Dynamic SQL on page 1962](#).

## Program variables and host variables

Application programs can use program variables within SQL statements. In SPL, you put the program variable in the SQL statement as syntax allows. For example, a DELETE statement can use a program variable in its WHERE clause.

The following code example shows a program variable in SPL.

```
CREATE PROCEDURE delete_item (drop_number INT)
DELETE FROM items WHERE order_num = drop_number
```

In applications that use embedded SQL statements, the SQL statements can refer to the contents of program variables. A program variable that is named in an embedded SQL statement is called a *host variable* because the SQL statement is thought of as a guest in the program.

The following example shows a DELETE statement as it might appear when it is embedded in the Informix® ESQL/C source program:

```
EXEC SQL delete FROM items
WHERE order_num = :onum;
```

In this program, you see an ordinary DELETE statement, as [Modify data on page 1901](#) describes. When the Informix® ESQL/C program is executed, a row of the **items** table is deleted; multiple rows can also be deleted.

The statement contains one new feature. It compares the **order\_num** column to an item written as **:onum**, which is the name of a host variable.

An SQL API product provides a way to delimit the names of host variables when they appear in the context of an SQL statement. In Informix® ESQL/C, a host variable can be introduced with either a dollar sign (\$) or a colon (:). The colon is the ANSI-compatible format. The example statement asks the database server to delete rows in which the order number equals the current contents of the host variable named **:onum**. This numeric variable was declared and assigned a value earlier in the program.

In Informix® ESQL/C, an SQL statement can be introduced with either a leading dollar sign (\$) or the words EXEC SQL.

The differences of syntax as illustrated in the preceding examples are trivial; the essential point is that the SQL API and SPL languages let you perform the following tasks:

- Embed SQL statements in a source program as if they were executable statements of the host language.
- Use program variables in SQL expressions the way literal values are used.

If you have programming experience, you can immediately see the possibilities. In the example, the order number to be deleted is passed in the variable **onum**. That value comes from any source that a program can use. It can be read from a file, the program can prompt a user to enter it, or it can be read from the database. The DELETE statement itself can be part of a subroutine (in which case **onum** can be a parameter of the subroutine); the subroutine can be called once or repetitively.

In short, when you embed SQL statements in a program, you can apply to them all the power of the host language. You can hide the SQL statements under many interfaces, and you can embellish the SQL functions in many ways.

## Call the database server

Executing an SQL statement is essentially calling the database server as a subroutine. Information must pass from the program to the database server, and information must be returned from the database server to the program.

Some of this communication is done through host variables. You can think of the host variables named in an SQL statement as the parameters of the procedure call to the database server. In the preceding example, a host variable acts as a parameter of the WHERE clause. Host variables receive data that the database server returns, as [Retrieve multiple rows on page 1955](#) describes.

## SQL Communications Area

The database server always returns a result code, and possibly other information about the effect of an operation, in a data structure known as the SQL Communications Area (SQLCA). If the database server executes an SQL statement in a user-defined routine, the SQLCA of the calling application contains the values that the SQL statement triggers in the routine.

The principal fields of the SQLCA are listed in [Table 88: Values of SQLCODE on page 1948](#) through [Table 90: Fields of SQLWARN on page 1950](#). The syntax that you use to describe a data structure such as the SQLCA, as well as the syntax that you use to refer to a field in it, differs among programming languages. For details, see your SQL API publication.

In particular, the subscript by which you name one element of the SQLERRD and SQLWARN arrays differs. Array elements are numbered starting with zero in Informix® ESQL/C, but starting with one in other languages. In this discussion, the fields are named with specific words such as `third`, and you must translate these words into the syntax of your programming language.

You can also use the SQLSTATE variable of the GET DIAGNOSTICS statement to detect, handle, and diagnose errors. See [SQLSTATE value on page 1951](#).

## SQLCODE field

The SQLCODE field is the primary return code of the database server. After every SQL statement, SQLCODE is set to an integer value as the following table shows. When that value is zero, the statement is performed without error. In particular,

when a statement is supposed to return data into a host variable, a code of zero means that the data has been returned and can be used. Any nonzero code means the opposite. No useful data was returned to host variables.

**Table 88. Values of SQLCODE**

| Return value      | Interpretation   |
|-------------------|--|
| $value < 0$       | Specifies an error code.   |
| $value = 0$       | Indicates success.   |
| $0 < value < 100$ | After a DESCRIBE statement, an integer value that represents the type of SQL statement that is described.  |
| 100               | After a successful query that returns no rows, indicates the NOT FOUND condition. NOT FOUND can also occur in an ANSI-compliant database after an INSERT INTO/SELECT, UPDATE, DELETE, or SELECT... INTO TEMP statement fails to access any rows. |

## End of data

The database server sets SQLCODE to 100 when the statement is performed correctly but no rows are found. This condition can occur in two situations.

The first situation involves a query that uses a cursor. ([Retrieve multiple rows on page 1955](#) describes queries that use cursors.) In these queries, the FETCH statement retrieves each value from the active set into memory. After the last row is retrieved, a subsequent FETCH statement cannot return any data. When this condition occurs, the database server sets SQLCODE to 100, which indicates `end of data, no rows found`.

The second situation involves a query that does not use a cursor. In this case, the database server sets SQLCODE to 100 when no rows satisfy the query condition. In databases that are not ANSI compliant, only a SELECT statement that returns no rows causes SQLCODE to be set to 100.

In ANSI-compliant databases, SELECT, DELETE, UPDATE, and INSERT statements all set SQLCODE to 100 if no rows are returned.

## Negative Codes

When something unexpected goes wrong during a statement, the database server returns a negative number in SQLCODE to explain the problem. The meanings of these codes are documented in the online error message file.

## SQLERRD array

Some error codes that can be reported in SQLCODE reflect general problems. The database server can set a more detailed code in the second field of SQLERRD that reveals the error that the database server I/O routines or the operating system encountered.

The integers in the SQLERRD array are set to different values following different statements. The first and fourth elements of the array are used only in Informix® ESQL/C. The following table shows how the fields are used.

**Table 89. Fields of SQLERRD**

| Field   | Interpretation   |
|---------|--|
| First   | After a successful PREPARE statement for a SELECT, UPDATE, INSERT, or DELETE statement, or after a Select cursor is opened, this field contains the estimated number of rows affected.   |
| Second  | When SQLCODE contains an error code, this field contains either zero or an additional error code, called the ISAM error code, that explains the cause of the main error. After a successful insert operation of a single row, this field contains the value of any SERIAL, BIGSERIAL, or SERIAL8 value generated for that row. (This field is not updated, however, when a serial column is directly inserted as a triggered action by a trigger on a table, or by an INSTEAD OF trigger on a view.) |
| Third   | After a successful multirow insert, update, or delete operation, this field contains the number of rows that were processed. After a multirow insert, update, or delete operation that ends with an error, this field contains the number of rows that were successfully processed before the error was detected.  |
| Fourth  | After a successful PREPARE statement for a SELECT, UPDATE, INSERT, or DELETE statement, or after a select cursor has been opened, this field contains the estimated weighted sum of disk accesses and total rows processed.  |
| Fifth   | After a syntax error in a PREPARE, EXECUTE IMMEDIATE, DECLARE, or static SQL statement, this field contains the offset in the statement text where the error was detected.   |
| Sixth   | After a successful fetch of a selected row, or a successful insert, update, or delete operation, this field contains the rowid (physical address) of the last row that was processed. Whether this rowid value corresponds to a row that the database server returns to the user depends on how the database server processes a query, particularly for SELECT statements.   |
| Seventh | Reserved.  |

These additional details can be useful. For example, you can use the value in the third field to report how many rows were deleted or updated. When your program prepares an SQL statement that the user enters and an error is found, the value in the fifth field enables you to display the exact point of error to the user. (DB-Access uses this feature to position the cursor when you ask to modify a statement after an error.)

## SQLWARN array

The eight character fields in the SQLWARN array are set to either a blank or to **w** to indicate a variety of special conditions. Their meanings depend on the statement just executed.

A set of warning flags appears when a database opens, that is, following a CONNECT, DATABASE, or CREATE DATABASE statement. These flags tell you some characteristics of the database as a whole.

A second set of flags appears following any other statement. These flags reflect unusual events that occur during the statement, which are usually not serious enough to be reflected by SQLCODE.

Both sets of SQLWARN values are summarized in the following table.

**Table 90. Fields of SQLWARN**

| Field   | When opening or connecting to a database   | All other SQL operations  |
|---------|--|---|
| First   | Set to <code>w</code> when any other warning field is set to <code>w</code> . If blank, others need not be checked.  | Set to <code>w</code> when any other warning field is set to <code>w</code> .   |
| Second  | Set to <code>w</code> when the database now open uses a transaction log.   | Set to <code>w</code> if a column value is truncated when it is fetched into a host variable using a FETCH or a SELECT...INTO statement. On a REVOKE ALL statement, set to <code>w</code> when not all seven table-level privileges are revoked.  |
| Third   | Set to <code>w</code> when the database now open is ANSI compliant.  | Set to <code>w</code> when a FETCH or SELECT statement returns an aggregate function (SUM, AVG, MIN, MAX) value that is NULL.   |
| Fourth  | Set to <code>w</code> when the database server is HCL Informix®.   | On a SELECT ... INTO, FETCH ... INTO, or EXECUTE ... INTO statement, set to <code>w</code> when the number of projection list items is not the same as the number of host variables given in the INTO clause to receive them. On a GRANT ALL statement, set to <code>w</code> when not all seven table-level access privileges are granted. |
| Fifth   | Set to <code>w</code> when the database server stores the FLOAT data type in DECIMAL form (done when the host system lacks support for FLOAT types).   | Set to <code>w</code> after a DESCRIBE statement if the prepared object contains a DELETE statement or an UPDATE statement without a WHERE clause.  |
| Sixth   | Reserved.  | Set to <code>w</code> following execution of a statement that does not use ANSI-standard SQL syntax (provided the <b>DBANSIWARN</b> environment variable is set).   |
| Seventh | Set to <code>w</code> when the application is connected to a database server that is the secondary server in a data-replication pair. That is, the server is available only for read operations. | Set to <code>w</code> when a data fragment (a dbspace) has been skipped during query processing (when the DATASKIP feature is on).  |
| Eighth  | Set to <code>w</code> when client DB_LOCALE does not match the database locale. For more information, see the <i>Informix® GLS User's Guide</i> .  | Set to <code>w</code> when SET EXPLAIN ON AVOID_EXECUTE statement prevents query execution.   |

## SQLERRM character string

SQLERRM can store a character string of up to 72 bytes. The SQLERRM character string contains identifiers, such as a table names, that are placed in the error message. For some networked applications, it contains an error message that the networking software generates.

If an INSERT operation fails because a constraint is violated, the name of the constraint that failed is written to SQLERRM.

 **Tip:** If an error string is longer than 72 bytes, the overflow is silently discarded. In some contexts, this can result in the loss of information about runtime errors.

## SQLSTATE value

Certain Informix® products, such as Informix® ESQL/C, support the SQLSTATE value in compliance with X/Open and ANSI SQL standards. The GET DIAGNOSTICS statement reads the SQLSTATE value to diagnose errors after you run an SQL statement. The database server returns a result code in a five-character string that is stored in a variable called SQLSTATE. The SQLSTATE error code, or value, tells you the following information about the most recently executed SQL statement:

- If the statement was successful
- If the statement was successful but generated warnings
- If the statement was successful but generated no data
- If the statement failed

For more information on the GET DIAGNOSTICS statement, the SQLSTATE variable, and the meaning of the SQLSTATE return codes, see the GET DIAGNOSTICS statement in the *Informix® Guide to SQL: Syntax*.

 **Tip:** If your Informix® product supports GET DIAGNOSTICS and SQLSTATE, it is recommended that you use them as the primary structure to detect, handle, and diagnose errors. Using SQLSTATE allows you to detect multiple errors, and it is ANSI compliant.

## Retrieve single rows

The set of rows that a SELECT statement returns is its *active set*. A *singleton* SELECT statement returns a single row. You can use embedded SELECT statements to retrieve single rows from the database into host variables. When a SELECT statement returns more than one row of data, however, a program must use a *cursor* to retrieve rows one at a time. Multiple-row select operations are discussed in [Retrieve multiple rows on page 1955](#).

To retrieve a single row of data, simply embed a SELECT statement in your program. The following example shows how you can write the embedded SELECT statement using Informix® ESQL/C:

```
EXEC SQL SELECT avg (total_price)
INTO :avg_price
FROM items
WHERE order_num in
(SELECT order_num from orders
WHERE order_date < date('6/1/98') );
```

The INTO clause is the only detail that distinguishes this statement from any example in [Compose SELECT statements on page 1773](#) or [Compose advanced SELECT statements on page 1862](#). This clause specifies the host variables that are to receive the data that is produced.

When the program executes an embedded SELECT statement, the database server performs the query. The example statement selects an aggregate value so that it produces exactly one row of data. The row has only a single column, and its value is deposited in the host variable named **avg\_price**. Subsequent lines of the program can use that variable.

You can use statements of this kind to retrieve single rows of data into host variables. The single row can have as many columns as desired. If a query produces more than one row of data, the database server cannot return any data. It returns an error code instead.

You should list as many host variables in the INTO clause as there are items in the select list. If, by accident, these lists are of different lengths, the database server returns as many values as it can and sets the warning flag in the fourth field of SQLWARN.

## Data type conversion

The following Informix® ESQL/C example retrieves the average of a DECIMAL column, which is itself a DECIMAL value. However, the host variable into which the average of the DECIMAL column is placed is not required to have that data type.

```
EXEC SQL SELECT avg (total_price) into :avg_price
FROM items;
```

The declaration of the receiving variable **avg\_price** in the previous example of Informix® ESQL/C code is not shown. The declaration could be any one of the following definitions:

```
int avg_price;
double avg_price;
char avg_price[16];
dec_t avg_price; /* typedef of decimal number structure */
```

The data type of each host variable that is used in a statement is noted and passed to the database server with the statement. The database server does its best to convert column data into the form that the receiving variables use. Almost any conversion is allowed, although some conversions cause a precision loss. The results of the preceding example differ, depending on the data type of the receiving host variable, as the following table shows.

| Data type | Result   |
|-----------|--|
| FLOAT     | The database server converts the decimal result to FLOAT, possibly truncating some fractional digits. If the magnitude of a decimal exceeds the maximum magnitude of the FLOAT format, an error is returned. |

| Data type | Result  |
|-----------|---|
| INTEGER   | The database server converts the result to INTEGER, truncating fractional digits if necessary. If the integer part of the converted number does not fit the receiving variable, an error occurs.                                      |
| CHARACTER | The database server converts the decimal value to a CHARACTER string. If the string is too long for the receiving variable, it is truncated. The second field of SQLWARN is set to W and the value in the SQLSTATE variable is 01004. |

## What if the program retrieves a NULL value?

NULL values can be stored in the database, but the data types that programming languages support do not recognize a NULL state. A program must have some way to recognize a NULL item to avoid processing it as data.

*Indicator variables* meet this need in SQL APIs. An indicator variable is an additional variable that is associated with a host variable that might receive a NULL item. When the database server puts data in the main variable, it also puts a special value in the indicator variable to show whether the data is NULL. In the following Informix® ESQL/C example, a single row is selected, and a single value is retrieved into the host variable **op\_date**:

```
EXEC SQL SELECT paid_date
        INTO :op_date:op_d_ind
        FROM orders
        WHERE order_num = $the_order;
if (op_d_ind < 0) /* data was null */
    rstrdate ('01/01/1900', :op_date);
```

Because the value might be NULL, an indicator variable named **op\_d\_ind** is associated with the host variable. (It must be declared as a short integer elsewhere in the program.)

Following execution of the SELECT statement, the program tests the indicator variable for a negative value. A negative number (usually `-1`) means that the value retrieved into the main variable is NULL. If the variable is NULL, this program uses the Informix® ESQL/C library function to assign a default value to the host variable. (The function `rstrdate` is part of the Informix® ESQL/C product.)

The syntax that you use to associate an indicator variable with a host variable differs with the language you are using, but the principle is the same in all languages.

## Dealing with errors

Although the database server automatically handles conversion between data types, several things still can go wrong with a SELECT statement. In SQL programming, as in any kind of programming, you must anticipate errors and provide for them at every point.

## End of data

One common event is that no rows satisfy a query. This event is signalled by an SQLSTATE code of 02000 and by a code of 100 in SQLCODE after a SELECT statement. This code indicates an error or a normal event, depending entirely on your application. If you are sure a row or rows should satisfy the query (for example, if you are reading a row using a key value that you just read from a row of another table), then the end-of-data code represents a serious failure in the logic of the program. On the other hand, if you select a row based on a key that a user supplies or some other source supplies that is less reliable than a program, a lack of data can be a normal event.

## End of data with databases that are not ANSI compliant

If your database is not ANSI compliant, the end-of-data return code, 100, is set in SQLCODE following SELECT statements only. In addition, the SQLSTATE value is set to 02000. (Other statements, such as INSERT, UPDATE, and DELETE, set the third element of SQLERRD to show how many rows they affected; [Modify data through SQL programs on page 1968](#) covers this topic.)

## Serious errors

Errors that set SQLCODE to a negative value or SQLSTATE to a value that begins with anything other than 00, 01, or 02 are usually serious. Programs that you have developed and that are in production should rarely report these errors. Nevertheless, it is difficult to anticipate every problematic situation, so your program must be able to deal with these errors.

For example, a query can return error -206, which means that a table specified in the query is not in the database. This condition occurs if someone dropped the table after the program was written, or if the program opened the wrong database through some error of logic or mistake in input.

## Interpret end of data with aggregate functions

A SELECT statement that uses an aggregate function such as SUM, MIN, or AVG always succeeds in returning at least one row of data, even when no rows satisfy the WHERE clause. An aggregate value based on an empty set of rows is null, but it exists nonetheless.

However, an aggregate value is also null if it is based on one or more rows that all contain null values. If you must be able to detect the difference between an aggregate value that is based on no rows and one that is based on some rows that are all null, you must include a COUNT function in the statement and an indicator variable on the aggregate value. You can then work out the following cases.

| Count Value | Indicator | Case                              |
|-------------|-----------|-----------------------------------|
| 0           | -1        | Zero rows selected                |
| >0          | -1        | Some rows selected; all were null |

| Count Value | Indicator | Case                        |
|-------------|-----------|-----------------------------|
| >0          | 0         | Some non-null rows selected |

## Default values

You can handle these inevitable errors in many ways. In some applications, more lines of code are used to handle errors than to execute functionality. In the examples in this section, however, one of the simplest solutions, the default value, should work, as the following example shows:

```
avg_price = 0; /* set default for errors */
EXEC SQL SELECT avg (total_price)
      INTO :avg_price:null_flag
      FROM items;
if (null_flag < 0) /* probably no rows */
  avg_price = 0; /* set default for 0 rows */
```

The previous example deals with the following considerations:

- If the query selects some non-null rows, the correct value is returned and used. This result is the expected and most frequent one.
- If the query selects no rows, or in the much less likely event, selects only rows that have null values in the **total\_price** column (a column that should never be null), the indicator variable is set, and the default value is assigned.
- If any serious error occurs, the host variable is left unchanged; it contains the default value initially set. At this point in the program, the programmer sees no need to trap such errors and report them.

## Retrieve multiple rows

When any chance exists that a query could return more than one row, the program must execute the query differently. Multirow queries are handled in two stages. First, the program starts the query. (No data is returned immediately.) Then the program requests the rows of data one at a time.

These operations are performed using a special data object called a *cursor*. A cursor is a data structure that represents the current state of a query. The following list shows the general sequence of program operations:

1. The program *declares* the cursor and its associated SELECT statement, which merely allocates storage to hold the cursor.
2. The program *opens* the cursor, which starts the execution of the associated SELECT statement and detects any errors in it.
3. The program *fetches* a row of data into host variables and processes it.
4. The program *closes* the cursor after the last row is fetched.
5. When the cursor is no longer needed, the program *frees* the cursor to deallocate the resources it uses.

These operations are performed with SQL statements named DECLARE, OPEN, FETCH, CLOSE, and FREE.

## Declare a cursor

You use the DECLARE statement to declare a cursor. This statement gives the cursor a name, specifies its use, and associates it with a statement. The following example is written in Informix® ESQL/C:

```
EXEC SQL DECLARE the_item CURSOR FOR
  SELECT order_num, item_num, stock_num
  INTO :o_num, :i_num, :s_num
  FROM items
  FOR READ ONLY;
```

The declaration gives the cursor a name (**the\_item** in this case) and associates it with a SELECT statement. ([Modify data through SQL programs on page 1968](#) discusses how a cursor can also be associated with an INSERT statement.)

The SELECT statement in this example contains an INTO clause. The INTO clause specifies which variables receive data. You can also use the FETCH statement to specify which variables receive data, as [Locate the INTO clause on page 1957](#) discusses.

The DECLARE statement is not an active statement; it merely establishes the features of the cursor and allocates storage for it. You can use the cursor declared in the preceding example to read through the **items** table once. Cursors can be declared to read backward and forward (see [Cursor input modes on page 1958](#)). This cursor, because it lacks a FOR UPDATE clause and because it is designated FOR READ ONLY, is used only to read data, not to modify it. [Modify data through SQL programs on page 1968](#) covers the use of cursors to modify data.

## Open a cursor

The program opens the cursor when it is ready to use it. The OPEN statement activates the cursor. It passes the associated SELECT statement to the database server, which begins the search for matching rows. The database server processes the query to the point of locating or constructing the first row of output. It does not actually return that row of data, but it does set a return code in SQLSTATE and in SQLCODE for SQL APIs. The following example shows the OPEN statement in Informix® ESQL/C:

```
EXEC SQL OPEN the_item;
```

Because the database server is seeing the query for the first time, it might detect a number of errors. After the program opens the cursor, it should test SQLSTATE or SQLCODE. If the SQLSTATE value is greater than 02000 or the SQLCODE contains a negative number, the cursor is not usable. An error might be present in the SELECT statement, or some other problem might prevent the database server from executing the statement.

If SQLSTATE is equal to 00000, or SQLCODE contains a zero, the SELECT statement is syntactically valid, and the cursor is ready to use. At this point, however, the program does not know if the cursor can produce any rows.

## Fetch rows

The program uses the `FETCH` statement to retrieve each row of output. This statement names a cursor and can also name the host variables that receive the data. The following example shows the completed Informix® ESQL/C code:

```
EXEC SQL DECLARE the_item CURSOR FOR
  SELECT order_num, item_num, stock_num
     INTO :o_num, :i_num, :s_num
     FROM items;
EXEC SQL OPEN the_item;
while(SQLCODE == 0)
{
  EXEC SQL FETCH the_item;
  if(SQLCODE == 0)
    printf("%d, %d, %d", o_num, i_num, s_num);
}
```

## Detect end of data

In the previous example, the `WHILE` condition prevents execution of the loop in case the `OPEN` statement returns an error. The same condition terminates the loop when `SQLCODE` is set to `100` to signal the end of data. However, the loop contains a test of `SQLCODE`. This test is necessary because, if the `SELECT` statement is valid yet finds no matching rows, the `OPEN` statement returns a zero, but the first fetch returns `100` (end of data) and no data. The following example shows another way to write the same loop:

```
EXEC SQL DECLARE the_item CURSOR FOR
  SELECT order_num, item_num, stock_num
     INTO :o_num, :i_num, :s_num
     FROM items;
EXEC SQL OPEN the_item;
if(SQLCODE == 0)
  EXEC SQL FETCH the_item;      /* fetch 1st row*/
while(SQLCODE == 0)
{
  printf("%d, %d, %d", o_num, i_num, s_num);
  EXEC SQL FETCH the_item;
}
```

In this version, the case of no returned rows is handled early, so no second test of `SQLCODE` exists within the loop. These versions have no measurable difference in performance because the time cost of a test of `SQLCODE` is a tiny fraction of the cost of a fetch.

## Locate the INTO clause

The `INTO` clause names the host variables that are to receive the data that the database server returns. The `INTO` clause must appear in either the `SELECT` or the `FETCH` statement. However it cannot appear in both statements. The following example specifies host variables in the `FETCH` statement:

```
EXEC SQL DECLARE the_item CURSOR FOR
  SELECT order_num, item_num, stock_num
```

```

        FROM items;
EXEC SQL OPEN the_item;
while(SQLCODE == 0)
{
    EXEC SQL FETCH the_item INTO :o_num, :i_num, :s_num;
    if(SQLCODE == 0)
        printf("%d, %d, %d", o_num, i_num, s_num);
}

```

This form lets you fetch different rows into different locations. For example, you could use this form to fetch successive rows into successive elements of an array.

## Cursor input modes

For purposes of input, a cursor operates in one of two modes, *sequential* or *scrolling*. A sequential cursor can fetch only the next row in sequence, so a sequential cursor can read through a table only once each time the cursor is opened. A scroll cursor can fetch the next row or any of the output rows, so a scroll cursor can read the same rows multiple times. The following example shows a sequential cursor declared in Informix® ESQL/C.

```

EXEC SQL DECLARE pcurs cursor for
    SELECT customer_num, lname, city
    FROM customer;

```

After the cursor is opened, it can be used only with a sequential fetch that retrieves the next row of data, as the following example shows:

```

EXEC SQL FETCH p_curs into:cnum, :curname, :ccity;

```

Each sequential fetch returns a new row.

A scroll cursor is declared with the keywords `SCROLL CURSOR`, as the following example from Informix® ESQL/C shows:

```

EXEC SQL DECLARE s_curs SCROLL CURSOR FOR
    SELECT order_num, order_date FROM orders
    WHERE customer_num > 104

```

Use the scroll cursor with a variety of fetch options. For example, the `ABSOLUTE` option specifies the absolute row position of the row to fetch.

```

EXEC SQL FETCH ABSOLUTE :numrow s_curs
    INTO :nordr, :nodat

```

This statement fetches the row whose position is given in the host variable **numrow**. You can also fetch the current row again, or you can fetch the first row and then scan through all the rows again. However, these features can cause the application to run more slowly, as the next section describes. For additional options that apply to scroll cursors, see the `FETCH` statement in the *Informix® Guide to SQL: Syntax*.

## Active set of a cursor

Once a cursor is opened, it stands for some selection of rows. The set of all rows that the query produces is called the *active set* of the cursor. It is easy to think of the active set as a well-defined collection of rows and to think of the cursor as pointing to one row of the collection. This situation is true as long as no other programs are modifying the same data concurrently.

## Create the active set

When a cursor is opened, the database server does whatever is necessary to locate the first row of selected data. Depending on how the query is phrased, this action can be easy, or it can require a great deal of work and time. Consider the following declaration of a cursor:

```
EXEC SQL DECLARE easy CURSOR FOR
  SELECT fname, lname FROM customer
  WHERE state = 'NJ'
```

Because this cursor queries only a single table in a simple way, the database server quickly determines whether any rows satisfy the query and identifies the first one. The first row is the only row the cursor finds at this time. The rest of the rows in the active set remain unknown. As a contrast, consider the following declaration of a cursor:

```
EXEC SQL DECLARE hard SCROLL CURSOR FOR
  SELECT C.customer_num, O.order_num, sum (items.total_price)
  FROM customer C, orders O, items I
  WHERE C.customer_num = O.customer_num
  AND O.order_num = I.order_num
  AND O.paid_date is null
  GROUP BY C.customer_num, O.order_num
```

The active set of this cursor is generated by joining three tables and grouping the output rows. The optimizer might be able to use indexes to produce the rows in the correct order, but generally the use of ORDER BY or GROUP BY clauses requires the database server to generate all the rows, copy them to a temporary table, and sort the table, before it can determine which row to present first.

In cases where the active set is entirely generated and saved in a temporary table, the database server can take quite some time to open the cursor. Afterwards, the database server could tell the program exactly how many rows the active set contains. However, this information is not made available. One reason is that you can never be sure which method the optimizer uses. If the optimizer can avoid sorts and temporary tables, it does so; but small changes in the query, in the sizes of the tables, or in the available indexes can change the methods of the optimizer.

## Active set for a sequential cursor

The database server attempts to use as few resources as possible to maintain the active set of a cursor. If it can do so, the database server never retains more than the single row that is fetched next. It can do this for most sequential cursors. On each fetch, it returns the contents of the current row and locates the next one.

## Active set for a SCROLL cursor

All the rows in the active set for a SCROLL cursor must be retained until the cursor closes because the database server cannot be sure which row the program will ask for next.

Most frequently, the database server implements the active set of a scroll cursor as a temporary table. The database server might not fill this table immediately, however (unless it created a temporary table to process the query). Usually it creates the temporary table when the cursor is opened. Then, the first time a row is fetched, the database server copies it into the temporary table and returns it to the program. When a row is fetched for a second time, it can be taken from the temporary table. This scheme uses the fewest resources, in the event that the program abandons the query before it fetches all the rows. Rows that are never fetched are not created or saved.

## Active set and concurrency

When only one program is using a database, the members of the active set cannot change. This situation describes most personal computers, and it is the easiest situation to think about. But some programs must be designed for use in a multiprogramming system, where two, three, or dozens of different programs can work on the same tables simultaneously.

When other programs can update the tables while your cursor is open, the idea of the active set becomes less useful. Your program can see only one row of data at a time, but all other rows in the table can be changing.

In the case of a simple query, when the database server holds only one row of the active set, any other row can change. The instant after your program fetches a row, another program can delete the same row, or update it so that if it is examined again, it is no longer part of the active set.

When the active set, or part of it, is saved in a temporary table, *stale data* can present a problem. That is, the rows in the actual tables from which the active-set rows are derived can change. If they do, some of the active-set rows no longer reflect the current table contents.

These ideas seem unsettling at first, but as long as your program only reads the data, stale data does not exist, or rather, all data is equally stale. The active set is a snapshot of the data as it is at one moment. A row is different the next day; it does not matter if it is also different in the next millisecond. To put it another way, no practical difference exists between changes that occur while the program is running and changes that are saved and applied the instant that the program terminates.

The only time that stale data can cause a problem is when the program intends to use the input data to modify the same database; for example, when a banking application must read an account balance, change it, and write it back. [Modify data through SQL programs on page 1968](#) discusses programs that modify data.

## Parts-explosion problem

When you use a cursor supplemented by program logic, you can solve problems that plain SQL cannot solve. One of these problems is the parts-explosion problem, sometimes called bill-of-materials processing. At the heart of this problem is a recursive relationship among objects; one object contains other objects, which contain yet others.

The problem is usually stated in terms of a manufacturing inventory. A company makes a variety of parts, for example. Some parts are discrete, but some are assemblages of other parts.

These relationships are documented in a single table, which might be called **contains**. The column **contains.parent** holds the part numbers of parts that are assemblages. The column **contains.child** has the part number of a part that is a component of the parent. If part number 123400 is an assembly of nine parts, nine rows exist with 123400 in the first column and other part numbers in the second. The following figure shows one of the rows that describe part number 123400.

Figure 381. Parts-explosion problem

| CONTAINS |        |
|----------|--------|
| PARENT   | CHILD  |
| FKNN     | FKNN   |
| 123400   | 432100 |
| 432100   | 765899 |

Here is the parts-explosion problem: given a part number, produce a list of all parts that are components of that part. The following example is a sketch of one solution, as implemented in Informix® ESQL/C:

```
int part_list[200];

boom(top_part)
int top_part;
{
    long this_part, child_part;
    int next_to_do = 0, next_free = 1;
    part_list[next_to_do] = top_part;

    EXEC SQL DECLARE part_scan CURSOR FOR
        SELECT child INTO child_part FROM contains
            WHERE parent = this_part;
    while(next_to_do < next_free)
    {
        this_part = part_list[next_to_do];
        EXEC SQL OPEN part_scan;
        while(SQLCODE == 0)
        {
            EXEC SQL FETCH part_scan;
            if(SQLCODE == 0)
            {
                part_list[next_free] = child_part;
                next_free += 1;
            }
        }
        EXEC SQL CLOSE part_scan;
        next_to_do += 1;
    }
    return (next_free - 1);
}
```

Technically speaking, each row of the **contains** table is the head node of a directed acyclic graph, or *tree*. The function performs a breadth-first search of the tree whose root is the part number passed as its parameter. The function uses a cursor named **part\_scan** to return all the rows with a particular value in the **parent** column. The innermost `while` loop opens

the **part\_scan** cursor, fetches each row in the selection set, and closes the cursor when the part number of each component has been retrieved.

This function addresses the heart of the parts-explosion problem, but the function is not a complete solution. For example, it does not allow for components that appear at more than one level in the tree. Furthermore, a practical **contains** table would also have a column **count**, giving the count of **child** parts used in each **parent**. A program that returns a total count of each component part is much more complicated.

The iterative approach described previously is not the only way to approach the parts-explosion problem. If the number of generations has a fixed limit, you can solve the problem with a single SELECT statement using nested, outer self-joins.

If up to four generations of parts can be contained within one top-level part, the following SELECT statement returns all of them:

```
SELECT a.parent, a.child, b.child, c.child, d.child
FROM contains a
     OUTER (contains b,
           OUTER (contains c, outer contains d) )
WHERE a.parent = top_part_number
     AND a.child = b.parent
     AND b.child = c.parent
     AND c.child = d.parent
```

This SELECT statement returns one row for each line of descent rooted in the part given as **top\_part\_number**. Null values are returned for levels that do not exist. (Use indicator variables to detect them.) To extend this solution to more levels, select additional nested outer joins of the **contains** table. You can also revise this solution to return counts of the number of parts at each level.

## Dynamic SQL

Although static SQL is useful, it requires that you know the exact content of every SQL statement at the time you write the program. For example, you must state exactly which columns are tested in any WHERE clause and exactly which columns are named in any select list.

No problem exists when you write a program to perform a well-defined task. But the database tasks of some programs cannot be perfectly defined in advance. In particular, a program that must respond to an interactive user might need to compose SQL statements in response to what the user enters.

Dynamic SQL allows a program to form an SQL statement during execution, so that user input determines the contents of the statement. This action is performed in the following steps:

1. The program assembles the text of an SQL statement as a character string, which is stored in a program variable.
2. It executes a PREPARE statement, which asks the database server to examine the statement text and prepare it for execution.
3. It uses the EXECUTE statement to execute the prepared statement.

In this way, a program can construct and then use any SQL statement, based on user input of any kind. For example, it can read a file of SQL statements and prepare and execute each one.

DB-Access, a utility that you can use to explore SQL interactively, is the Informix® ESQL/C program that constructs, prepares, and executes SQL statements dynamically. For example, DB-Access lets you use simple, interactive menus to specify the columns of a table. When you are finished, DB-Access builds the necessary CREATE TABLE or ALTER TABLE statement dynamically and prepares and executes it.

## Prepare a statement

In form, a dynamic SQL statement is like any other SQL statement that is written into a program, except that it cannot contain the names of any host variables.

A prepared SQL statement has two restrictions. First, if it is a SELECT statement, it cannot include the INTO *variable* clause. The INTO *variable* clause specifies host variables into which column data is placed, and host variables are not allowed in the text of a prepared object. Second, wherever the name of a host variable normally appears in an expression, a question mark (?) is written as a placeholder in the PREPARE statement. Only the PREPARE statement can specify question mark (?) placeholders.

You can prepare a statement in this form for execution with the PREPARE statement. The following example is written in Informix® ESQL/C:

```
EXEC SQL prepare query_2 from
    'SELECT * from orders
     WHERE customer_num = ? and order_date > ?';
```

The two question marks in this example indicate that when the statement is executed, the values of host variables are used at those two points.

You can prepare almost any SQL statement dynamically. The only statements that you cannot prepare are the ones directly concerned with dynamic SQL and cursor management, such as the PREPARE and OPEN statements. After you prepare an UPDATE or DELETE statement, it is a good idea to test the fifth field of SQLWARN to see if you used a WHERE clause (see [SQLWARN array on page 1949](#)).

The result of preparing a statement is a data structure that represents the statement. This data structure is not the same as the string of characters that produced it. In the PREPARE statement, you give a name to the data structure; it is **query\_2** in the preceding example. This name is used to execute the prepared SQL statement.

The PREPARE statement does not limit the character string to one statement. It can contain multiple SQL statements, separated by semicolons. The following example shows a fairly complex transaction in Informix® ESQL/C:

```
strcpy(big_query, "UPDATE account SET balance = balance + ?
WHERE customer_id = ?; \ UPDATE teller SET balance =
balance + ? WHERE teller_id = ?;");
EXEC SQL PREPARE big1 FROM :big_query;
```

When this list of statements is executed, host variables must provide values for six place-holding question marks. Although it is more complicated to set up a multistatement list, performance is often better because fewer exchanges take place between the program and the database server.

## Execute prepared SQL

After you prepare a statement, you can execute it multiple times. Statements other than SELECT statements, and SELECT statements that return only a single row, are executed with the EXECUTE statement.

The following Informix® ESQL/C code prepares and executes a multistatement update of a bank account:

```
EXEC SQL BEGIN DECLARE SECTION;
char bigquery[270] = "begin work;";
EXEC SQL END DECLARE SECTION;
stcat ("update account set balance = balance + ? where ", bigquery);
stcat ("acct_number = ?;', bigquery);
stcat ("update teller set balance = balance + ? where ", bigquery);
stcat ("teller_number = ?;', bigquery);
stcat ("update branch set balance = balance + ? where ", bigquery);
stcat ("branch_number = ?;', bigquery);
stcat ("insert into history values(timestamp, values);", bigquery);

EXEC SQL prepare bigq from :bigquery;

EXEC SQL execute bigq using :delta, :acct_number, :delta,
    :teller_number, :delta, :branch_number;

EXEC SQL commit work;
```

The USING clause of the EXECUTE statement supplies a list of host variables whose values are to take the place of the question marks in the prepared statement. If a SELECT (or EXECUTE FUNCTION) returns only one row, you can use the INTO clause of EXECUTE to specify the host variables that receive the values.

## Dynamic host variables

SQL APIs, which support dynamically allocated data objects, take dynamic statements one step further. They let you dynamically allocate the host variables that receive column data.

Dynamic allocation of variables makes it possible to take an arbitrary SELECT statement from program input, determine how many values it produces and their data types, and allocate the host variables of the appropriate types to hold them.

The key to this ability is the DESCRIBE statement. It takes the name of a prepared SQL statement and returns information about the statement and its contents. It sets SQLCODE to specify the type of statement; that is, the verb with which it begins. If the prepared statement is a SELECT statement, the DESCRIBE statement also returns information about the selected output data. If the prepared statement is an INSERT statement, the DESCRIBE statement returns information about the input parameters. The data structure to which a DESCRIBE statement returns information is a predefined data structure that is allocated for this purpose and is known as a system-descriptor area. If you are using Informix® ESQL/C, you can use a system-descriptor area or, as an alternative, an **sqlda** structure.

The data structure that a DESCRIBE statement returns or references for a SELECT statement includes an array of structures. Each structure describes the data that is returned for one item in the select list. The program can examine the array and discover that a row of data includes a decimal value, a character value of a certain length, and an integer.

With this information, the program can allocate memory to hold the retrieved values and put the necessary pointers in the data structure for the database server to use.

## Free prepared statements

A prepared SQL statement occupies space in memory. With some database servers, it can consume space that the database server owns as well as space that belongs to the program. This space is released when the program terminates, but in general, you should free this space when you finish with it.

You can use the FREE statement to release this space. The FREE statement takes either the name of a statement or the name of a cursor that was declared for a statement name, and releases the space allocated to the prepared statement. If more than one cursor is defined on the statement, freeing the statement does not free the cursor.

## Quick execution

For simple statements that do not require a cursor or host variables, you can combine the actions of the PREPARE, EXECUTE, and FREE statements into a single operation. The following example shows how the EXECUTE IMMEDIATE statement takes a character string, prepares it, executes it, and frees the storage in one operation:

```
EXEC SQL execute immediate 'drop index my_temp_index';
```

This capability makes it easy to write simple SQL operations. However, because no USING clause is allowed, the EXECUTE IMMEDIATE statement cannot be used for SELECT statements.

## Embed data-definition statements

Data-definition statements, the SQL statements that create databases and modify the definitions of tables, are not usually put into programs. The reason is that they are rarely performed. A database is created once, but it is queried and updated many times.

The creation of a database and its tables is generally done interactively, using DB-Access. These tools can also be run from a file of statements, so that the creation of a database can be done with one operating-system command. The data-definition statements are documented in the *Informix® Guide to SQL: Syntax* and the *Informix® Database Design and Implementation Guide*.

## Grant and revoke privileges in applications

One task related to data definition is performed repeatedly: granting and revoking privileges. Because privileges must be granted and revoked frequently, possibly by users who are not skilled in SQL, one strategy is to package the GRANT and REVOKE statements in programs to give them a simpler, more convenient user interface.

The GRANT and REVOKE statements are especially good candidates for dynamic SQL. Each statement takes the following parameters:

- A list of one or more privileges
- A table name
- The name of a user

You probably need to supply at least some of these values based on program input (from the user, command-line parameters, or a file) but none can be supplied in the form of a host variable. The syntax of these statements does not allow host variables at any point.

An alternative is to assemble the parts of a statement into a character string and to prepare and execute the assembled statement. Program input can be incorporated into the prepared statement as characters.

The following Informix® ESQL/C function assembles a GRANT statement from parameters, and then prepares and executes it:

```
char priv_to_grant[100];
char table_name[20];
char user_id[20];

table_grant(priv_to_grant, table_name, user_id)
char *priv_to_grant;
char *table_name;
char *user_id;
{
    EXEC SQL BEGIN DECLARE SECTION;
    char grant_stmt[200];
    EXEC SQL END DECLARE SECTION;

    sprintf(grant_stmt, " GRANT %s ON %s TO %s",
        priv_to_grant, table_name, user_id);
    PREPARE the_grant FROM :grant_stmt;
    if(SQLCODE == 0)
        EXEC SQL EXECUTE the_grant;
    else
        printf("Sorry, got error # %d attempting %s",
            SQLCODE, grant_stmt);

    EXEC SQL FREE the_grant;
}
```

The opening statement of the function that the following example shows specifies its name and its three parameters. The three parameters specify the privileges to grant, the name of the table on which to grant privileges, and the ID of the user to receive them.

```
table_grant(priv_to_grant, table_name, user_id)
char *priv_to_grant;
char *table_name;
char *user_id;
```

The function uses the statements in the following example to define a local variable, **grant\_stmt**, which is used to assemble and hold the GRANT statement:

```
EXEC SQL BEGIN DECLARE SECTION;
    char grant_stmt[200];
EXEC SQL END DECLARE SECTION;
```

As the following example illustrates, the GRANT statement is created by concatenating the constant parts of the statement and the function parameters:

```
sprintf(grant_stmt, " GRANT %s ON %s TO %s",priv_to_grant,
table_name, user_id);
```

This statement concatenates the following six character strings:

- 'GRANT'
- The parameter that specifies the privileges to be granted
- 'ON'
- The parameter that specifies the table name
- 'TO'
- The parameter that specifies the user

The result is a complete GRANT statement composed partly of program input. The PREPARE statement passes the assembled statement text to the database server for parsing.

If the database server returns an error code in SQLCODE following the PREPARE statement, the function displays an error message. If the database server approves the form of the statement, it sets a zero return code. This action does not guarantee that the statement is executed properly; it means only that the statement has correct syntax. It might refer to a nonexistent table or contain many other kinds of errors that can be detected only during execution. The following portion of the example checks that **the\_grant** was prepared successfully before executing it:

```
if(SQLCODE == 0)
    EXEC SQL EXECUTE the_grant;
else
    printf("Sorry, got error # %d attempting %s", SQLCODE, grant_stmt);
```

If the preparation is successful, `SQLCODE = 0`, the next step executes the prepared statement.

## Assign roles

Alternatively, the DBA can define a role with the CREATE ROLE statement, and use the GRANT and REVOKE statements to cancel or assign roles to users, and to grant and revoke privileges of roles. For example:

```
GRANT engineer TO nmartin;
```

The SET ROLE statement is needed to activate a non-default role. For more information on roles and privileges, see [Access-management strategies on page 1765](#) and [Privileges on a database and on its objects on page 1922](#). For more information on the GRANT and REVOKE statements, see the *Informix® Database Design and Implementation Guide*. For more information about the syntax of these statements, see *Informix® Guide to SQL: Syntax*.

## Summary

SQL statements can be written into programs as if they were normal statements of the programming language. Program variables can be used in WHERE clauses, and data from the database can be fetched into them. A preprocessor translates the SQL code into procedure calls and data structures.

Statements that do not return data, or queries that return only one row of data, are written like ordinary imperative statements of the language. Queries that can return more than one row are associated with a cursor that represents the current row of data. Through the cursor, the program can fetch each row of data as it is needed.

Static SQL statements are written into the text of the program. However, the program can form new SQL statements dynamically, as it runs, and execute them also. In the most advanced cases, the program can obtain information about the number and types of columns that a query returns and dynamically allocate the memory space to hold them.

## Modify data through SQL programs

The previous chapter describes how to insert or embed SQL statements, especially the SELECT statement, into programs written in other languages. Embedded SQL enables a program to retrieve rows of data from a database.

This chapter discusses the issues that arise when a program needs to delete, insert, or update rows to modify the database. As in [SQL programming on page 1944](#), this chapter prepares you for reading your Informix® embedded language publication.

The general use of the INSERT, UPDATE, and DELETE statements is discussed in [Modify data on page 1901](#). This chapter examines their use from within a program. You can easily embed the statements in a program, but it can be difficult to handle errors and to deal with concurrent modifications from multiple programs.

## The DELETE statement

To delete rows from a table, a program executes a DELETE statement. The DELETE statement can specify rows in the usual way, with a WHERE clause, or it can refer to a single row, the last one fetched through a specified cursor.

Whenever you delete rows, you must consider whether rows in other tables depend on the deleted rows. This problem of coordinated deletions is covered in [Modify data on page 1901](#). The problem is the same when deletions are made from within a program.

## Direct deletions

You can embed a DELETE statement in a program. The following example uses Informix® ESQL/C:

```
EXEC SQL delete from items
WHERE order_num = :onum;
```

You can also prepare and execute a statement of the same form dynamically. In either case, the statement works directly on the database to affect one or more rows.

The WHERE clause in the example uses the value of a host variable named **onum**. Following the operation, results are posted in SQLSTATE and in the **sqlca** structure, as usual. The third element of the SQLERRD array contains the count of rows deleted

even if an error occurs. The value in `SQLCODE` shows the overall success of the operation. If the value is not negative, no errors occurred and the third element of `SQLERRD` is the count of all rows that satisfied the `WHERE` clause and were deleted.

## Errors during direct deletions

When an error occurs, the statement ends prematurely. The values in `SQLSTATE` and in `SQLCODE` and the second element of `SQLERRD` explain its cause, and the count of rows reveals how many rows were deleted. For many errors, that count is zero because the errors prevented the database server from beginning the operation. For example, if the named table does not exist, or if a column tested in the `WHERE` clause is renamed, no deletions are attempted.

However, certain errors can be discovered after the operation begins and some rows are processed. The most common of these errors is a lock conflict. The database server must obtain an exclusive lock on a row before it can delete that row. Other programs might be using the rows from the table, preventing the database server from locking a row. Because the issue of locking affects all types of modifications, [Programming for a multiuser environment on page 1978](#), discusses it.

Other, rarer types of errors can strike after deletions begin. For example, hardware errors that occur while the database is being updated.

## Transaction logging

The best way to prepare for any kind of error during a modification is to use transaction logging. In the event of an error, you can tell the database server to put the database back the way it was. The following example is based on the example in the section [Direct deletions on page 1968](#), which is extended to use transactions:

```
EXEC SQL begin work;           /* start the transaction*/
EXEC SQL delete from items
    where order_num = :onum;
del_result = sqlca.sqlcode;    /* save two error */
del_isamno = sqlca.sqlerrd[1]; /* code numbers */
del_rowcnt = sqlca.sqlerrd[2]; /* and count of rows */
if (del_result < 0)           /* problem found: */
    EXEC SQL rollback work;    /* put everything back */
else                           /* everything worked OK:*/
    EXEC SQL commit work;      /* finish transaction */
```

A key point in this example is that the program saves the important return values in the `sqlca` structure before it ends the transaction. Both the `ROLLBACK WORK` and `COMMIT WORK` statements, like other SQL statements, set return codes in the `sqlca` structure. However, if you want to report the codes that the error generated, you must save them before executing `ROLLBACK WORK`. The `ROLLBACK WORK` statement removes all of the pending transaction, including its error codes.

The advantage of using transactions is that the database is left in a known, predictable state no matter what goes wrong. No question remains about how much of the modification is completed; either all of it or none of it is completed.

In a database with logging, if a user does not start an explicit transaction, the database server initiates an internal transaction prior to execution of the statement and terminates the transaction after execution completes or fails. If the

statement execution succeeds, the internal transaction is committed. If the statement fails, the internal transaction is rolled back.

## Coordinated deletions

The usefulness of transaction logging is particularly clear when you must modify more than one table. For example, consider the problem of deleting an order from the demonstration database. In the simplest form of the problem, you must delete rows from two tables, **orders** and **items**, as the following example of Informix® ESQL/C shows:

```
EXEC SQL BEGIN WORK;
EXEC SQL DELETE FROM items
  WHERE order_num = :o_num;
if (SQLCODE >= 0)
{
  EXEC SQL DELETE FROM orders
    WHERE order_num == :o_num;

{
  if (SQLCODE >= 0)
    EXEC SQL COMMIT WORK;

{
  else
  {
    printf("Error %d on DELETE", SQLCODE);
    EXEC SQL ROLLBACK WORK;
  }
}
```

The logic of this program is much the same whether or not transactions are used. If they are not used, the person who sees the error message has a much more difficult set of decisions to make. Depending on when the error occurred, one of the following situations applies:

- No deletions were performed; all rows with this order number remain in the database.
- Some, but not all, item rows were deleted; an order record with only some items remains.
- All item rows were deleted, but the order row remains.
- All rows were deleted.

In the second and third cases, the database is corrupted to some extent; it contains partial information that can cause some queries to produce wrong answers. You must take careful action to restore consistency to the information. When transactions are used, all these uncertainties are prevented.

## Delete with a cursor

You can also write a DELETE statement with a cursor to delete the row that was last fetched. Deleting rows in this manner lets you program deletions based on conditions that cannot be tested in a WHERE clause, as the following example shows.

The following example applies only to databases that are not ANSI compliant because of the way that the beginning and ending of the transaction are set up.

**Warning:** The design of the Informix® ESQL/C function in this example is unsafe. It depends on the current isolation level for correct operation. Isolation levels are discussed later in the chapter. For more information on isolation levels, see [Programming for a multiuser environment on page 1978](#). Even when the function works as intended, its effects depend on the physical order of rows in the table, which is not generally a good idea.

```
int delDupOrder()
{
    int ord_num;
    int dup_cnt, ret_code;

    EXEC SQL declare scan_ord cursor for
        select order_num, order_date
            into :ord_num, :ord_date
            from orders for update;
    EXEC SQL open scan_ord;
    if (sqlca.sqlcode != 0)
        return (sqlca.sqlcode);
    EXEC SQL begin work;
    for(;;)
    {
        EXEC SQL fetch next scan_ord;
        if (sqlca.sqlcode != 0) break;
        dup_cnt = 0; /* default in case of error */
        EXEC SQL select count(*) into dup_cnt from orders
            where order_num = :ord_num;
        if (dup_cnt > 1)
        {
            EXEC SQL delete from orders
                where current of scan_ord;
            if (sqlca.sqlcode != 0)
                break;
        }
    }
    ret_code = sqlca.sqlcode;
    if (ret_code == 100)          /* merely end of data */
        EXEC SQL commit work;
    else /* error on fetch or on delete */
        EXEC SQL rollback work;
    return (ret_code);
}
```

The purpose of the function is to delete rows that contain duplicate order numbers. In fact, in the demonstration database, the **orders.order\_num** column has a unique index, so duplicate rows cannot occur in it. However, a similar function can be written for another database; this one uses familiar column names.

The function declares **scan\_ord**, a cursor to scan all rows in the **orders** table. It is declared with the FOR UPDATE clause, which states that the cursor can modify data. If the cursor opens properly, the function begins a transaction and then loops over rows of the table. For each row, it uses an embedded SELECT statement to determine how many rows of the table have the order number of the current row. (This step fails without the correct isolation level, as [Programming for a multiuser environment on page 1978](#) describes.)

In the demonstration database, with its unique index on this table, the count returned to **dup\_cnt** is always one. However, if it is greater, the function deletes the current row of the table, reducing the count of duplicates by one.

Cleanup functions of this sort are sometimes needed, but they generally need more sophisticated design. This function deletes all duplicate rows except the last one that the database server returns. That order has nothing to do with the content of the rows or their meanings. You can improve the function in the previous example by adding, perhaps, an ORDER BY clause to the cursor declaration. However, you cannot use ORDER BY and FOR UPDATE together. [An insert example on page 1974](#) presents a better approach.

## The INSERT statement

You can embed the INSERT statement in programs. Its form and use in a program are the same as described in [Modify data on page 1901](#) with the additional feature that you can use host variables in expressions, both in the VALUES and WHERE clauses. Moreover, in a program you have the additional ability to insert rows with a cursor.

## An insert cursor

The DECLARE CURSOR statement has many variations. Most are used to create cursors for different kinds of scans over data, but one variation creates a special kind of cursor, called an *insert cursor*. You use an insert cursor with the PUT and FLUSH statements to efficiently insert rows into a table in bulk.

## Declare an insert cursor

To create an insert cursor, declare a cursor to be for an INSERT statement instead of a SELECT statement. You cannot use such a cursor to fetch rows of data; you can use it only to insert them.

When you open an insert cursor, a buffer is created in memory to hold a block of rows. The buffer receives rows of data as the program produces them; then they are passed to the database server in a block when the buffer is full. The buffer reduces the amount of communication between the program and the database server, and it lets the database server insert the rows with less difficulty. As a result, the insertions go faster.

The buffer is always made large enough to hold at least two rows of inserted values. It is large enough to hold more than two rows when the rows are shorter than the minimum buffer size.

## Insert with a cursor

The code in the previous example ([Declare an insert cursor on page 1972](#)) prepares an insert cursor for use. The continuation, as the following example shows, demonstrates how the cursor can be used. For simplicity, this example assumes that a function named next\_cust returns either information about a new customer or null data to signal the end of input.

```

EXEC SQL BEGIN WORK;
EXEC SQL OPEN new_custs;
while(SQLCODE == 0)
{
    next_cust();
    if(the_company == NULL)
        break;
    EXEC SQL PUT new_custs;
}
if(SQLCODE == 0)                /* if no problem with PUT */
{
    EXEC SQL FLUSH new_custs;    /* write any rows left */
    if(SQLCODE == 0)            /* if no problem with FLUSH */
        EXEC SQL COMMIT WORK;  /* commit changes */
}
else
    EXEC SQL ROLLBACK WORK;     /* else undo changes */

```

The code in this example calls `next_cust` repeatedly. When it returns non-null data, the `PUT` statement sends the returned data to the row buffer. When the buffer fills, the rows it contains are automatically sent to the database server. The loop normally ends when `next_cust` has no more data to return. Then the `FLUSH` statement writes any rows that remain in the buffer, after which the transaction terminates.

Re-examine the information about the `INSERT` statement. See [The INSERT statement on page 1972](#). The statement by itself, not part of a cursor definition, inserts a single row into the **customer** table. In fact, the whole apparatus of the insert cursor can be dropped from the example code, and the `INSERT` statement can be written into the code where the `PUT` statement now stands. The difference is that an insert cursor causes a program to run somewhat faster.

## Status codes after PUT and FLUSH

When a program executes a `PUT` statement, the program should test whether the row is placed in the buffer successfully. If the new row fits in the buffer, the only action of `PUT` is to copy the row to the buffer. No errors can occur in this case. However, if the row does not fit, the entire buffer load is passed to the database server for insertion, and an error can occur.

The values returned into the SQL Communications Area (SQLCA) give the program the information it needs to sort out each case. `SQLCODE` and `SQLSTATE` are set to zero after every `PUT` statement if no error occurs and to a negative error code if an error occurs.

The database server sets the third element of `SQLERRD` to the number of rows actually inserted into the table, as follows

- Zero, if the new row is merely moved to the buffer
- The number of rows that are in the buffer, if the buffer load is inserted without error
- The number of rows inserted before an error occurs, if one did occur

Read the code once again to see how `SQLCODE` is used (see the previous example). First, if the `OPEN` statement yields an error, the loop is not executed because the `WHILE` condition fails, the `FLUSH` operation is not performed, and the transaction rolls back. Second, if the `PUT` statement returns an error, the loop ends because of the `WHILE` condition, the `FLUSH` operation

is not performed, and the transaction rolls back. This condition can occur only if the loop generates enough rows to fill the buffer at least once; otherwise, the PUT statement cannot generate an error.

The program might end the loop with rows still in the buffer, possibly without inserting any rows. At this point, the SQL status is zero, and the FLUSH operation occurs. If the FLUSH operation produces an error code, the transaction rolls back. Only when all inserts are successfully performed is the transaction committed.

## Rows of constants

The insert cursor mechanism supports one special case where high performance is easy to obtain. In this case, all the values listed in the INSERT statement are constants: no expressions and no host variables are listed, just literal numbers and strings of characters. No matter how many times such an INSERT operation occurs, the rows it produces are identical. When the rows are identical, copying, buffering, and transmitting each identical row is pointless.

Instead, for this kind of INSERT operation, the PUT statement does nothing except to increment a counter. When a FLUSH operation is finally performed, a single copy of the row and the count of inserts are passed to the database server. The database server creates and inserts that many rows in one operation.

You do not usually insert a quantity of identical rows. You can insert identical rows when you first establish a database to populate a large table with null data.

## An insert example

[Delete with a cursor on page 1970](#) contains an example of the DELETE statement whose purpose is to look for and delete duplicate rows of a table. A better way to perform this task is to select the desired rows instead of deleting the undesired ones. The code in the following Informix® ESQL/C example shows one way to do this task:

```
EXEC SQL BEGIN DECLARE SECTION;
  long last_ord = 1;
  struct {
    long int o_num;
    date    o_date;
    long    c_num;
    char    o_shipinst[40];
    char    o_backlog;
    char    o_po[10];
    date    o_shipdate;
    decimal o_shipwt;
    decimal o_shipchg;
    date    o_paidddate;
  } ord_row;
EXEC SQL END DECLARE SECTION;

EXEC SQL BEGIN WORK;
EXEC SQL INSERT INTO new_orders
  SELECT * FROM orders main
  WHERE 1 = (SELECT COUNT(*) FROM orders minor
```

```

        WHERE main.order_num = minor.order_num);
EXEC SQL COMMIT WORK;

EXEC SQL DECLARE dup_row CURSOR FOR
  SELECT * FROM orders main INTO :ord_row
    WHERE 1 < (SELECT COUNT(*) FROM orders minor
      WHERE main.order_num = minor.order_num)
    ORDER BY order_date;
EXEC SQL DECLARE ins_row CURSOR FOR
  INSERT INTO new_orders VALUES (:ord_row);

EXEC SQL BEGIN WORK;
EXEC SQL OPEN ins_row;
EXEC SQL OPEN dup_row;
while(SQLCODE == 0)
{
  EXEC SQL FETCH dup_row;
  if(SQLCODE == 0)
  {
    if(ord_row.o_num != last_ord)
      EXEC SQL PUT ins_row;
    last_ord = ord_row.o_num;
    continue;
  }
  break;
}
if(SQLCODE != 0 && SQLCODE != 100)
  EXEC SQL ROLLBACK WORK;
else
  EXEC SQL COMMIT WORK;
EXEC SQL CLOSE ins_row;
EXEC SQL CLOSE dup_row;

```

This example begins with an ordinary INSERT statement, which finds all the nonduplicated rows of the table and inserts them into another table, presumably created before the program started. That action leaves only the duplicate rows. (In the demonstration database, the **orders** table has a unique index and cannot have duplicate rows. Assume that this example deals with some other database.)

The code in the previous example then declares two cursors. The first, called **dup\_row**, returns the duplicate rows in the table. Because **dup\_row** is for input only, it can use the ORDER BY clause to impose some order on the duplicates other than the physical record order used in the example on page [Delete with a cursor on page 1970](#). In this example, the duplicate rows are ordered by their dates (the oldest one remains), but you can use any other order based on the data.

The second cursor, **ins\_row**, is an insert cursor. This cursor takes advantage of the ability to use a C structure, **ord\_row**, to supply values for all columns in the row.

The remainder of the code examines the rows that are returned through **dup\_row**. It inserts the first one from each group of duplicates into the new table and disregards the rest.

For the sake of brevity, the preceding example uses the simplest kind of error handling. If an error occurs before all rows have been processed, the sample code rolls back the active transaction.

## How many rows were affected?

When your program uses a cursor to select rows, it can test SQLCODE for 100 (or SQLSTATE for 02000), the end-of-data return code. This code is set to indicate that no rows, or no more rows, satisfy the query conditions. For databases that are not ANSI compliant, the end-of-data return code is set in SQLCODE or SQLSTATE only following SELECT statements; it is not used following DELETE, INSERT, or UPDATE statements. For ANSI-compliant databases, SQLCODE is also set to 100 for updates, deletes, and inserts that affect zero rows.

A query that finds no data is not a success. However, an UPDATE or DELETE statement that happens to update or delete no rows is still considered a success. It updated or deleted the set of rows that its WHERE clause said it should; however, the set was empty.

In the same way, the INSERT statement does not set the end-of-data return code even when the source of the inserted rows is a SELECT statement, and the SELECT statement selected no rows. The INSERT statement is a success because it inserted as many rows as it was asked to (that is, zero).

To find out how many rows are inserted, updated, or deleted, a program can test the third element of SQLERRD. The count of rows is there, regardless of the value (zero or negative) in SQLCODE.

## The UPDATE statement

You can embed the UPDATE statement in a program in any of the forms that [Modify data on page 1901](#) describes with the additional feature that you can name host variables in expressions, both in the SET and WHERE clauses. Moreover, a program can update the row that a cursor addresses.

## An update cursor

An *update cursor* permits you to delete or update the current row; that is, the most recently fetched row. The following example in Informix® ESQL/C shows the declaration of an update cursor:

```
EXEC SQL
  DECLARE names CURSOR FOR
    SELECT fname, lname, company
    FROM customer
  FOR UPDATE;
```

The program that uses this cursor can fetch rows in the usual way.

```
EXEC SQL
  FETCH names INTO :FNAME, :LNAME, :COMPANY;
```

If the program then decides that the row needs to be changed, it can do so.

```
if (strcmp(COMPANY, "SONY") ==0)
{
  EXEC SQL
    UPDATE customer
```

```

    SET fname = 'Midori', lname = 'Tokugawa'
    WHERE CURRENT OF names;
}

```

The words `CURRENT OF names` take the place of the usual test expressions in the `WHERE` clause. In other respects, the `UPDATE` statement is the same as usual, even including the specification of the table name, which is implicit in the cursor name but still required.

## The purpose of the keyword `UPDATE`

The purpose of the keyword `UPDATE` in a cursor is to let the database server know that the program can update (or delete) any row that it fetches. The database server places a more demanding lock on rows that are fetched through an update cursor and a less demanding lock when it fetches a row for a cursor that is not declared with that keyword. This action results in better performance for ordinary cursors and a higher level of concurrent use in a multiprocessing system.

([Programming for a multiuser environment on page 1978](#) discusses levels of locks and concurrent use.)

**Important:** A normal update inside the `FETCH` loop of a cursor cannot guarantee that the updated rows are not fetched again after the `UPDATE`. The `WHERE CURRENT OF` specification relates the `UPDATE` to the update cursor, and guarantees that each row is updated no more than once, by internally keeping a list of the rows that have already been updated. These rows will not be fetched again by the update cursor. See the [FOR UPDATE clause on page](#) .

## Update specific columns

The following example has updated specific columns of the preceding example of an update cursor:

```

EXEC SQL
  DECLARE names CURSOR FOR
    SELECT fname, lname, company, phone
      INTO :FNAME, :LNAME, :COMPANY, :PHONE FROM customer
    FOR UPDATE OF fname, lname
END-EXEC.

```

Only the **fname** and **lname** columns can be updated through this cursor. A statement such as the following one is rejected as an error:

```

EXEC SQL
  UPDATE customer
    SET company = 'Siemens'
    WHERE CURRENT OF names
END-EXEC.

```

If the program attempts such an update, an error code is returned and no update occurs. An attempt to delete with `WHERE CURRENT OF` is also rejected, because deletion affects all columns.

## UPDATE keyword not always needed

The ANSI standard for SQL does not provide for the FOR UPDATE clause in a cursor definition. When a program uses an ANSI-compliant database, it can update or delete with any cursor.

## Cleanup a table

A final, hypothetical example of how to use an update cursor presents a problem that should never arise with an established database but could arise in the initial design phases of an application.

In the example, a large table named **target** is created and populated. A character column, **dactyl**, inadvertently acquires some null values. These rows should be deleted. Furthermore, a new column, **serials**, is added to the table with the ALTER TABLE statement. This column is to have unique integer values installed. The following example shows the Informix® ESQL/C code you use to accomplish these tasks:

```
EXEC SQL BEGIN DECLARE SECTION;
char dcol[80];
short dcolint;
int sequence;
EXEC SQL END DECLARE SECTION;

EXEC SQL DECLARE target_row CURSOR FOR
  SELECT datcol
     INTO :dcol:dcolint
     FROM target
     FOR UPDATE OF serials;
EXEC SQL BEGIN WORK;
EXEC SQL OPEN target_row;
if (sqlca.sqlcode == 0) EXEC SQL FETCH NEXT target_row;
for(sequence = 1; sqlca.sqlcode == 0; ++sequence)
{
  if (dcolint < 0) /* null datcol */
    EXEC SQL DELETE WHERE CURRENT OF target_row;
  else
    EXEC SQL UPDATE target SET serials = :sequence
      WHERE CURRENT OF target_row;
}
if (sqlca.sqlcode >= 0)
  EXEC SQL COMMIT WORK;
else EXEC SQL ROLLBACK WORK;
```

## Summary

A program can execute the INSERT, DELETE, and UPDATE statements, as [Modify data on page 1901](#) describes. A program can also scan through a table with a cursor, updating or deleting selected rows. It can also use a cursor to insert rows, with the benefit that the rows are buffered and sent to the database server in blocks.

In all these activities, you must make sure that the program detects errors and returns the database to a known state when an error occurs. The most important tool for doing this is transaction logging. Without transaction logging, it is more difficult to write programs that can recover from errors.

## Programming for a multiuser environment

This section describes several programming issues you need to be aware of when you work in a multiuser environment.

If your database is contained in a single-user workstation and does not access data from another computer, your programs can modify data freely. In all other cases, you must allow for the possibility that, while your program is modifying data, another program is reading or modifying the same data. This situation is described as *concurrency*: two or more independent uses of the same data at the same time. This section addresses concurrency, locking, and isolation levels.

This section also describes the statement cache feature, which can reduce per-session memory allocation and speed up query processing. The statement cache stores statements that can then be shared among different user sessions that use identical SQL statements.

## Concurrency and performance

Concurrency is crucial to good performance in a multiprogramming system. When access to the data is *serialized* so that only one program at a time can use it, processing slows dramatically.

## Locks and integrity

Unless controls are placed on the use of data, concurrency can lead to a variety of negative effects. Programs can read obsolete data, or modifications can be lost even though they were apparently completed.

To prevent errors of this kind, the database server imposes a system of *locks*. A lock is a claim, or reservation, that a program can place on a piece of data. The database server guarantees that, as long as the data is locked, no other program can modify it. When another program requests the data, the database server either makes the program wait or turns it back with an error.

## Locks and performance

Because a lock serializes access to one piece of data, it reduces concurrency; any other programs that want access to that data must wait. The database server can place a lock on a single row, a disk page, a whole table, or an entire database. (A disk page might hold multiple rows and a row might require multiple disk pages.) The more locks it places and the larger the objects it locks, the more concurrency is reduced. The fewer the locks and the smaller the locked objects, the greater concurrency and performance can be.

The following sections discuss how you can achieve the following goals with your program:

- Place all the locks necessary to ensure data integrity.
- Lock the fewest, smallest pieces of data possible consistent with the preceding goal.

## Concurrency issues

To understand the hazards of concurrency, you must think in terms of multiple programs, each executing at its own speed. Suppose that your program is fetching rows through the following cursor:

```
EXEC SQL DECLARE sto_cursor CURSOR FOR
  SELECT * FROM stock
  WHERE manu_code = 'ANZ';
```

The transfer of each row from the database server to the program takes time. During and between transfers, other programs can perform other database operations. At about the same time that your program fetches the rows produced by that query, another user's program might execute the following update:

```
EXEC SQL UPDATE stock
  SET unit_price = 1.15 * unit_price
  WHERE manu_code = 'ANZ';
```

In other words, both programs are reading through the same table, one fetching certain rows and the other changing the same rows. The following scenarios are possible:

1. The other program finishes its update before your program fetches its first row.
 

Your program shows you only updated rows.
2. Your program fetches every row before the other program has a chance to update it.
 

Your program shows you only original rows.
3. After your program fetches some original rows, the other program catches up and goes on to update some rows that your program has yet to read; then it executes the COMMIT WORK statement.
 

Your program might return a mixture of original rows and updated rows.
4. Same as number 3, except that after updating the table, the other program issues a ROLLBACK WORK statement.
 

Your program can show you a mixture of original rows and updated rows that no longer exist in the database.

The first two possibilities are harmless. In possibility number 1, the update is complete before your query begins. It makes no difference whether the update finished a microsecond ago or a week ago.

In possibility number 2, your query is, in effect, complete before the update begins. The other program might have been working just one row behind yours, or it might not start until tomorrow night; it does not matter.

The last two possibilities, however, can be important to the design of some applications. In possibility number 3, the query returns a mix of updated and original data. That result can be detrimental in some applications. In others, such as one that is taking an average of all prices, it might not matter at all.

Possibility number 4 can be disastrous if a program returns some rows of data that, because their transaction was cancelled, can no longer be found in the table.

Another concern arises when your program uses a cursor to update or delete the last-fetched row. Erroneous results occur with the following sequence of events:

- Your program fetches the row.
- Another program updates or deletes the row.
- Your program updates or deletes WHERE CURRENT OF *cursor\_name*.

To control concurrent events such as these, use the locking and *isolation level* features of the database server.

## How locks work

Informix® database servers support a complex, flexible set of locking features that the topics in this section describe.

## Kinds of locks

The following table shows the types of locks that Informix® database servers support for different situations.

| Lock type              | Use  |
|------------------------|--|
| Shared                 | A shared lock reserves its object for reading only. It prevents the object from changing while the lock remains. More than one program can place a shared lock on the same object. More than one object can read the record while it is locked in shared mode.   |
| Exclusive              | An exclusive lock reserves its object for the use of a single program. This lock is used when the program intends to change the object.  |
| Exclusive-sive         | You cannot place an exclusive lock where any other kind of lock exists. After you place an exclusive lock, you cannot place another lock on the same object.   |
| Promotable (or update) | A promotable (or update) lock establishes the intent to update. You can only place it where no other promotable or exclusive lock exists. You can place promotable locks on records that already have shared locks. When the program is about to change the locked object, you can promote the promotable lock to an exclusive lock, but only if no other locks, including shared locks, are on the record at the time the lock would change from promotable to exclusive. If a shared lock was on the record when the promotable lock was set, you must drop the shared lock (or before the promotable lock can be promoted to an exclusive lock. |
| Update                 |  |

## Lock scope

You can apply locks to entire databases, entire tables, disk pages, single rows, or index-key values. The size of the object that is being locked is referred to as the *scope* of the lock (also called the *lock granularity*). In general, the larger the scope of a lock, the more concurrency is reduced, but the simpler programming becomes.

## Database locks

You can lock an entire database. The act of opening a database places a shared lock on the name of the database. A database is opened with the `CONNECT`, `DATABASE`, or `CREATE DATABASE` statements. As long as a program has a database open, the shared lock on the name prevents any other program from dropping the database or putting an exclusive lock on it.

The following statement shows how you might lock an entire database exclusively:

```
DATABASE database_one EXCLUSIVE
```

This statement succeeds if no other program has opened that database. After the lock is placed, no other program can open the database, even for reading, because its attempt to place a shared lock on the database name fails.

A database lock is released only when the database closes. That action can be performed explicitly with the `DISCONNECT` or `CLOSE DATABASE` statements or implicitly by executing another `DATABASE` statement.

Because locking a database reduces concurrency in that database to zero, it makes programming simple; concurrent effects cannot happen. However, you should lock a database only when no other programs need access. Database locking is often used before applying massive changes to data during off-peak hours.

## Table locks

You can lock entire tables. In some cases, the database server performs this action automatically. You can also use the `LOCK TABLE` statement to lock an entire table explicitly.

The `LOCK TABLE` statement or the database server can place the following types of table locks:

### Shared lock

No users can write to the table. In shared mode, the database server places one shared lock on the table, which informs other users that no updates can be performed. In addition, the database server adds locks for every row updated, deleted, or inserted.

### Exclusive lock

No other users can read from or write to the table. In exclusive mode, the database server places only one exclusive lock on the table, no matter how many rows it updates. An exclusive table lock prevents any concurrent use of the table and, therefore, can have a serious effect on performance if many other programs are contending for the use of the table. However, when you need to update most of the rows in a table, place an exclusive lock on the table.

## Lock a table with the LOCK TABLE statement

A transaction tells the database server to use table-level locking for a table with the `LOCK TABLE` statement. The following example shows how to place an exclusive lock on a table:

```
LOCK TABLE tab1 IN EXCLUSIVE MODE
```

The following example shows how to place a shared lock on a table:

```
LOCK TABLE tab2 IN SHARE MODE
```

 **Tip:** You can set the isolation level for your database server to achieve the same degree of protection as the shared table lock while providing greater concurrency.

## When the database server automatically locks a table

The database server always locks an entire table while it performs operations for any of the following statements:

- ALTER FRAGMENT
- ALTER INDEX
- ALTER TABLE
- CREATE INDEX
- DROP INDEX
- RENAME COLUMN
- RENAME TABLE

Completion of the statement (or end of the transaction) releases the lock. An entire table can also be locked automatically during certain queries.

## Avoid table locking with the ONLINE keyword

For indexes that are not defined with the IN TABLE keyword option, you can minimize the duration of an exclusive lock on the indexed table when you CREATE or DROP an index using the ONLINE keyword.

While the index is being created or dropped online, no DDL operations on the table are supported, but operations that were concurrent when the CREATE INDEX or DROP INDEX statement was issued can be completed. The specified index is not created or dropped until no other processes are concurrently accessing the table. Then locks are held briefly to write the system catalog data associated with the index. This increases the availability of the system, because the table is still readable by ongoing and new sessions. The following statement shows how to use the ONLINE keyword to avoid automatic table locking with a CREATE INDEX statement:

```
CREATE INDEX idx_1 ON customer (lname) ONLINE;
```

For in-table indexes, however, that are defined with the IN TABLE keyword option, the indexed table remains locked for the duration of the CREATE INDEX or DROP INDEX operation that includes the ONLINE keyword. Attempted access by other sessions to the locked table would fail with at least one of these errors:

```
107: ISAM error: record is locked.
211: Cannot read system catalog (systables).
710: Table (table.tix) has been dropped, altered or renamed.
```

## Row and key locks

You can lock one row of a table. A program can lock one row or a selection of rows while other programs continue to work on other rows of the same table.

Row and key locking are not the default behaviors. You must specify row-level locking when you create the table. The following example creates a table with row-level locking:

```
CREATE TABLE tab1
(
  col1...
) LOCK MODE ROW;
```

If you specify a LOCK MODE clause when you create a table, you can later change the lock mode with the ALTER TABLE statement. The following statement changes the lock mode on the reservations table to page-level locking:

```
ALTER TABLE tab1 LOCK MODE PAGE
```

In certain cases, the database server has to lock a row that does not exist. To do this, the database server places a lock on an index-key value. Key locks are used identically to row locks. When the table uses row locking, key locks are implemented as locks on imaginary rows. When the table uses page locking, a key lock is placed on the index page that contains the key or that would contain the key if it existed.

When you insert, update, or delete a key (performed automatically when you insert, update, or delete a row), the database server creates a lock on the key in the index.

Row and key locks generally provide the best performance overall when you update a relatively small number of rows because they increase concurrency. However, the database server incurs some overhead in obtaining a lock.

When one or more rows in a table are locked by an exclusive lock, the effect on other users partly depends on their transaction isolation level. Other users whose isolation levels is not Dirty Read might encounter transactions that fail because the exclusive lock was not released within a specified time limit.

For Committed Read or Dirty Read isolation level operations that attempt to access tables on which a concurrent session has set exclusive row-level locks, the risk of locking conflicts can be reduced by enabling transactions to read the most recently committed version of the data in the locked rows, rather than waiting for the transaction that set the lock to be committed or rolled back. Enabling access to the last committed version of exclusively locked rows can be accomplished in several ways:

- For an individual session, issue this SQL statement

```
SET ISOLATION TO COMMITTED READ LAST COMMITTED;
```

- For all sessions using the Committed Read or Read Committed isolation level, the DBA can set the USELASTCOMMITTED configuration parameter to 'ALL' or to 'COMMITTED READ'.
- For an individual session using the Committed Read or Read Committed isolation level, any user can issue the SET ENVIRONMENT USELASTCOMMITTED statement with 'ALL' or 'COMMITTED READ' as the value of this session environment option.

- For all sessions using Dirty Read or Read Uncommitted isolation levels, the DBA can set the USELASTCOMMITTED configuration parameter to 'ALL' or to 'DIRTY READ'.
- For an individual session using the Dirty Read or Read Uncommitted isolation levels, any user can issue the SET ENVIRONMENT USELASTCOMMITTED statement with 'ALL' or 'DIRTY READ' as the value of this session environment option.

This LAST COMMITTED feature is useful only when row-level locking is in effect, rather than when another session holds an exclusive lock on the entire table. This feature is disabled for any table on which the LOCK TABLE statement applies a table-level lock. See the description of the SET ENVIRONMENT statement in the *Informix® Guide to SQL: Syntax* and the description of the USELASTCOMMITTED configuration parameter in for more information about this feature for concurrent access to tables in which some rows are locked by exclusive locks, and for restrictions on the kinds of tables that can support this feature.

## Page locks

The database server stores data in units called *disk pages*. A disk page contains one or more rows. In some cases, it is better to lock a disk page than to lock individual rows on it. For example, with operations that require changing a large number of rows, you might choose page-level locking because row-level locking (one lock per row) might not be cost effective.

If you do not specify a LOCK MODE clause when you create a table, the default behavior for the database server is page-level locking. With page locking, the database server locks the entire page that contains the row. If you update several rows that are stored on the same page, the database server uses only one lock for the page.

## Set the row or page lock mode for all CREATE TABLE statements

HCL Informix® allows you to set the lock mode to page-level locking or row-level locking for all newly created tables for a single user (per session) or for multiple users (per server). You no longer need to specify the lock mode every time that you create a new table with the CREATE TABLE statement.

If you want every new table created within your session to be created with a particular lock mode, you have to set the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable. For example, for every new table created within your session to be created with lock mode row, set **IFX\_DEF\_TABLE\_LOCKMODE** to ROW. To override this behavior, use the CREATE TABLE or ALTER TABLE statements and redefine the LOCK MODE clause.

## Single-user lock mode

Set the single-user lock mode if all of the new tables that you create in your session require the same lock mode. Set the single-user lock mode with the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable. For example, for every new table created within your session to be created with row-level locking, set **IFX\_DEF\_TABLE\_LOCKMODE** to ROW. To override this behavior, use the CREATE TABLE or ALTER TABLE statements and redefine the LOCK MODE clause. For more information on setting environment variables, see the *Informix® Guide to SQL: Reference*.

## Multiple-user lock mode

Database administrators can use the multiple-user lock mode to create greater concurrency by designating the lock mode for all users on the same server. All tables that any user creates on that server will then have the same lock mode. To enable multiple-user lock mode, set the **IFX\_DEF\_TABLE\_LOCKMODE** environment variable before starting the database server or set the **DEF\_TABLES\_LOCKMODE** configuration parameter.

## Rules of precedence

Locking mode for CREATE TABLE or ALTER TABLE has the following rules of precedence, listed in order of highest precedence to lowest:

1. CREATE TABLE or ALTER TABLE SQL statements that use the LOCK MODE clause
2. Single-user environment variable setting
3. Multi-user environment variable setting in the server environment
4. Configuration parameters in the configuration file
5. Default behavior (page-level locking)

## Coarse index locks

When you change the lock mode of an index from normal to coarse lock mode, index-level locks are acquired on the index instead of item-level or page-level locks, which are the normal locks. This mode reduces the number of lock calls on an index.

Use the coarse lock mode when you know the index is not going to change; that is, when read-only operations are performed on the index.

Use the normal lock mode to have the database server place item-level or page-level locks on the index as necessary. Use this mode when the index gets updated frequently.

When the database server executes the command to change the lock mode to coarse, it acquires an exclusive lock on the table for the duration of the command. Any transactions that are currently using a lock of finer granularity must complete before the database server switches to the coarse lock mode.

## Smart-large-object locks

Locks on a CLOB or BLOB column are separate from the lock on the row. Smart large objects are locked only when they are accessed. When you lock a table that contains a CLOB or BLOB column, no smart large objects are locked. If accessed for writing, the smart large object is locked in update mode, and the lock is promoted to exclusive when the actual write occurs. If accessed for reading, the smart large object is locked in shared mode. The database server recognizes the transaction isolation mode, so if Repeatable Read isolation level is set, the database server does not release smart-large-object read locks before end of transaction.

When the database server retrieves a row and updates a smart large object that the row points to, only the smart large object is exclusively locked during the time it is being updated.

## Byte-range locks

You can lock a range of bytes for a smart large object. Byte-range locks allow a transaction to selectively lock only those bytes that are accessed so that writers and readers simultaneously can access different byte ranges in the same smart large object.

For information about how to use byte-range locks, see your *Informix® Performance Guide*.

Byte-range locks support deadlock detection. For information about deadlock detection, see [Handle a deadlock on page 1996](#).

## Duration of a lock

The program controls the duration of a database lock. A database lock is released when the database closes.

Depending on whether the database uses transactions, table lock durations vary. If the database does not use transactions (that is, if no transaction log exists and you do not use a COMMIT WORK statement), a table lock remains until it is removed by the execution of the UNLOCK TABLE statement.

The duration of table, row, and index locks depends on what SQL statements you use and on whether transactions are in use.

When you use transactions, the end of a transaction releases all table, row, page, and index locks. When a transaction ends, all locks are released.

## Locks while modifying

When the database server fetches a row through an update cursor, it places a promotable lock on the fetched row. If this action succeeds, the database server knows that no other program can alter that row. Because a promotable lock is not exclusive, other programs can continue to read the row. A promotable lock can improve performance because the program that fetched the row can take some time before it issues the UPDATE or DELETE statement, or it can simply fetch the next row. When it is time to modify a row, the database server obtains an exclusive lock on the row. If it already has a promotable lock, it changes that lock to exclusive status.

The duration of an exclusive row lock depends on whether transactions are in use. If they are not in use, the lock is released as soon as the modified row is written to disk. When transactions are in use, all such locks are held until the end of the transaction. This action prevents other programs from using rows that might be rolled back to their original state.

When transactions are in use, a key lock is used whenever a row is deleted. Using a key lock prevents the following error from occurring:

- Program A deletes a row.
- Program B inserts a row that has the same key.

- Program A rolls back its transaction, forcing the database server to restore its deleted row.

What is to be done with the row inserted by Program B?

By locking the index, the database server prevents a second program from inserting a row until the first program commits its transaction.

The locks placed while the database server reads various rows are controlled by the current isolation level, as discussed in the next section.

## Lock with the SELECT statement

The type and duration of locks that the database server places depend on the isolation set in the application and whether the SELECT statement is within an update cursor.

This section describes the different isolation levels and update cursors.

## Set the isolation level

The *isolation level* is the degree to which your program is isolated from the concurrent actions of other programs. The database server offers a choice of isolation levels that reflect a different set of rules for how a program uses locks when it reads data.

To set the isolation level, use either the SET ISOLATION or SET TRANSACTION statement. The SET TRANSACTION statement also lets you set access modes. For more information about access modes, see [Control data modification with access modes on page 1994](#).

## SET TRANSACTION versus SET ISOLATION

The SET TRANSACTION statement complies with ANSI SQL-92. This statement is similar to the Informix® SET ISOLATION statement; however, the SET ISOLATION statement is not ANSI compliant and does not provide access modes.

The following table shows the relationships between the isolation levels that you set with the SET TRANSACTION and SET ISOLATION statements.

| <b>SET TRANSACTION correlates with</b> | <b>SET ISOLATION</b>        |
|--|-----------------------------|
| Read Uncommitted                       | Dirty Read                  |
| Read Committed                         | Committed Read              |
| Not Supported                          | Cursor Stability            |
| (ANSI) Repeatable Read                 | (Informix®) Repeatable Read |
| Serializable                           | (Informix®) Repeatable Read |

The major difference between the SET TRANSACTION and SET ISOLATION statements is the behavior of the isolation levels within transactions. The SET TRANSACTION statement can be issued only once for a transaction. Any cursors opened during that transaction are guaranteed to have that isolation level (or access mode if you are defining an access mode). With the SET ISOLATION statement, after a transaction is started, you can change the isolation level more than once within the transaction. The following examples illustrate the difference between the use of SET ISOLATION and the use of SET TRANSACTION.

## SET ISOLATION

```
EXEC SQL BEGIN WORK;
EXEC SQL SET ISOLATION TO DIRTY READ;
EXEC SQL SELECT ... ;
EXEC SQL SET ISOLATION TO REPEATABLE READ;
EXEC SQL INSERT ... ;
EXEC SQL COMMIT WORK;
-- Executes without error
```

## SET TRANSACTION

```
EXEC SQL BEGIN WORK;
EXEC SQL SET TRANSACTION ISOLATION LEVEL TO SERIALIZABLE;
EXEC SQL SELECT ... ;
EXEC SQL SET TRANSACTION ISOLATION LEVEL TO READ COMMITTED;
Error -876: Cannot issue SET TRANSACTION once a transaction has started.
```

## ANSI Read Uncommitted and HCL Informix® Dirty Read isolation

The simplest isolation level, ANSI Read Uncommitted and Informix® Dirty Read, amounts to virtually no isolation. When a program fetches a row, it places no locks, and it respects none; it simply copies rows from the database without regard to what other programs are doing.

A program always receives complete rows of data. Even under ANSI Read Uncommitted or Informix® Dirty Read isolation, a program never sees a row in which some columns are updated and some are not. However, a program that uses ANSI Read Uncommitted or Informix® Dirty Read isolation sometimes reads updated rows before the updating program ends its transaction. If the updating program later rolls back its transaction, the reading program processes data that never really existed (possibility number 4 on page 1980 in the list of concurrency issues).

ANSI Read Uncommitted or Informix® Dirty Read is the most efficient isolation level. The reading program never waits and never makes another program wait. It is the preferred level in any of the following cases:

- All tables are static; that is, concurrent programs only read and never modify data.
- The table is held in an exclusive lock.
- Only one program is using the table.

## ANSI Read Committed and HCL Informix® Committed Read isolation

When a program requests the ANSI Read Committed or HCL Informix® Committed Read isolation level, the database server guarantees that it never returns a row that is not committed to the database. This action prevents reading data that is not committed and that is subsequently rolled back.

ANSI Read Committed or HCL Informix® Committed Read is implemented simply. Before it fetches a row, the database server tests to determine whether an updating process placed a lock on the row; if not, it returns the row. Because rows that have been updated (but that are not yet committed) have locks on them, this test ensures that the program does not read uncommitted data.

ANSI Read Committed or HCL Informix® Committed Read does not actually place a lock on the fetched row, so this isolation level is almost as efficient as ANSI Read Uncommitted or HCL Informix® Dirty Read. This isolation level is appropriate to use when each row of data is processed as an independent unit, without reference to other rows in the same or other tables.

Locking conflicts can occur in ANSI Read Committed or HCL Informix® Committed Read sessions, however, if the attempt to place the test lock is not successful because a concurrent session holds a shared lock on the row. To avoid waiting for concurrent transactions to release shared locks (by committing or rolling back), Informix® supports the Last Committed option to the Committed Read isolation level. When this Last Committed option is in effect, a shared lock by another session causes the query to return the most recently committed version of the row.

The Last Committed feature can also be activated by setting the USELASTCOMMITTED configuration parameter to 'COMMITTED READ' or to 'ALL', or by setting USELASTCOMMITTED session environment option in the SET ENVIRONMENT statement in the **sysdbopen()** procedure when the user connects to the database. For more information about the Last Committed option to the ANSI Read Committed or HCL Informix® Committed Read isolation levels, see the description of the SET ISOLATION statement in the *Informix® Guide to SQL: Syntax*. For information about the USELASTCOMMITTED configuration parameter, see the .

## HCL Informix® Cursor Stability isolation

The next level, Cursor Stability, is available only with the Informix® SQL statement SET ISOLATION.

When Cursor Stability is in effect, Informix® places a lock on the latest row fetched. It places a shared lock for an ordinary cursor or a promotable lock for an update cursor. Only one row is locked at a time; that is, each time a row is fetched, the lock on the previous row is released (unless that row is updated, in which case the lock holds until the end of the transaction). Because Cursor Stability locks only one row at a time, it restricts concurrency less than a table lock or database lock.

Cursor Stability ensures that a row does not change while the program examines it. Such row stability is important when the program updates some other table based on the data it reads from the row. Because of Cursor Stability, the program is assured that the update is based on current information. It prevents the use of *stale data*.

The following example illustrates effective use of Cursor Stability isolation. In terms of the demonstration database, Program A wants to insert a new stock item for manufacturer Hero (HRO). Concurrently, Program B wants to delete manufacturer HRO and all stock associated with it. The following sequence of events can occur:

1. Program A, operating under Cursor Stability, fetches the HRO row from the **manufact** table to learn the manufacturer code. This action places a shared lock on the row.
2. Program B issues a DELETE statement for that row. Because of the lock, the database server makes the program wait.
3. Program A inserts a new row in the **stock** table using the manufacturer code it obtained from the **manufact** table.
4. Program A closes its cursor on the **manufact** table or reads a different row of it, releasing its lock.
5. Program B, released from its wait, completes the deletion of the row and goes on to delete the rows of **stock** that use manufacturer code HRO, including the row that Program A just inserted.

If Program A used a lesser level of isolation, the following sequence could occur:

1. Program A reads the HRO row of the **manufact** table to learn the manufacturer code. No lock is placed.
2. Program B issues a DELETE statement for that row. It succeeds.
3. Program B deletes all rows of **stock** that use manufacturer code HRO.
4. Program B ends.
5. Program A, not aware that its copy of the HRO row is now invalid, inserts a new row of **stock** using the manufacturer code HRO.
6. Program A ends.

At the end, a row occurs in **stock** that has no matching manufacturer code in **manufact**. Furthermore, Program B apparently has a bug; it did not delete the rows that it was supposed to delete. Use of the Cursor Stability isolation level prevents these effects.

The preceding scenario could be rearranged to fail even with Cursor Stability. All that is required is for Program B to operate on tables in the reverse sequence to Program A. If Program B deletes from **stock** before it removes the row of **manufact**, no degree of isolation can prevent an error. Whenever this kind of error is possible, all programs that are involved must use the same sequence of access.

## ANSI Serializable, ANSI Repeatable Read, and HCL Informix® Repeatable Read isolation

Where ANSI Serializable or ANSI Repeatable Read are required, a single isolation level is provided, called HCL Informix® Repeatable Read. This is logically equivalent to ANSI Serializable. Because ANSI Serializable is more restrictive than ANSI Repeatable Read, HCL Informix® Repeatable Read can be used when ANSI Repeatable Read is desired (although HCL Informix® Repeatable Read is more restrictive than is necessary in such contexts).

The Repeatable Read isolation level asks the database server to put a lock on every row the program examines and fetches. The locks that are placed are shareable for an ordinary cursor and promotable for an update cursor. The locks are placed individually as each row is examined. They are not released until the cursor closes or a transaction ends.

Repeatable Read allows a program that uses a scroll cursor to read selected rows more than once and to be sure that they are not modified or deleted between readings. ([SQL programming on page 1944](#) describes scroll cursors.) No lower isolation level guarantees that rows still exist and are unchanged the second time they are read.

Repeatable Read isolation places the largest number of locks and holds them the longest. Therefore, it is the level that reduces concurrency the most. If your program uses this level of isolation, think carefully about how many locks it places, how long they are held, and what the effect can be on other programs.

In addition to the effect on concurrency, the large number of locks can be a problem. The database server records the number of locks by each program in a lock table. If the maximum number of locks is exceeded, the lock table fills up, and the database server cannot place a lock. An error code is returned. The person who administers the Informix® database server system can monitor the lock table and tell you when it is heavily used.

The isolation level in an ANSI-compliant database is set to Serializable by default. The Serializable isolation level is required to ensure that operations behave according to the ANSI standard for SQL.

## Update cursors

An update cursor is a special kind of cursor that applications can use when the row might potentially be updated. To use an update cursor, execute `SELECT FOR UPDATE` in your application. Update cursors use *promotable locks*; that is, the database server places an update lock (meaning other users can still view the row) when the application fetches the row, but the lock is changed to an exclusive lock when the application updates the row using an update cursor and `UPDATE...WHERE CURRENT OF`.

The advantage of using an update cursor is that you can view the row with the confidence that other users cannot change it or view it with an update cursor while you are viewing it and before you update it.

**i** **Tip:** In an ANSI-compliant database, update cursors are unnecessary because any select cursor behaves the same as an update cursor.

The pseudocode in the following figure shows when the database server places and releases locks with a cursor.

Figure 382. Locks Placed for Update

```

declare update cursor
begin work
open the cursor
fetch the row      ← Add an update lock for this row.
do stuff
update the row (use WHERE CURRENT OF) ← Promote lock to
commit work      ← Release lock.                exclusive.

```

## Retain update locks

If a user has the isolation level set lower than Repeatable Read, the database server releases update locks placed on rows as soon as the next row is fetched from a cursor. With this feature, you can use the `RETAIN UPDATE LOCKS` clause to retain an update lock until the end of a transaction when you set any of the following isolation levels:

- Dirty Read
- Committed Read
- Cursor Stability

This feature lets you avoid the overhead of Repeatable Read isolation level or workarounds such as dummy updates on a row. When the RETAIN UPDATE LOCKS feature is turned on and an update lock is implicitly placed on a row during a fetch of a SELECT...FOR UPDATE statement, the update lock is not released until the end of the transaction. With the RETAIN UPDATE LOCKS feature, only update locks are held until end of transaction, whereas the Repeatable Read isolation level holds both update locks and shared locks until end of transaction.

The following example shows how to use the RETAIN UPDATE LOCKS clause when you set the isolation level to Committed Read.

```
SET ISOLATION TO COMMITTED READ RETAIN UPDATE LOCKS
```

To turn off the RETAIN UPDATE LOCKS feature, set the isolation level without the RETAIN UPDATE LOCKS clause. When you turn off the feature, update locks are not released directly. However, from this point on, a subsequent fetch releases the update lock of the immediately preceding fetch but not of earlier fetch operations. A close cursor releases the update lock on the current row.

For more information about how to use the RETAIN UPDATE LOCKS feature when you specify an isolation level, see the *Informix® Guide to SQL: Syntax*.

## Exclusive locks that occur with some SQL statements

When you execute an INSERT, UPDATE, or DELETE statement, the database server uses *exclusive locks*. An exclusive lock means that no other users can update or delete the item until the database server removes the lock. In addition, no other users can view the row unless they are using the Dirty Read isolation level.

When the database server removes the exclusive lock depends on whether the database supports transaction logging.

For more information about these exclusive locks, see [Locks placed with INSERT, UPDATE, and DELETE statements on page](#).

## The behavior of the lock types

Informix® database servers store locks in an internal lock table. When the database server reads a row, it checks if the row or its associated page, table, or database is listed in the lock table. If it is in the lock table, the database server must also check the lock type. The lock table can contain the following types of locks.

| Lock name | Description    | Statement usually placing the lock |
|-----------|----------------|------------------------------------|
| S         | Shared lock    | SELECT                             |
| X         | Exclusive lock | INSERT, UPDATE, DELETE             |
| U         | Update lock    | SELECT in an update cursor         |

| Lock name | Description | Statement usually placing the lock         |
|-----------|-------------|--|
| B         | Byte lock   | Any statement that updates VARCHAR columns |

In addition, the lock table might store *intent locks*. An intent lock can be an intent shared (IS), intent exclusive (IX), or intent shared exclusive (SIX). An intent lock is the lock the database server (lock manager) places on a higher granularity object when a lower granularity object needs to be locked. For example, when a user locks a row or page in Shared lock mode, the database server places an IS (intent shared) lock on the table to provide an instant check that no other user holds an X lock on the table. In this case, intent locks are placed on the table only and not on the row or page. Intent locks can be placed at the level of a row, page, or table only.

The user does not have direct control over intent locks; the lock manager internally manages all intent locks.

The following table shows what locks a user (or the database server) can place if another user (or the database server) holds a certain type of lock. For example, if one user holds an exclusive lock on an item, another user requesting any kind of lock (exclusive, update or shared) receives an error. In addition, the database server is unable to place any intent locks on an item if a user holds an exclusive lock on the item.

|                  | Hold X lock | Hold U lock | Hold S lock | Hold IS lock | Hold SIX lock | Hold IX lock |
|------------------|-------------|-------------|-------------|--------------|---------------|--------------|
| Request X lock   | No          | No          | No          | No           | No            | No           |
| Request U lock   | No          | No          | Yes         | Yes          | No            | No           |
| Request S lock   | No          | Yes         | Yes         | Yes          | No            | No           |
| Request IS lock  | No          | Yes         | Yes         | Yes          | Yes           | Yes          |
| Request SIX lock | No          | No          | No          | Yes          | No            | No           |
| Request IX lock  | No          | No          | No          | Yes          | No            | Yes          |

For information about how locking affects performance, see your *Informix® Performance Guide*.

## Control data modification with access modes

Informix® database servers support access modes. Access modes affect read and write concurrency for rows within transactions and are set with the SET TRANSACTION statement. You can use access modes to control data modification among shared files.

Transactions are read-write by default. If you specify that a transaction is read-only, that transaction cannot perform the following tasks:

- Insert, delete, or update table rows
- Create, alter, or drop any database object such as a schema, table, temporary table, index, or stored routine
- Grant or revoke privileges
- Update statistics
- Rename columns or tables

Read-only access mode prohibits updates.

You can execute stored routines in a read-only transaction as long as the routine does not try to perform any restricted operations.

For information about how to use the SET TRANSACTION statement to specify an access mode, see the *Informix® Guide to SQL: Syntax*.

## Set the lock mode

The lock mode determines what happens when your program encounters locked data. One of the following situations occurs when a program attempts to fetch or modify a locked row:

- The database server immediately returns an error code in SQLCODE or SQLSTATE to the program.
- The database server suspends the program until the program that placed the lock removes the lock.
- The database server suspends the program for a time and then, if the lock is not removed, the database server sends an error-return code to the program.

You choose among these results with the SET LOCK MODE statement.

## Waiting for locks

When a user encounters a lock, the default behavior of a database server is to return an error to the application. If you prefer to wait indefinitely for a lock (this choice is best for many applications), you can execute the following SQL statement:

```
SET LOCK MODE TO WAIT
```

When this lock mode is set, your program usually ignores the existence of other concurrent programs. When your program needs to access a row that another program has locked, it waits until the lock is removed, then proceeds. In most cases, the delays are imperceptible.

You can also wait for a specific number of seconds, as in the following example:

```
SET LOCK MODE TO WAIT 20
```

## Not waiting for locks

The disadvantage of waiting for locks is that the wait might become long (although properly designed applications should hold their locks briefly). When the possibility of a long delay is not acceptable, a program can execute the following statement:

```
SET LOCK MODE TO NOT WAIT
```

When the program requests a locked row, it immediately receives an error code (for example, error -107 *Record is locked*), and the current SQL statement terminates. The program must roll back its current transaction and try again.

The initial setting is not waiting when a program starts up. If you are using SQL interactively and see an error related to locking, set the lock mode to wait. If you are writing a program, consider making that one of the first embedded SQL statements that the program executes.

## Limited time wait

You can ask the database server to set an upper limit on a wait with the following statement:

```
SET LOCK MODE TO WAIT 17
```

This statement places an upper limit of 17 seconds on the length of any wait. If a lock is not removed in that time, the error code is returned.

## Handle a deadlock

A *deadlock* is a situation in which a pair of programs blocks the progress of each other. Each program has a lock on some object that the other program wants to access. A deadlock arises only when all programs concerned set their lock modes to wait for locks.

The Informix® database server detects deadlocks immediately when they only involve data at a single network server. It prevents the deadlock from occurring by returning an error code (error -143 `ISAM error: deadlock detected`) to the second program to request a lock. The error code is the one the program receives if it sets its lock mode to not wait for locks. If your program receives an error code related to locks even after it sets lock mode to wait, you know the cause is an impending deadlock.

## Handling external deadlock

A deadlock can also occur between programs on different database servers. In this case, the database server cannot instantly detect the deadlock. (Perfect deadlock detection requires excessive communications traffic among all database servers in a network.) Instead, each database server sets an upper limit on the amount of time that a program can wait to obtain a lock on data at a different database server. If the time expires, the database server assumes that a deadlock was the cause and returns a lock-related error code.

In other words, when external databases are involved, every program runs with a maximum lock-waiting time. The DBA can set or modify the maximum for the database server.

## Simple concurrency

If you are not sure which choice to make concerning locking and concurrency, you can use the following guideline: If your application accesses non-static tables, and there is no risk of deadlock, have your program execute the following statements when it starts up (immediately after the first `CONNECT` or `DATABASE` statement):

```
SET LOCK MODE TO WAIT  
SET ISOLATION TO REPEATABLE READ
```

Ignore the return codes from both statements. Proceed as if no other programs exist. If no performance problems arise, you do not need to read this section again.

## Hold cursors

When transaction logging is used, HCL Informix® guarantees that anything done within a transaction can be rolled back at the end of it. To handle transactions reliably, the database server normally applies the following rules:

- When a transaction ends, all cursors are closed.
- When a transaction ends, all locks are released.

The rules that are used to handle transactions reliably are normal with most database systems that support transactions, and they do not cause any trouble for most applications. However, circumstances exist in which using standard transactions with cursors is not possible. For example, the following code works fine without transactions. However, when transactions are added, closing the cursor conflicts with using two cursors simultaneously.

```
EXEC SQL DECLARE master CURSOR FOR
EXEC SQL DECLARE detail CURSOR FOR FOR UPDATE
EXEC SQL OPEN master;
while(SQLCODE == 0)
{
  EXEC SQL FETCH master INTO
  if(SQLCODE == 0)
  {
    EXEC SQL BEGIN WORK;
    EXEC SQL OPEN detail USING
    EXEC SQL FETCH detail
    EXEC SQL UPDATE WHERE CURRENT OF detail
    EXEC SQL COMMIT WORK;
  }
}
EXEC SQL CLOSE master;
```

In this design, one cursor is used to scan a table. Selected records are used as the basis for updating a different table. The problem is that when each update is treated as a separate transaction (as the pseudocode in the previous example shows), the COMMIT WORK statement following the UPDATE closes all cursors, including the master cursor.

The simplest alternative is to move the COMMIT WORK and BEGIN WORK statements to be the last and first statements, respectively, so that the entire scan over the master table is one large transaction. Treating the scan of the master table as one large transaction is sometimes possible, but it can become impractical if many rows need to be updated. The number of locks can be too large, and they are held for the duration of the program.

A solution that Informix® database servers support is to add the keywords WITH HOLD to the declaration of the master cursor. Such a cursor is referred to as a *hold cursor* and is not closed at the end of a transaction. The database server still closes all other cursors, and it still releases all locks, but the hold cursor remains open until it is explicitly closed.

Before you attempt to use a hold cursor, you must be sure that you understand the locking mechanism described here, and you must also understand the programs that are running concurrently. Whenever COMMIT WORK is executed, all locks are released, including any locks placed on rows fetched through the hold cursor.

The removal of locks has little importance if the cursor is used as intended, for a single forward scan over a table. However, you can specify `WITH HOLD` for any cursor, including update cursors and scroll cursors. Before you do this, you must understand the implications of the fact that all locks (including locks on entire tables) are released at the end of a transaction.

## The SQL statement cache

The SQL statement cache is a feature that lets you store in a buffer identical SQL statements that are executed repeatedly so the statements can be reused among different user sessions without the need for per-session memory allocation. Statement caching can dramatically improve performance for applications that contain a large number of prepared statements. However, performance improvements are less dramatic when statement caching is used to cache statements that are prepared once and executed many times.

Use SQL to turn on or turn off statement caching for an individual database session when statement caching is enabled for the database server. The following statement shows how to use SQL to turn on caching for the current database session:

```
SET STATEMENT CACHE ON
```

The following statement shows how to use SQL to turn off caching for the current database session:

```
SET STATEMENT CACHE OFF
```

If you attempt to turn on or turn off statement caching when caching is disabled, the database server returns an error.

For information about syntax for the `SET STATEMENT CACHE` statement, see the *Informix® Guide to SQL: Syntax*. For information about the `STMT_CACHE` and `STMT_CACHE_SIZE` configuration parameters, see the and your *Informix® Performance Guide*. For information about the **`STMT_CACHE`** environment variable, see the *Informix® Guide to SQL: Reference*.

## Summary

Whenever multiple programs have access to a database concurrently (and when at least one of them can modify data), all programs must allow for the possibility that another program can change the data even as they read it. The database server provides a mechanism of locks and isolation levels that usually allow programs to run as if they were alone with the data.

The `SET STATEMENT CACHE` statement allows you to store in a buffer identical SQL statements that are used repeatedly. When statement caching is turned on, the database server stores the identical statements so they can be reused among different user sessions without the need for per-session memory allocation.

## Create and use SPL routines

This section describes how to create and use SPL routines. An SPL routine is a user-defined routine written in Informix® Stored Procedure Language (SPL). Informix® SPL is an extension to SQL that provides flow control, such as looping and branching. Anyone who has the Resource privilege on a database can create an SPL routine.

Routines written in SQL are parsed, optimized as far as possible, and then stored in the system catalog tables in executable format. An SPL routine might be a good choice for SQL-intensive tasks. SPL routines can execute routines written in C or other external languages, and external routines can execute SPL routines.

You can use SPL routines to perform any task that you can perform in SQL and to expand what you can accomplish with SQL alone. Because SPL is a language native to the database, and because SPL routines are parsed and optimized when they are created rather than at runtime, SPL routines can improve performance for some tasks. SPL routines can also reduce traffic between a client application and the database server and reduce program complexity.

The syntax for each SPL statement is described in the *Informix® Guide to SQL: Syntax*. Examples accompany the syntax for each statement.

## Introduction to SPL routines

An SPL *routine* is a generic term that includes SPL *procedures* and SPL *functions*. An SPL procedure is a routine written in SPL and SQL that does not return a value. An SPL function is a routine written in SPL and SQL that returns a single value, a value with a complex data type, or multiple values. Generally, a routine written in SPL that returns a value is an SPL function.

You use SQL and SPL statements to write an SPL routine. SPL statements can be used only inside the CREATE PROCEDURE, CREATE PROCEDURE FROM, CREATE FUNCTION, and CREATE FUNCTION FROM statements. All these statements are available with SQL APIs such as Informix® ESQL/C. The CREATE PROCEDURE and CREATE FUNCTION statements are available with DB-Access.

To list all SPL routines in a database, run this command, which creates and displays the schema for a database:

```
dbschema -d database_name -f all
```

## What you can do with SPL routines

You can accomplish a wide range of objectives with SPL routines, including improving database performance, simplifying writing applications, and limiting or monitoring access to data.

Because an SPL routine is stored in an executable format, you can use it to execute frequently repeated tasks to improve performance. When you execute an SPL routine rather than straight SQL code, you can bypass repeated parsing, validity checking, and query optimization.

You can use an SPL routine in a data-manipulation SQL statement to supply values to that statement. For example, you can use a routine to perform the following actions:

- Supply values to be inserted into a table
- Supply a value that makes up part of a condition clause in a SELECT, DELETE, or UPDATE statement

These actions are two possible uses of a routine in a data-manipulation statement, but others exist. In fact, any expression in a data-manipulation SQL statement can consist of a routine call.

You can also issue SQL statements in an SPL routine to hide those SQL statements from a database user. Rather than having all users learn how to use SQL, one experienced SQL user can write an SPL routine to encapsulate an SQL activity and let others know that the routine is stored in the database so that they can execute it.

You can write an SPL routine to be run with the DBA privilege by a user who does not have the DBA privilege. This feature allows you to limit and control access to data in the database. Alternatively, an SPL routine can monitor the users who access certain tables or data. For more information about how to use SPL routines to control access to data, see the *Informix® Database Design and Implementation Guide*.

You also can write SPL routines that use Dynamic SQL. For an overview with detailed examples of how to create and use prepared objects and Dynamic SQL in SPL routines, see this article: [Dynamic SQL support in Informix® Dynamic Server Stored Procedure Language](#).

## SPL routines format

An SPL routine consists of a beginning statement, a statement block, and an ending statement. Within the statement block, you can use SQL or SPL statements.

## The CREATE PROCEDURE or CREATE FUNCTION statement

You must first decide if the routine that you are creating returns values or not. If the routine does not return a value, use the CREATE PROCEDURE statement to create an SPL procedure. If the routine returns a value, use the CREATE FUNCTION statement to create an SPL function.

To create an SPL routine, use one CREATE PROCEDURE or CREATE FUNCTION statement to write the body of the routine and register it.

## Begin and end the routine

To create an SPL routine that does not return values, start with the CREATE PROCEDURE statement and end with the END PROCEDURE keyword. The following figure shows how to begin and end an SPL procedure.

Figure 383. Begin and end an SPL procedure.

```
CREATE PROCEDURE new_price( per_cent REAL )
. . .
END PROCEDURE;
```

For more information about naming conventions, see the Identifier segment in the *Informix® Guide to SQL: Syntax*.

To create an SPL function that returns one or more values, start with the CREATE FUNCTION statement and end with the END FUNCTION keyword. The following figure shows how to begin and end an SPL function.

Figure 384. Begin and end an SPL function.

```
CREATE FUNCTION discount_price( per_cent REAL)
RETURNING MONEY;
. . .
END FUNCTION;
```

In SPL routines, the END PROCEDURE or END FUNCTION keywords are required.

**Important:** For compatibility with earlier HCL Informix® products, you can use CREATE PROCEDURE with a RETURNING clause to create a user-defined routine that returns a value. Your code will be easier to read and to maintain, however, if you use CREATE PROCEDURE for SPL routines that do not return values (SPL procedures) and CREATE FUNCTION for SPL routines that return one or more values (SPL functions).

## Specify a routine name

You specify a name for the SPL routine immediately following the CREATE PROCEDURE or CREATE FUNCTION statement and before the parameter list, as the figure shows.

Figure 385. Specify a name for the SPL routine.

```
CREATE PROCEDURE add_price (arg INT )
```

HCL Informix® allows you to create more than one SPL routine with the same name but with different parameters. This feature is known as *routine overloading*. For example, you might create each of the following SPL routines in your database:

```
CREATE PROCEDURE multiply (a INT, b FLOAT)
CREATE PROCEDURE multiply (a INT, b SMALLINT)
CREATE PROCEDURE multiply (a REAL, b REAL)
```

If you call a routine with the name **multiply()**, the database server evaluates the name of the routine and its arguments to determine which routine to execute.

*Routine resolution* is the process in which the database server searches for a routine signature that it can use, given the name of the routine and a list of arguments. Every routine has a *signature* that uniquely identifies the routine based on the following information:

- The type of routine (procedure or function)
- The routine name
- The number of parameters
- The data types of the parameters
- The order of the parameters

The routine signature is used in a CREATE, DROP, or EXECUTE statement if you enter the full parameter list of the routine. For example, each statement in the following figure uses a routine signature.

Figure 386. Routine signatures.

```
CREATE FUNCTION multiply(a INT, b INT);
DROP PROCEDURE end_of_list(n SET, row_id INT);
EXECUTE FUNCTION compare_point(m point, n point);
```

## Add a specific name

Because HCL Informix® supports routine overloading, an SPL routine might not be uniquely identified by its name alone. However, a routine can be uniquely identified by a *specific name*. A specific name is a unique identifier that you define in the CREATE PROCEDURE or CREATE FUNCTION statement, in addition to the routine name. A specific name is defined with the SPECIFIC keyword and is unique in the database. Two routines in the same database cannot have the same specific name, even if they have different owners.

A specific name can be up to 128 bytes long. The following figure shows how to define the specific name **calc1** in a CREATE FUNCTION statement that creates the calculate() function.

Figure 387. Define the specific name.

```
CREATE FUNCTION calculate(a INT, b INT, c INT)
  RETURNING INT
  SPECIFIC calc1;
. . .
END FUNCTION;
```

Because the owner **bsmith** has given the SPL function the specific name **calc1**, no other user can define a routine-SPL or external-with the specific name **calc1**. Now you can refer to the routine as **bsmith.calculate** or with the SPECIFIC keyword **calc1** in any statement that requires the SPECIFIC keyword.

## Add a parameter list

When you create an SPL routine, you can define a parameter list so that the routine accepts one or more arguments when it is invoked. The parameter list is optional.

A parameter to an SPL routine must have a name and can be defined with a default value. The following are the categories of data types that a parameter can specify:

- Built-in data types
- Opaque data types
- Distinct data types
- Row types
- Collection types
- Smart large objects (CLOB and BLOB)

The parameter list cannot specify any of the following data types directly:

- SERIAL
- SERIAL8
- BIGSERIAL
- TEXT
- BYTE

For the serial data types, however, a routine can return numerically equivalent values that are cast to a corresponding integer type (INT, INT8, or BIGINT). Similarly, for a routine to support the simple large object data types, the parameter list can include the REFERENCES keyword to return a descriptor that points to the storage location of the TEXT or BYTE object.

The following figure shows examples of parameter lists.

Figure 388. Examples of different parameter lists.

```
CREATE PROCEDURE raise_price(per_cent INT);

CREATE FUNCTION raise_price(per_cent INT DEFAULT 5);

CREATE PROCEDURE update_emp(n employee_t);
CREATE FUNCTION update_nums( list1 LIST(ROW (a VARCHAR(10),
                                             b VARCHAR(10),
                                             c INT) NOT NULL ));
```

When you define a parameter, you accomplish two tasks at once:

- You request that the user supply a value when the routine is executed.
- You implicitly define a variable (with the same name as the parameter name) that you can use as a local variable in the body of the routine.

If you define a parameter with a default value, the user can execute the SPL routine with or without the corresponding argument. If the user executes the SPL routine without the argument, the database server assigns the parameter the default value as an argument.

When you invoke an SPL routine, you can give an argument a NULL value. SPL routines handle NULL values by default. However, you cannot give an argument a NULL value if the argument is a collection element.

## Simple large objects as parameters

Although you cannot define a parameter with a simple large object (a large object that contains TEXT or BYTE data types), you can use the REFERENCES keyword to define a parameter that points to a simple large object, as the following figure shows.

Figure 389. Use of the REFERENCES keyword.

```
CREATE PROCEDURE proc1(lo_text REFERENCES TEXT)

CREATE FUNCTION proc2(lo_byte REFERENCES BYTE DEFAULT NULL)
```

The REFERENCES keyword means that the SPL routine is passed a descriptor that contains a pointer to the simple large object, not the object itself.

## Undefined arguments

When you invoke an SPL routine, you can specify all, some, or none of the defined arguments. If you do not specify an argument, and if its corresponding parameter does not have a default value, the argument, which is used as a variable within the SPL routine, is given a status of *undefined*.

Undefined is a special status used for SPL variables that have no value. The SPL routine executes without error, as long as you do not attempt to use the variable that has the status undefined in the body of the routine.

The undefined status is not the same as a NULL value. (The NULL value means that the value is not known, or does not exist, or is not applicable.)

## Add a return clause

If you use CREATE FUNCTION to create an SPL routine, you must specify a return clause that returns one or more values.

 **Tip:** If you use the CREATE PROCEDURE statement to create an SPL routine, you have the option of specifying a return clause. Your code will be easier to read and to maintain, however, if you instead use the CREATE FUNCTION statement to create a routine that returns values.

To specify a return clause, use the RETURNING or RETURNS keyword with a list of data types the routine will return. The data types can be any SQL data types except SERIAL, SERIAL8, TEXT, or BYTE.

The return clause in the following figure specifies that the SPL routine will return an INT value and a REAL value.

Figure 390. Specify the return clause.

```
FUNCTION find_group(id INT)
  RETURNING INT, REAL;
. . .
END FUNCTION;
```

After you specify a return clause, you must also specify a RETURN statement in the body of the routine that explicitly returns the values to the calling routine. For more information on writing the RETURN statement, see [Return values from an SPL function on page 2028](#).

To specify that the function should return a simple large object (a TEXT or BYTE value), you must use the REFERENCES clause, as in the following figure, because an SPL routine returns only a pointer to the object, not the object itself.

Figure 391. Use of the REFERENCES clause.

```
CREATE FUNCTION find_obj(id INT)
  RETURNING REFERENCES BYTE;
```

## Add display labels

You can use CREATE FUNCTION to create a routine that specifies names for the display labels for the values returned. If you do not specify names for the display labels, the labels will display as **expression**.

In addition, although using CREATE FUNCTION for routines that return values is recommended, you can use CREATE PROCEDURE to create a routine that returns values and specifies display labels for the values returned.

If you choose to specify a display label for one return value, you must specify a display label for every return value. In addition, each return value must have a unique display label.

To add display labels, you must specify a return clause, use the RETURNING keyword. The return clause in the following figure specifies that the routine will return an INT value with a `serial_num` display label, a CHAR value with a `name` display label, and an INT value with a `points` display label. You could use either CREATE FUNCTION or CREATE PROCEDURE in the following figure.

Figure 392. Specify the return clause.

```
CREATE FUNCTION p(inval INT DEFAULT 0)
  RETURNING INT AS serial_num, CHAR (10) AS name, INT AS points;
  RETURN (inval + 1002), "Newton", 100;
END FUNCTION;
```

The returned values and their display labels are shown in the following figure.

Figure 393. Returned values and their display labels.

| <code>serial_num</code> | <code>name</code> | <code>points</code> |
|-------------------------|-------------------|---------------------|
| 1002                    | Newton            | 100                 |

**Tip:** Because you can specify display labels for return values directly in a SELECT statement, when a SPL routine is used in a SELECT statement, the labels will display as **expression**. For more information on specifying display labels for return values in a SELECT statement, see [Compose SELECT statements on page 1773](#).

## Specify whether the SPL function is variant

When you create an SPL function, the function is variant by default. A function is variant if it returns different results when it is invoked with the same arguments or if it modifies a database or variable state. For example, a function that returns the current date or time is a variant function.

Although SPL functions are variant by default, if you specify WITH NOT VARIANT when you create a function, the function cannot contain any SQL statements. You can define a functional index only on a nonvariant function.

## Add a modifier

When you write SPL functions, you can use the WITH clause to add a modifier to the CREATE FUNCTION statement. In the WITH clause, you can specify the COMMUTATOR or NEGATOR functions. The other modifiers are for external routines.

**Restriction:** You can use the COMMUTATOR or NEGATOR modifiers with SPL functions only. You cannot use any modifiers with SPL procedures.

## The COMMUTATOR modifier

The COMMUTATOR modifier allows you to specify an SPL function that is the *commutator function* of the SPL function you are creating. A commutator function accepts the same arguments as the SPL function you are creating, but in opposite order, and returns the same value. The commutator function might be more cost effective for the SQL optimizer to execute.

For example, the functions `lessthan(a,b)`, which returns TRUE if **a** is less than **b**, and `greaterthan(b,a)`, which returns TRUE if **b** is greater than or equal to **a**, are commutator functions. The following figure uses the WITH clause to define a commutator function.

Figure 394. Define a commutator function.

```
CREATE FUNCTION lessthan( a dtype1, b dtype2 )
  RETURNING BOOLEAN
  WITH ( COMMUTATOR = greaterthan );
. . .
END FUNCTION;
```

The optimizer might use `greaterthan(b,a)` if it is less expensive to execute than `lessthan(a,b)`. To specify a commutator function, you must own both the commutator function and the SPL function you are writing. You must also grant the user of your SPL function the Execute privilege on both functions.

For a detailed description of granting privileges, see the description of the GRANT statement in the *Informix® Guide to SQL: Syntax*.

## The NEGATOR modifier

The NEGATOR modifier is available for Boolean functions. Two Boolean functions are *negator functions* if they take the same arguments, in the same order, and return complementary Boolean values.

For example, the functions `equal(a,b)`, which returns TRUE if **a** is equal to **b**, and `notequal(a,b)`, which returns FALSE if **a** is equal to **b**, are negator functions. The optimizer might choose to execute the negator function you specify if it is less expensive than the original function.

The following figure shows how to use the WITH clause of a CREATE FUNCTION statement to specify a negator function.

Figure 395. Specify a negator function.

```
CREATE FUNCTION equal( a dtype1, b dtype2 )
  RETURNING BOOLEAN
  WITH ( NEGATOR = notequal );
. . .
END FUNCTION;
```

**Tip:** By default, any SPL routine can handle NULL values that are passed to it in the argument list. In other words, the HANDLESNULLS modifier is set to YES for SPL routines, and you cannot change its value.

For more information on the COMMUTATOR and NEGATOR modifiers, see the Routine Modifier segment in the *Informix® Guide to SQL: Syntax*.

## Specify a DOCUMENT clause

The DOCUMENT and WITH LISTING IN clauses follow END PROCEDURE or END FUNCTION statements.

The DOCUMENT clause lets you add comments to your SPL routine that another routine can select from the system catalog tables, if needed. The DOCUMENT clause in the following figure contains a usage statement that shows a user how to run the SPL routine.

Figure 396. Usage statement that shows a user how to run the SPL routine.

```
CREATE FUNCTION raise_prices(per_cent INT)
. . .
END FUNCTION
DOCUMENT "USAGE: EXECUTE FUNCTION raise_prices (xxx)",
        "xxx = percentage from 1 - 100";
```

Remember to place single or double quotation marks around the literal clause. If the literal clause extends past one line, place quotation marks around each line.

## Specify a listing file

The WITH LISTING IN option allows you to direct any compile-time warnings that might occur to a file.

The following figure shows how to log the compile-time warnings in `/tmp/warn_file` when you work on UNIX™.

Figure 397. Log the compile-time warnings on UNIX™.

```
CREATE FUNCTION raise_prices(per_cent INT)
. . .
END FUNCTION
WITH LISTING IN '/tmp/warn_file'
```

The following figure shows how to log the compile-time warnings in `\tmp\listfile` when you work on Windows™.

Figure 398. Log the compile-time warnings on Windows™.

```
CREATE FUNCTION raise_prices(per_cent INT)
. . .
END FUNCTION
WITH LISTING IN 'C:\tmp\listfile'
```

Always remember to place single or double quotation marks around the file name or path name.

## Add comments

You can add a comment to any line of an SPL routine, even a blank line.

To add a comment, use any of the following comment notation styles:

- Place a double hyphen ( `--` ) at the left of the comment.
- Enclose the comment text between a pair of braces ( `{ .. }` ).
- Delimit the comment between C-style "slash and asterisk" comment indicators ( `/* .. */` ).

To add a multiple-line comment, take one of the following actions:

- Place a double hyphen before each line of the comment
- Enclose the entire comment within the pair of braces.
- Place `/*` at the left of the first line of the comment, and place `*/` at the end of the last line of the comment.

Braces as comment indicators are Informix® an extension to the ANSI/ISO standard for the SQL language. All three comment styles are also valid in SPL routines.

If you use braces or C-style comment indicators to delimit the text of a comment, the opening indicator must be in the same style as the closing indicator.

All the examples in the following figure are valid comments.

Figure 399. Valid comment examples.

```
SELECT * FROM customer -- Selects all columns and rows

SELECT * FROM customer
  -- Selects all columns and rows
  -- from the customer table

SELECT * FROM customer
  { Selects all columns and rows
    from the customer table }

SELECT * FROM customer
  /* Selects all columns and rows
    from the customer table */
```

**Important:** Braces ( `{}` ) can be used to delimit comments and also to delimit the list of elements in a collection. To ensure that the parser correctly recognizes the end of a comment or list of elements in a collection, use the double hyphen ( `--` ) for comments in an SPL routine that handles collection data types.

## Example of a complete routine

The following CREATE FUNCTION statement creates a routine that reads a customer address:

```
CREATE FUNCTION read_address      (lastname CHAR(15)) -- one argument
  RETURNING CHAR(15), CHAR(15), CHAR(20), CHAR(15),CHAR(2)
  CHAR(5); -- 6 items

DEFINE p_lname,p_fname, p_city CHAR(15);
  --define each routine variable
DEFINE p_add CHAR(20);
DEFINE p_state CHAR(2);
DEFINE p_zip CHAR(5);

SELECT fname, address1, city, state, zipcode
  INTO p_fname, p_add, p_city, p_state, p_zip
  FROM customer
```

```

WHERE lname = lastname;

RETURN p_fname, lastname, p_add, p_city, p_state, p_zip;
--6 items
END FUNCTION;

DOCUMENT 'This routine takes the last name of a customer as',
--brief description
'its only argument. It returns the full name and address',
'of the customer.'

WITH LISTING IN 'pathname' -- modify this pathname according
-- to the conventions that your operating system requires

-- compile-time warnings go here
; -- end of the routine read_address

```

## Create an SPL routine in a program

To use an SQL API to create an SPL routine, put the text of the CREATE PROCEDURE or CREATE FUNCTION statement in a file. Use the CREATE PROCEDURE FROM or CREATE FUNCTION FROM statement and refer to that file to compile the routine. For example, to create a routine to read a customer name, you can use a statement such as the one in the previous example and store it in a file. If the file is named `read_add_source`, the following statement compiles the **read\_address** routine:

```
CREATE PROCEDURE FROM 'read_add_source';
```

The following example shows how the previous SQL statement looks in the Informix® ESQL/C program:

```

/* This program creates whatever routine is in *
 * the file 'read_add_source'.
 */
#include <stdio.h>
EXEC SQL include sqlca;
EXEC SQL include sqllda;
EXEC SQL include datetime;
/* Program to create a routine from the pwd */

main()
{
EXEC SQL database play;
EXEC SQL create procedure from 'read_add_source';
}

```

## Dropping a routine in a local or remote database

After you create an SPL routine, you cannot change the body of the routine. Instead, you need to drop the routine and re-create it. Before you drop the routine, however, make sure that you have a copy of its text somewhere outside the database.

In general, use DROP PROCEDURE with an SPL procedure name and DROP FUNCTION with an SPL function name, as the following figure shows.

Figure 400. DROP PROCEDURE and DROP FUNCTION.

```
DROP PROCEDURE raise_prices;
DROP FUNCTION read_address;
```

 **Tip:** You can also use DROP PROCEDURE with a function name to drop an SPL function. However, it is recommended that you use DROP PROCEDURE only with procedure names and DROP FUNCTION only with function names.

If the database has other routines of the same name (overloaded routines), you cannot drop the SPL routine by its routine name alone. To drop a routine that has been overloaded, you must specify either its signature or its specific name. The following figure shows two ways that you might drop a routine that is overloaded.

Figure 401. Drop a routine that is overloaded.

```
DROP FUNCTION calculate(INT, INT, INT);
-- this is a signature

DROP SPECIFIC FUNCTION calc1;
-- this is a specific name
```

If you do not know the type of a routine (function or procedure), you can use the DROP ROUTINE statement to drop it. DROP ROUTINE works with either functions or procedures. DROP ROUTINE also has a SPECIFIC keyword, as the following figure shows.

Figure 402. The DROP ROUTINE statement.

```
DROP ROUTINE calculate;
DROP SPECIFIC ROUTINE calc1;
```

Before you drop an SPL routine stored on a remote database server, be aware of the following restriction. You can drop an SPL routine with a fully qualified routine name in the form `database@dbservername:owner.routinename` only if the routine name alone, without its arguments, is enough to identify the routine.

### Restrictions on data types in distributed operations

SPL routines that access tables in databases of non-local database servers, or that are invoked as UDRs of a database of another database server, can only have non-opaque built-in data types as their arguments or returned values.

If the tables or the UDR resides on another database of the same Informix® instance, however, the arguments and returned values of routines written in SPL (or in external languages that Informix® supports) can be the built-in opaque data types BLOB, BOOLEAN, CLOB, and LVARCHAR. They can also be UDTs or DISTINCT data types if the following conditions are true:

- The remote database has the same server as the current database.
- The UDT arguments are explicitly cast to a built-in data type.
- The DISTINCT types are based on built-in types and are explicitly cast to built-in types.
- The SPL routine and all the casts are defined in all participating databases.

## Define and use variables

Any variable that you use in an SPL routine, other than a variable that is implicitly defined in the parameter list of the routine, must be defined in the body of the routine.

The value of a variable is held in memory; the variable is not a database object. Therefore, rolling back a transaction does not restore the values of SPL variables.

To define a variable in an SPL routine, use the DEFINE statement. DEFINE is not an executable statement. DEFINE must appear after the CREATE PROCEDURE statement and before any other statements. The examples in the following figure are all legal variable definitions.

Figure 403. Variable definitions.

```
DEFINE a INT;
DEFINE person person_t;
DEFINE GLOBAL gl_out INT DEFAULT 13;
```

For more information on DEFINE, see the description in the *Informix® Guide to SQL: Syntax*.

An SPL variable has a name and a data type. The variable name must be a valid identifier, as described in the Identifier segment in the *Informix® Guide to SQL: Syntax*.

## Declare local variables

You can define a variable to be either *local* or *global* in scope. This section describes local variables. In an SPL routine, local variables:

- Are valid only for the duration of the SPL routine
- Are reset to their initial values or to a value the user passes to the routine, each time the routine is executed
- Cannot have default values

You can define a local variable on any of the following data types:

- Built-in data types (except SERIAL, SERIAL8, BIGSERIAL, TEXT, or BYTE)
- Any extended data type (row type, opaque, distinct, or collection type) that is defined in the database prior to execution of the SPL routine

The scope of a local variable is the statement block in which it is declared. You can use the same variable name outside the statement block with a different definition.

For more information on defining global variables, see [Declare global variables on page 2018](#).

## Scope of local variables

A local variable is valid within the statement block in which it is defined and within any nested statement blocks, unless you redefine the variable within the statement block.

In the beginning of the SPL procedure in the following figure, the integer variables **x**, **y**, and **z** are defined and initialized.

Figure 404. Define and initialize variables.

```
CREATE PROCEDURE scope()
  DEFINE x,y,z INT;
  LET x = 5;
  LET y = 10;
  LET z = x + y; --z is 15
  BEGIN
    DEFINE x, q INT;
    DEFINE z CHAR(5);
    LET x = 100;
    LET q = x + y; -- q = 110
    LET z = 'silly'; -- z receives a character value
  END
  LET y = x; -- y is now 5
  LET x = z; -- z is now 15, not 'silly'
END PROCEDURE;
```

The BEGIN and END statements mark a nested statement block in which the integer variables **x** and **q** are defined as well as the CHAR variable **z**. Within the nested block, the redefined variable **x** masks the original variable **x**. After the END statement, which marks the end of the nested block, the original value of **x** is accessible again.

## Declare variables of built-in data types

A variable that you declare as a built-in SQL data type can hold a value retrieved from a column of that built-in type. You can declare an SPL variable as most built-in types, except BIGSERIAL, SERIAL, and SERIAL8, as the following figure illustrates.

Figure 405. Built-in type variables.

```
DEFINE x INT;
DEFINE y INT8;
DEFINE name CHAR(15);
DEFINE this_day DATETIME YEAR TO DAY;
```

You can declare SPL variables of appropriate integer data types (such as BIGINT, INT, or INT8) to store the values of serial columns or of sequence objects.

## Declare variables for smart large objects

A variable for a BLOB or CLOB object (or a data type that contains a smart large object) does not contain the object itself but rather a pointer to the object. The following figure shows how to define a variable for BLOB and CLOB objects.

Figure 406. Variables for BLOB or CLOB objects.

```
DEFINE a_blob BLOB;
DEFINE b_clob CLOB;
```

## Declare variables for simple large objects

A variable for a simple large object (a TEXT or BYTE object) does not contain the object itself but rather a pointer to the object. When you define a variable on the TEXT or BYTE data type, you must use the keyword REFERENCES before the data type, as the following figure shows.

Figure 407. Use the REFERENCES keyword before the data type.

```
DEFINE t REFERENCES TEXT;
DEFINE b REFERENCES BYTE;
```

## Declare collection variables

In order to hold a collection fetched from the database, a variable must be of type SET, MULTISSET, or LIST.

**Important:** A collection variable must be defined as a local variable. You cannot define a collection variable as a global variable.

A variable of SET, MULTISSET, or LIST type is a collection variable that holds a collection of the type named in the DEFINE statement. The following figure shows how to define typed collection variables.

Figure 408. Define typed collection variables.

```
DEFINE a SET ( INT NOT NULL );

DEFINE b MULTISSET ( ROW ( b1 INT,
                          b2 CHAR(50),
                          ) NOT NULL );

DEFINE c LIST ( SET (DECIMAL NOT NULL) NOT NULL);
```

You must always define the elements of a collection variable as NOT NULL. In this example, the variable **a** is defined to hold a SET of non-NULL integers; the variable **b** holds a MULTISSET of non-NULL row types; and the variable **c** holds a LIST of non-NULL sets of non-NULL decimal values.

In a variable definition, you can nest complex types in any combination or depth to match the data types stored in your database.

You cannot assign a collection variable of one type to a collection variable of another type. For example, if you define a collection variable as a SET, you cannot assign another collection variable of MULTISSET or LIST type to it.

## Declare row-type variables

Row-type variables hold data from named or unnamed row types. You can define a *named row variable* or an *unnamed row variable*. Suppose you define the named row types that the following figure shows.

Figure 409. Named and unnamed row variables.

```
CREATE ROW TYPE zip_t
(
  z_code    CHAR(5),
  z_suffix  CHAR(4)
);

CREATE ROW TYPE address_t
(
  street    VARCHAR(20),
  city      VARCHAR(20),
  state     CHAR(2),
  zip       zip_t
);

CREATE ROW TYPE employee_t
(
  name      VARCHAR(30),
  address   address_t,
  salary    INTEGER
);

CREATE TABLE employee OF TYPE employee_t;
```

If you define a variable with the name of a named row type, the variable can only hold data of that row type. In the following figure, the **person** variable can only hold data of **employee\_t** type.

Figure 410. Defining the person variable.

```
DEFINE person employee_t;
```

To define a variable that holds data stored in an unnamed row type, use the ROW keyword followed by the fields of the row type, as the following figure shows.

Figure 411. Use the ROW keyword followed by the fields of the row type.

```
DEFINE manager ROW (name      VARCHAR(30),
                   department VARCHAR(30),
                   salary     INTEGER );
```

Because unnamed row types are type-checked for structural equivalence only, a variable defined with an unnamed row type can hold data from any unnamed row type that has the same number of fields and the same type definitions. Therefore, the variable **manager** can hold data from any of the row types in the following figure.

Figure 412. Unnamed row types.

```

ROW ( name      VARCHAR(30),
      department VARCHAR(30),
      salary    INTEGER );

ROW ( french    VARCHAR(30),
      spanish   VARCHAR(30),
      number    INTEGER );

ROW ( title     VARCHAR(30),
      musician  VARCHAR(30),
      price     INTEGER );

```

**Important:** Before you can use a row type variable, you must initialize the row variable with a LET statement or SELECTINTO statement.

## Declare opaque- and distinct-type variables

*Opaque-type variables* hold data retrieved from opaque data types. *Distinct-type variables* hold data retrieved from distinct data types. If you define a variable with an opaque data type or a distinct data type, the variable can only hold data of that type.

If you define an opaque data type named **point** and a distinct data type named **centerpoint**, you can define SPL variables to hold data from the two types, as the following figure shows.

Figure 413. Defining SPL variables to hold opaque and distinct data types.

```

DEFINE a point;
DEFINE b centerpoint;

```

The variable **a** can only hold data of type **point**, and **b** can only hold data of type **centerpoint**.

## Declare variables for column data with the LIKE clause

If you use the LIKE clause, the database server defines a variable to have the same data type as a column in a table or view.

If the column contains a collection, row type, or nested complex type, the variable has the complex or nested complex type defined in the column.

In the following figure, the variable **loc1** defines the data type for the **locations** column in the **image** table.

Figure 414. Define the loc1 data type for the locations column in the image table.

```

DEFINE loc1 LIKE image.locations;

```

## Declare PROCEDURE type variables

In an SPL routine, you can define a variable of type PROCEDURE and assign the variable the name of an existing SPL routine or external routine. Defining a variable of PROCEDURE type indicates that the variable is a call to a user-defined routine, not a built-in routine of the same name.

For example, the statement in the following figure defines **length** as an SPL procedure or SPL function, not as the built-in LENGTH function.

Figure 415. Define length as an SPL procedure.

```
DEFINE length PROCEDURE;
LET x = length( a,b,c );
```

This definition disables the built-in LENGTH function within the scope of the statement block. You would use such a definition if you had already created an SPL or external routine with the name LENGTH.

Because HCL Informix® supports routine overloading, you can define more than one SPL routine or external routine with the same name. If you call any routine from an SPL routine, Informix® determines which routine to use, based on the arguments specified and the routine determination rules. For information about routine overloading and routine determination, see *Informix® User-Defined Routines and Data Types Developer's Guide*.

**Tip:** If you create an SPL routine with the same name as an aggregate function (SUM, MAX, MIN, AVG, COUNT) or with the name **extend**, you must qualify the routine name with an owner name.

## Subscripts with variables

You can use subscripts with variables of CHAR, VARCHAR, NCHAR, NVARCHAR, BYTE, or TEXT data type. The subscripts indicate the starting and ending character positions that you want to use within the variable.

Subscripts must always be constants. You cannot use variables as subscripts. The following figure illustrates how to use a subscript with a CHAR(15) variable.

Figure 416. A subscript with a CHAR(15) variable.

```
DEFINE name CHAR(15);
LET name[4,7] = 'Ream';
SELECT fname[1,3] INTO name[1,3] FROM customer
WHERE lname = 'Ream';
```

In this example, the customer's last name is placed between positions 4 and 7 of **name**. The first three characters of the customer's first name is retrieved into positions 1 through 3 of **name**. The part of the variable that is delimited by the two subscripts is referred to as a *substring*.

## Variable and keyword ambiguity

If you declare a variable whose name is an SQL keyword, ambiguities can occur. The following rules for identifiers help you avoid ambiguities for SPL variables, SPL routine names, and built-in function names:

- Defined variables take the highest precedence.
- Routines defined with the PROCEDURE keyword in a DEFINE statement take precedence over SQL functions.
- SQL functions take precedence over SPL routines that exist but are not identified with the PROCEDURE keyword in a DEFINE statement.

In general, avoid using an ANSI-reserved word for the name of the variable. For example, you cannot define a variable with the name **count** or **max** because they are the names of aggregate functions. For a list of the reserved keywords that you should avoid using as variable names, see the Identifier segment in the *Informix® Guide to SQL: Syntax*.

For information about ambiguities between SPL routine names and SQL function names, see the *Informix® Guide to SQL: Syntax*.

## Variables and column names

If you use the same identifier for an SPL variable that you use for a column name, the database server assumes that each instance of the identifier is a variable. Qualify the column name with the table name, using dot notation, in order to use the identifier as a column name.

In the SELECT statement in the following figure, **customer.lname** is a column name and **lname** is a variable name.

Figure 417. Column names and variable names in a SELECT statement.

```
CREATE PROCEDURE table_test()

  DEFINE lname CHAR(15);
  LET lname = 'Miller';

  SELECT customer.lname INTO lname FROM customer
     WHERE customer_num = 502;
  . . .
END PROCEDURE;
```

## Variables and SQL functions

If you use the same identifier for an SPL variable as for an SQL function, the database server assumes that an instance of the identifier is a variable and disallows the use of the SQL function. You cannot use the SQL function within the block of code in which the variable is defined. The example in the following figure shows a block within an SPL procedure in which the variable called **user** is defined. This definition disallows the use of the USER function in the BEGIN END block.

Figure 418. A procedure that disallows the use of the USER function in the BEGIN END block.

```

CREATE PROCEDURE user_test()
  DEFINE name CHAR(10);
  DEFINE name2 CHAR(10);
  LET name = user; -- the SQL function

BEGIN
  DEFINE user CHAR(15); -- disables user function
  LET user = 'Miller';
  LET name = user; -- assigns 'Miller' to variable name
END
. . .
LET name2 = user; -- SQL function again

```

## Declare global variables

A *global variable* has its value stored in memory and is available to other SPL routines, run by the same user session, on the same database. A global variable has the following characteristics:

- It requires a default value.
- It can be used in any SPL routine, although it must be defined in each routine in which it is used.
- It carries its value from one SPL routine to another until the session ends.

**Restriction:** You cannot define a collection variable as a global variable.

The following figure shows two SPL functions that share a global variable.

Figure 419. Two SPL functions that share a global variable.

```

CREATE FUNCTION func1() RETURNING INT;
  DEFINE GLOBAL gvar INT DEFAULT 2;
  LET gvar = gvar + 1;
  RETURN gvar;
END FUNCTION;

CREATE FUNCTION func2() RETURNING INT;
  DEFINE GLOBAL gvar INT DEFAULT 5;
  LET gvar = gvar + 1;
  RETURN gvar;
END FUNCTION;

```

Although you must define a global variable with a default value, the variable is only set to the default the first time you use it. If you execute the two functions in the following figure in the order given, the value of **gvar** would be 4.

Figure 420. Global variable default values.

```

EXECUTE FUNCTION func1();
EXECUTE FUNCTION func2();

```

But if you execute the functions in the opposite order, as the following figure shows, the value of **gvar** would be 7.

Figure 421. Global variable default values.

```
EXECUTE FUNCTION func2();
EXECUTE FUNCTION func1();
```

For more information, see [Executing routines on page 2050](#).

## Assign values to variables

Within an SPL routine, use the LET statement to assign values to the variables you have already defined.

If you do not assign a value to a variable, either by an argument passed to the routine or by a LET statement, the variable has an undefined value.

An undefined value is different from a NULL value. If you attempt to use a variable with an undefined value within the SPL routine, you receive an error.

You can assign a value to a routine variable in any of the following ways:

- Use a LET statement.
- Use a SELECT INTO statement.
- Use a CALL statement with a procedure that has a RETURNING clause.
- Use an EXECUTE PROCEDURE INTO or EXECUTE FUNCTION INTO statement.

## The LET statement

With a LET statement, you can use one or more variable names with an equal (=) sign and a valid expression or function name. Each example in the following figure is a valid LET statement.

Figure 422. Valid LET statements.

```
LET a = 5;
LET b = 6; LET c = 10;
LET a,b = 10,c+d;
LET a,b = (SELECT cola,colb
          FROM tab1 WHERE cola=10);
LET d = func1(x,y);
```

HCL Informix® allows you to assign a value to an opaque-type variable, a row-type variable, or a field of a row type. You can also return the value of an external function or another SPL function to an SPL variable.

Suppose you define the named row types **zip\_t** and **address\_t**, as [Figure 409: Named and unnamed row variables. on page 2014](#) shows. Anytime you define a row-type variable, you must initialize the variable before you can use it. The following figure shows how you might define and initialize a row-type variable. You can use any row-type value to initialize the variable.

Figure 423. Define and initialize a row-type variable.

```
DEFINE a address_t;
LET a = ROW ('A Street', 'Nowhere', 'AA',
            ROW(NULL, NULL))::address_t
```

After you define and initialize the row-type variable, you can write the LET statements that the following figure shows.

Figure 424. Write the LET statements.

```
LET a.zip.z_code = 32601;
LET a.zip.z_suffix = 4555;
-- Assign values to the fields of address_t
```

**Tip:** Use dot notation in the form **variable.field** or **variable.field.field** to access the fields of a row type, as [Handle row-type data on page 2031](#) describes.

Suppose you define an opaque-type **point** that contains two values that define a two-dimensional point, and the text representation of the values is '**(x,y)**'. You might also have a function `circum()` that calculates the circumference of a circle, given the point '**(x,y)**' and a radius **r**.

If you define an opaque-type **center** that defines a point as the center of a circle, and a function `circum()` that calculates the circumference of a circle, based on a point and the radius, you can write variable declarations for each. In the following figure, **c** is an opaque type variable and **d** holds the value that the external function `circum()` returns.

Figure 425. Writing variable declarations.

```
DEFINE c point;
DEFINE r REAL;
DEFINE d REAL;

LET c = '(29.9,1.0)' ;
-- Assign a value to an opaque type variable

LET d = circum( c, r );
-- Assign a value returned from circum()
```

The *Informix® Guide to SQL: Syntax* describes in detail the syntax of the LET statement.

## Other ways to assign values to variables

You can use the SELECT statement to fetch a value from the database and assign it directly to a variable, as the following figure shows.

Figure 426. Fetch a value from the database and assign it directly to a variable.

```
SELECT fname, lname INTO a, b FROM customer
WHERE customer_num = 101
```

Use the CALL or EXECUTE PROCEDURE statements to assign values returned by an SPL function or an external function to one or more SPL variables. You might use either of the statements in the following figure to return the full name and address from the SPL function `read_address` into the specified SPL variables.

Figure 427. Return the full name and address from the SPL function.

```
EXECUTE FUNCTION read_address('Smith')
  INTO p_fname, p_lname, p_add, p_city, p_state,
      p_zip;

CALL read_address('Smith')
  RETURNING p_fname, p_lname, p_add, p_city,
           p_state, p_zip;
```

## Expressions in SPL routines

You can use any SQL expression in an SPL routine, except for an aggregate expression. The *Informix® Guide to SQL: Syntax* provides the complete syntax and descriptions for SQL expressions.

The following examples contain SQL expressions:

```
var1
var1 + var2 + 5
read_address('Miller')
read_address(lastname = 'Miller')
get_duedate(acct_num) + 10 UNITS DAY
  fname[1,5] || ' ' || lname '(415)' || get_phonenum(cust_name)
```

## Writing the statement block

Every SPL routine has at least one statement block, which is a group of SQL and SPL statements between the CREATE statement and the END statement. You can use any SPL statement or any allowed SQL statement within a statement block. For a list of SQL statements that are not allowed within an SPL statement block, see the description of the statement block segment in the *Informix® Guide to SQL: Syntax*.

## Implicit and explicit statement blocks

In an SPL routine, the *implicit statement block* extends from the end of the CREATE statement to the beginning of the END statement. You can also define an *explicit statement block*, which starts with a BEGIN statement and ends with an END statement, as the following figure shows.

Figure 428. Explicit statement block.

```
BEGIN
  DEFINE distance INT;
  LET distance = 2;
END
```

The explicit statement block allows you to define variables or processing that are valid only within the statement block. For example, you can define or redefine variables, or handle exceptions differently, for just the scope of the explicit statement block.

The SPL function in the following figure has an explicit statement block that redefines a variable defined in the implicit block.

Figure 429. An explicit statement block that redefines a variable defined in the implicit block.

```
CREATE FUNCTION block_demo()
  RETURNING INT;
  DEFINE distance INT;
  LET distance = 37;
  BEGIN
    DEFINE distance INT;
    LET distance = 2;
  END
  RETURN distance;

END FUNCTION;
```

In this example, the implicit statement block defines the variable **distance** and gives it a value of 37. The explicit statement block defines a different variable named **distance** and gives it a value of 2. However, the RETURN statement returns the value stored in the first **distance** variable, or 37.

## The FOREACH loop

A FOREACH loop defines a *cursor*, a specific identifier that points to one item in a group, whether a group of rows or the elements in a collection.

The FOREACH loop declares and opens a cursor, fetches rows from the database, works on each item in the group, and then closes the cursor. You must declare a cursor if a SELECT, EXECUTE PROCEDURE, or EXECUTE FUNCTION statement might return more than one row. After you declare the cursor, you place the SELECT, EXECUTE PROCEDURE, or EXECUTE FUNCTION statement within it.

An SPL routine that returns a group of rows is called a *cursor routine* because you must use a cursor to access the data it returns. An SPL routine that returns no value, a single value, or any other value that does not require a cursor is called a *noncursor routine*. The FOREACH loop declares and opens a cursor, fetches rows or a collection from the database, works on each item in the group, and then closes the cursor. You must declare a cursor if a SELECT, EXECUTE PROCEDURE, or EXECUTE FUNCTION statement might return more than one row or a collection. After you declare the cursor, you place the SELECT, EXECUTE PROCEDURE, or EXECUTE FUNCTION statement within it.

In a FOREACH loop, you can use an EXECUTE FUNCTION or SELECT INTO statement to execute an external function that is an iterator function.

## The FOREACH loop to define cursors

A FOREACH loop begins with the FOREACH keyword and ends with END FOREACH. Between FOREACH and END FOREACH, you can declare a cursor or use EXECUTE PROCEDURE or EXECUTE FUNCTION. The two examples in the following figure show the structure of FOREACH loops.

Figure 430. Structure of FOREACH loops.

```

FOREACH cursor FOR
  SELECT column INTO variable FROM table
  . . .
END FOREACH;

FOREACH
  EXECUTE FUNCTION name() INTO variable;
END FOREACH;

```

The following figure creates a routine that uses a FOREACH loop to operate on the **employee** table.

Figure 431. A FOREACH loop that operates on the employee table.

```

CREATE_PROCEDURE increase_by_pct( pct INTEGER )
  DEFINE s INTEGER;

  FOREACH sal_cursor FOR
    SELECT salary INTO s FROM employee
      WHERE salary > 35000
    LET s = s + s * ( pct/100 );
    UPDATE employee SET salary = s
      WHERE CURRENT OF sal_cursor;
  END FOREACH;

END PROCEDURE;

```

The routine in preceding figure performs these tasks within the FOREACH loop:

- Declares a cursor
- Selects one **salary** value at a time from **employee**
- Increases the salary by a percentage
- Updates **employee** with the new salary
- Fetches the next salary value

The SELECT statement is placed within a cursor because it returns all the salaries in the table greater than `35000`.

The WHERE CURRENT OF clause in the UPDATE statement updates only the row on which the cursor is currently positioned, and sets an *update cursor* on the current row. An update cursor places an update lock on the row so that no other user can update the row until your update occurs.

An SPL routine will set an update cursor automatically if an UPDATE or DELETE statement within the FOREACH loop uses the WHERE CURRENT OF clause. If you use WHERE CURRENT OF, you must explicitly reference the cursor within the FOREACH statement. If you are using an update cursor, you can add a BEGIN WORK statement before the FOREACH statement and a COMMIT WORK statement after END FOREACH, as the following figure shows.

Figure 432. Set an update cursor automatically.

```

BEGIN WORK;
  FOREACH sal_cursor FOR
    SELECT salary INTO s FROM employee WHERE salary > 35000;
    LET s = s + s * ( pct/100 );
    UPDATE employee SET salary = s WHERE CURRENT OF sal_cursor
  END FOREACH;
COMMIT WORK;

```

For each iteration of the FOREACH loop in the preceding figure, a new lock is acquired (if you use row level locking). The COMMIT WORK statement releases all of the locks (and commits all of the updated rows as a single transaction) after the last iteration of the FOREACH loop.

To commit an updated row after each iteration of the loop, you must open the cursor WITH HOLD, and include the BEGIN WORK and COMMIT WORK statements *within* the FOREACH loop, as in the following SPL routine.

Figure 433. Committing an updated row after each iteration of the loop.

```

CREATE PROCEDURE serial_update();
  DEFINE p_col2 INT;
  DEFINE i INT;
  LET i = 1;
  FOREACH cur_su WITH HOLD FOR
    SELECT col2 INTO p_col2 FROM customer WHERE 1=1
    BEGIN WORK;
      UPDATE customer SET customer_num = p_col2 WHERE CURRENT OF cur_su;
    COMMIT WORK;
    LET i = i + 1;
  END FOREACH;
END PROCEDURE;

```

SPL routine serial\_update() commits each row as a separate transaction.

## Restriction for FOREACH loops

Within a FOREACH loop, the SELECT query must complete execution before any DELETE, INSERT, or UPDATE operation that changes the data set of the SELECT cursor. One way to ensure that the SELECT query completes, use an ORDER BY clause in the SELECT statement. The ORDER BY clause creates an index on the columns and prevents errors caused by UPDATE, INSERT, DELETE statements modifying the query results of the SELECT statement in the same FOREACH loop

## An IF - ELIF - ELSE structure

The following SPL routine uses an IF - ELIF - ELSE structure to compare the two arguments that the routine accepts.

Figure 434. An IF - ELIF - ELSE structure to compare two arguments.

```

CREATE FUNCTION str_compare( str1 CHAR(20), str2 CHAR(20))
  RETURNING INTEGER;

  DEFINE result INTEGER;

  IF str1 > str2 THEN
    LET result = 1;
  ELIF str2 > str1 THEN
    LET result = -1;
  ELSE
    LET result = 0;
  END IF
  RETURN result;
END FUNCTION;

```

Suppose you define a table named **manager** with the columns that the following figure shows.

Figure 435. Define the manager table.

```

CREATE TABLE manager
(
  mgr_name  VARCHAR(30),
  department VARCHAR(12),
  dept_no   SMALLINT,
  direct_reports SET( VARCHAR(30) NOT NULL ),
  projects LIST( ROW ( pro_name VARCHAR(15),
  pro_members SET( VARCHAR(20) NOT NULL ) )
              NOT NULL),
  salary    INTEGER,
);

```

The following SPL routine uses an IF - ELIF - ELSE structure to check the number of elements in the SET in the **direct\_reports** column and call various external routines based on the results.

Figure 436. An IF - ELIF - ELSE structure to check the number of elements in the SET.

```

CREATE FUNCTION checklist( d SMALLINT )
  RETURNING VARCHAR(30), VARCHAR(12), INTEGER;

  DEFINE name VARCHAR(30);
  DEFINE dept VARCHAR(12);
  DEFINE num INTEGER;

  SELECT mgr_name, department,
         CARDINALITY(direct_reports)
  FROM manager INTO name, dept, num
  WHERE dept_no = d;
  IF num > 20 THEN
    EXECUTE FUNCTION add_mgr(dept);
  ELIF num = 0 THEN
    EXECUTE FUNCTION del_mgr(dept);
  ELSE
    RETURN name, dept, num;
  END IF;

END FUNCTION;

```

The `cardinality()` function counts the number of elements that a collection contains. For more information, see [Cardinality function on page 1845](#).

An IF - ELIF - ELSE structure in an SPL routine has up to the following four parts:

- An IF THEN condition

If the condition following the IF statement is TRUE, the routine executes the statements in the IF block. If the condition is false, the routine evaluates the ELIF condition.

The expression in an IF statement can be any valid condition, as the Condition segment of the *Informix® Guide to SQL: Syntax* describes. For the complete syntax and a detailed discussion of the IF statement, see the *Informix® Guide to SQL: Syntax*.

- One or more ELIF conditions (optional)

The routine evaluates the ELIF condition only if the IF condition is false. If the ELIF condition is true, the routine executes the statements in the ELIF block. If the ELIF condition is false, the routine either evaluates the next ELIF block or executes the ELSE statement.

- An ELSE condition (optional)

The routine executes the statements in the ELSE block if the IF condition and all of the ELIF conditions are false.

- An END IF statement

The END IF statement ends the statement block.

## Add WHILE and FOR loops

Both the WHILE and FOR statements create execution loops in SPL routines. A WHILE loop starts with a WHILE *condition*, executes a block of statements as long as the condition is true, and ends with END WHILE.

The following figure shows a valid WHILE condition. The routine executes the WHILE loop as long as the condition specified in the WHILE statement is true.

Figure 437. Routine to execute the WHILE loop as long as the condition specified in the WHILE statement is true.

```
CREATE PROCEDURE test_rows( num INT )

  DEFINE i INTEGER;
  LET i = 1;

  WHILE i < num
    INSERT INTO table1 (numbers) VALUES (i);
    LET i = i + 1;
  END WHILE;

END PROCEDURE;
```

The SPL routine in the previous figure accepts an integer as an argument and then inserts an integer value into the **numbers** column of **table1** each time it executes the WHILE loop. The values inserted start at `1` and increase to `num - 1`.

Be careful that you do not create an endless loop, as the following figure shows.

Figure 438. Routine to accept an integer as an argument and then insert an integer value into the numbers column.

```

CREATE PROCEDURE endless_loop()

  DEFINE i INTEGER;
  LET i = 1;
  WHILE ( 1 = 1 )          -- don't do this!
    LET i = i + 1;
    INSERT INTO table1 VALUES (i);
  END WHILE;

END PROCEDURE;

```

A FOR loop extends from a FOR statement to an END FOR statement and executes for a specified number of iterations, which are defined in the FOR statement. The following figure shows several ways to define the iterations in the FOR loop.

For each iteration of the FOR loop, the iteration variable (declared as *i* in the examples that follow) is reset, and the statements within the loop are executed with the new value of the variable.

Figure 439. Defining iterations in the FOR loop.

```

FOR i = 1 TO 10
. . .
END FOR;

FOR i = 1 TO 10 STEP 2
. . .
END FOR;

FOR i IN (2,4,8,14,22,32)
. . .
END FOR;

FOR i IN (1 TO 20 STEP 5, 20 to 1 STEP -5, 1,2,3,4,5)
. . .
END FOR;

```

In the first example, the SPL procedure executes the FOR loop as long as *i* is between 1 and 10, inclusive. In the second example, *i* steps from 1 to 3, 5, 7, and so on, but never exceeds 10. The third example checks whether *i* is within a defined set of values. In the fourth example, the SPL procedure executes the loop when *i* is 1, 6, 11, 16, 20, 15, 10, 5, 1, 2, 3, 4, or 5—in other words, 13 times.

**i Tip:** The main difference between a WHILE loop and a FOR loop is that a FOR loop is guaranteed to finish, but a WHILE loop is not. The FOR statement specifies the exact number of times the loop executes, unless a statement causes the routine to exit the loop. With WHILE, it is possible to create an endless loop.

## Exit a loop

In a FOR, FOREACH, LOOP, or WHILE loop that has no label, you can use the CONTINUE or EXIT statement to control the execution of the loop.

- CONTINUE causes the routine to skip the statements in the rest of the loop and move to the next iteration of the FOR, LOOP, or WHILE statement.
- EXIT ends the loop and causes the routine to continue executing with the first statement following the END FOR, the END LOOP, or the END WHILE keywords.

Remember that EXIT must be followed by the FOREACH keyword when it appears within a FOREACH statement that is the innermost loop of nested loop statements. EXIT can appear with no immediately following keyword when it appears within the FOR, LOOP, or WHILE statement, but an error is issued if you specify a keyword that does not match the loop statement from which the EXIT statement was issued. An error is also issued if EXIT appears outside the context of a loop statement.

For more information about loops in SPL routines, including labelled loops, see *Informix® Guide to SQL: Syntax*.

The following figure shows examples of CONTINUE and EXIT within a FOR loop.

Figure 440. Examples of CONTINUE and EXIT within a FOR loop.

```
FOR i = 1 TO 10
  IF i = 5 THEN
    CONTINUE FOR;
  . . .
  ELIF i = 8 THEN
    EXIT FOR;
  END IF;
END FOR;
```

**Tip:** You can use CONTINUE and EXIT to improve the performance of SPL routines so that loops do not execute unnecessarily.

## Return values from an SPL function

SPL functions can return one or more values. To have your SPL function return values, you need to include the following two parts:

1. Write a RETURNING clause in the CREATE PROCEDURE or CREATE FUNCTION statement that specifies the number of values to be returned and their data types.
2. In the body of the function, enter a RETURN statement that explicitly returns the values.

**Tip:** You can define a routine with the CREATE PROCEDURE statement that returns values, but in that case, the routine is actually a function. It is recommended that you use the CREATE FUNCTION statement when the routine returns values.

After you define a return clause (with a RETURNING statement), the SPL function can return values that match those specified in number and data type, or no values at all. If you specify a return clause, and the SPL routine returns no actual

values, it is still considered a function. In that case, the routine returns a NULL value for each value defined in the return clause.

An SPL function can return variables, expressions, or the result of another function call. If the SPL function returns a variable, the function must first assign the variable a value by one of the following methods:

- A LET statement
- A default value
- A SELECT statement
- Another function that passes a value into the variable

Each value an SPL function returns can be up to 32 kilobytes long.

**Important:** The return value for an SPL function must be a specific data type. You cannot specify a generic row or generic collection data type as a return type.

## Return a single value

The following figure shows how an SPL function can return a single value.

Figure 441. SPL function that returns a single value.

```
CREATE FUNCTION increase_by_pct(amt DECIMAL, pct DECIMAL)
  RETURNING DECIMAL;

  DEFINE result DECIMAL;

  LET result = amt + amt * (pct/100);

  RETURN result;

END FUNCTION;
```

The `increase_by_pct` function receives two arguments of DECIMAL value, an amount to be increased and a percentage by which to increase it. The return clause specifies that the function will return one DECIMAL value. The RETURN statement returns the DECIMAL value stored in **result**.

## Return multiple values

An SPL function can return more than one value from a single row of a table. The following figure shows an SPL function that returns two column values from a single row of a table.

Figure 442. SPL function that returns two column values from a single row of a table.

```
CREATE FUNCTION birth_date( num INTEGER )
  RETURNING VARCHAR(30), DATE;

  DEFINE n VARCHAR(30);
  DEFINE b DATE;

  SELECT name, bdate INTO n, b FROM emp_tab
    WHERE emp_no = num;
  RETURN n, b;

END FUNCTION;
```

The function returns two values (a name and birthdate) to the calling routine from one row of the **emp\_tab** table. In this case, the calling routine must be prepared to handle the VARCHAR and DATE values returned.

The following figure shows an SPL function that returns more than one value from more than one row.

Figure 443. SPL function that returns more than one value from more than one row.

```
CREATE FUNCTION birth_date_2( num INTEGER )
  RETURNING VARCHAR(30), DATE;
  DEFINE n VARCHAR(30);
  DEFINE b DATE;
  FOREACH cursor1 FOR
    SELECT name, bdate INTO n, b FROM emp_tab
      WHERE emp_no > num
    RETURN n, b WITH RESUME;
  END FOREACH;
END FUNCTION;
```

In preceding figure, the SELECT statement fetches two values from the set of rows whose employee number is higher than the number the user enters. The set of rows that satisfy the condition could contain one row, many rows, or zero rows. Because the SELECT statement can return many rows, it is placed within a cursor.

**Tip:** When a statement within an SPL routine returns no rows, the corresponding SPL variables are assigned NULL values.

The RETURN statement uses the WITH RESUME keywords. When RETURN WITH RESUME is executed, control is returned to the calling routine. But the next time the SPL function is called (by a FETCH or the next iteration of a cursor in the calling routine), all the variables in the SPL function keep their same values, and execution continues at the statement immediately following the RETURN WITH RESUME statement.

If your SPL routine returns multiple values, the calling routine must be able to handle the multiple values through a cursor or loop, as follows:

- If the calling routine is an SPL routine, it needs a FOREACH loop.
- If the calling routine is an ESQL/C program, it needs a cursor declared with the DECLARE statement.
- If the calling routine is an external routine, it needs a cursor or loop appropriate to the language in which the routine is written.

**Important:** The values returned by a UDR from external databases of a local server must be built-in data types or UDTs explicitly cast to built-in types or DISTINCT types based on built-in types and explicitly cast to built-in types. In addition, you must define the UDR and all the casts in the participating databases.

An example of SQL operations you can perform across databases follows:

```
database db1;
create table ltab1(lcol1 integer, lcol2 boolean, lcol3 lvarchar);
insert into ltab1 values(1, 't', "test string 1");

database db2;
create table rtab1(r1col1 boolean, r1col2 blob, r1col3 integer)
put r1col2 in (sbsp);
create table rtab2(r2col1 lvarchar, r2col2 clob) put r2col2 in (sbsp);
create table rtab3(r3col1 integer, r3col2 boolean,
r3col3 lvarchar, r3col4 circle);

create view rvw1 as select * from rtab3;
```

(The example is a cross-database Insert.)

```
database db1;
create view lvw1 as select * from db2:rtab2;
insert into db2:rtab1 values('t',
filetoblob('blobfile', 'client', 'db2:rtab1', 'r1col2'), 100);
insert into db2:rtab2 values("inserted directly to rtab2",
filetoclob('clobfile', 'client', 'db2:rtab2', 'r2col2'));
insert into db2:rtab3 (r3col1, r3col2, r3col3)
select lcol1, lcol2, lcol3 from ltab1;
insert into db2:rvw1 values(200, 'f', "inserted via rvw1");
insert into lvw1 values ("inserted via lvw1", NULL);
```

## Handle row-type data

In an SPL routine, you can use named ROW types and unnamed ROW types as parameter definitions, arguments, variable definitions, and return values. For information about how to declare a ROW variable in SPL, see [Declare row-type variables on page 2013](#).

The following figure defines a row type **salary\_t** and an **emp\_info** table, which are the examples that this section uses.

Figure 444. Define a row type **salary\_t** and an **emp\_info** table

```
CREATE ROW TYPE salary_t(base MONEY(9,2), bonus MONEY(9,2))

CREATE TABLE emp_info (emp_name VARCHAR(30), salary salary_t);
```

The **emp\_info** table has columns for the employee name and salary information.

## Precedence of dot notation

With HCL Informix®, a value that uses dot notation (as in **proj.name**) in an SQL statement in an SPL routine is interpreted as having one of three meanings, in the following order of precedence:

1. *variable.field*
2. *column.field*
3. *table.column*

In other words, the expression **proj.name** is first evaluated as *variable.field*. If the routine does not find a variable **proj**, it evaluates the expression as *column.field*. If the routine does not find a column **proj**, it evaluates the expression as *table.column*. (If the names cannot be resolved as identifiers of objects in the database or of variables or fields that were declared in the SPL routine, then an error is returned.)

## Update a row-type expression

From within an SPL routine, you can use a ROW variable to update a row-type expression. The following figure shows an SPL procedure **emp\_raise** that is used to update the **emp\_info** table when an employee's base salary increases by a certain percentage.

Figure 445. SPL procedure used to update the emp\_info table.

```
CREATE PROCEDURE emp_raise( name VARCHAR(30),
                          pct DECIMAL(3,2) )

  DEFINE row_var salary_t;

  SELECT salary INTO row_var FROM emp_info
     WHERE emp_name = name;

  LET row_var.base = row_var.base * pct;

  UPDATE emp_info SET salary = row_var
     WHERE emp_name = name;

END PROCEDURE;
```

The SELECT statement selects a row from the **salary** column of **emp\_info table** into the ROW variable **row\_var**.

The **emp\_raise** procedure uses SPL dot notation to directly access the **base** field of the variable **row\_var**. In this case, the dot notation means *variable.field*. The **emp\_raise** procedure recalculates the value of **row\_var.base** as `(row_var.base * pct)`. The procedure then updates the **salary** column of the **emp\_info** table with the new **row\_var** value.

**Important:** A row-type variable must be initialized as a row before its fields can be set or referenced. You can initialize a row-type variable with a SELECT INTO statement or LET statement.

## Handle collections

A *collection* is a group of elements of the same data type, such as a SET, MULTISET, or LIST.

A table might contain a collection stored as the contents of a column or as a field of a ROW type within a column. A collection can be either simple or nested. A *simple collection* is a SET, MULTISET, or LIST of built-in, opaque, or distinct data types. A *nested collection* is a collection that contains other collections.

## Collection data types

The following sections of the chapter rely on several different examples to show how you can manipulate collections in SPL programs.

The basics of handling collections in SPL programs are illustrated with the **numbers** table, as the following figure shows.

Figure 446. Handle collections in SPL programs.

```
CREATE TABLE numbers
(
  id INTEGER PRIMARY KEY,
  primes      SET( INTEGER NOT NULL ),
  evens       LIST( INTEGER NOT NULL ),
  twin_primes LIST( SET( INTEGER NOT NULL )
                  NOT NULL )
)
```

The **primes** and **evens** columns hold simple collections. The **twin\_primes** column holds a nested collection, a LIST of SETs. (Twin prime numbers are pairs of consecutive prime numbers whose difference is 2, such as 5 and 7, or 11 and 13. The **twin\_primes** column is designed to allow you to enter such pairs.

Some examples in this chapter use the **polygons** table in the following figure to illustrate how to manipulate collections. The **polygons** table contains a collection to represent two-dimensional graphical data. For example, suppose that you define an opaque data type named **point** that has two double-precision values that represent the **x** and **y** coordinates of a two-dimensional point whose coordinates might be represented as '1.0, 3.0'. Using the **point** data type, you can create a table that contains a set of points that define a polygon.

Figure 447. Manipulate collections.

```
CREATE OPAQUE TYPE point ( INTERNALLENGTH = 8 );

CREATE TABLE polygons
(
  id          INTEGER PRIMARY KEY,
  definition  SET( point NOT NULL )
);
```

The **definition** column in the **polygons** table contains a simple collection, a SET of **point** values.

## Prepare for collection data types

Before you can access and handle an individual element of a simple or nested collection, you must perform the following tasks:

- Declare a collection variable to hold the collection.
- Declare an element variable to hold an individual element of the collection.
- Select the collection from the database into the collection variable.

After you take these initial steps, you can insert elements into the collection or select and handle elements that are already in the collection.

Each of these steps is explained in the following sections, using the **numbers** table as an example.

 **Tip:** You can handle collections in any SPL routine.

## Declare a collection variable

Before you can retrieve a collection from the database into an SPL routine, you must declare a collection variable. The following figure shows how to declare a collection variable to retrieve the **primes** column from the **numbers** table.

Figure 448. Declare a collection variable.

```
DEFINE p_coll SET( INTEGER NOT NULL );
```

The DEFINE statement declares a collection variable **p\_coll**, whose type matches the data type of the collection stored in the **primes** column.

## Declare an element variable

After you declare a collection variable, you declare an element variable to hold individual elements of the collection. The data type of the element variable must match the data type of the collection elements.

For example, to hold an element of the SET in the **primes** column, use an element variable declaration such as the one that the following figure shows.

Figure 449. An element variable declaration.

```
DEFINE p INTEGER;
```

To declare a variable that holds an element of the **twin\_primes** column, which holds a nested collection, use a variable declaration such as the one that the following figure shows.

Figure 450. A variable declaration.

```
DEFINE s SET( INTEGER NOT NULL );
```

The variable **s** holds a SET of integers. Each SET is an element of the LIST stored in **twin\_primes**.

## Select a collection into a collection variable

After you declare a collection variable, you can fetch a collection into it. To fetch a collection into a collection variable, enter a SELECT INTO statement that selects the collection column from the database into the collection variable you have named.

For example, to select the collection stored in one row of the **primes** column of **numbers**, add a SELECT statement, such as the one that the following figure shows, to your SPL routine.

Figure 451. Add a SELECT statement to select the collection stored in one row.

```
SELECT primes INTO p_coll FROM numbers
WHERE id = 220;
```

The WHERE clause in the SELECT statement specifies that you want to select the collection stored in just one row of **numbers**. The statement places the collection into the collection variable **p\_coll**, which [Figure 448: Declare a collection variable. on page 2034](#) declares.

The variable **p\_coll** now holds a collection from the **primes** column, which could contain the value `SET {5,7,31,19,13}`.

## Insert elements into a collection variable

After you retrieve a collection into a collection variable, you can insert a value into the collection variable. The syntax of the INSERT statement varies slightly, depending on the type of the collection to which you want to add values.

### Insert into a SET or MULTISET

To insert into a SET or MULTISET stored in a collection variable, use an INSERT statement and follow the TABLE keyword with the collection variable, as the following figure shows.

Figure 452. Insert into a SET or MULTISET stored in a collection variable.

```
INSERT INTO TABLE(p_coll) VALUES(3);
```

The TABLE keyword makes the collection variable a collection-derived table. Collection-derived tables are described in the section [Handle collections in SELECT statements on page 1888](#). The collection that the previous figure derives is a virtual table of one column, with each element of the collection representing a row of the table. Before the insert, consider **p\_coll** as a virtual table that contains the rows (elements) that the following figure shows.

Figure 453. Virtual table elements.

```
5
7
31
19
13
```

After the insert, **p\_coll** might look like the virtual table that the following figure shows.

Figure 454. Virtual table elements.

```
5
7
31
19
13
3
```

Because the collection is a SET, the new value is added to the collection, but the position of the new element is undefined. The same principle is true for a MULTISET.

 **Tip:** You can only insert one value at a time into a simple collection.

## Insert into a LIST

If the collection is a LIST, you can add the new element at a specific point in the LIST or at the end of the LIST. As with a SET or MULTISSET, you must first define a collection variable and select a collection from the database into the collection variable.

The following figure shows the statements you need to define a collection variable and select a LIST from the **numbers** table into the collection variable.

Figure 455. Defining a collection variable and selecting a LIST.

```
DEFINE e_coll LIST(INTEGER NOT NULL);

SELECT evens INTO e_coll FROM numbers
WHERE id = 99;
```

At this point, the value of **e\_coll** might be `LIST {2,4,6,8,10}`. Because **e\_coll** holds a LIST, each element has a numbered position in the list. To add an element at a specific point in a LIST, add an *AT position* clause to the INSERT statement, as the following figure shows.

Figure 456. Add an element at a specific point in a LIST.

```
INSERT AT 3 INTO TABLE(e_coll) VALUES(12);
```

Now the LIST in **e\_coll** has the elements `{2,4,12,6,8,10}`, in that order.

The value you enter for the *position* in the AT clause can be a number or a variable, but it must have an INTEGER or SMALLINT data type. You cannot use a letter, floating-point number, decimal value, or expression.

## Check the cardinality of a LIST collection

At times you might want to add an element at the end of a LIST. In this case, you can use the `cardinality()` function to find the number of elements in a LIST and then enter a position that is greater than the value `cardinality()` returns.

HCL Informix® allows you to use the `cardinality()` function with a collection that is stored in a column but not with a collection that is stored in a collection variable. In an SPL routine, you can check the cardinality of a collection in a column with a SELECT statement and return the value to a variable.

Suppose that in the **numbers** table, the **evens** column of the row whose **id** column is 99 still contains the collection `LIST {2,4,6,8,10}`. This time, you want to add the element `12` at the end of the LIST. You can do so with the SPL procedure **end\_of\_list**, as the following figure shows.

Figure 457. The end\_of\_list SPL procedure.

```

CREATE PROCEDURE end_of_list()

  DEFINE n SMALLINT;
  DEFINE list_var LIST(INTEGER NOT NULL);

  SELECT CARDINALITY(evens) FROM numbers INTO n
    WHERE id = 100;

  LET n = n + 1;

  SELECT evens INTO list_var FROM numbers
    WHERE id = 100;

  INSERT AT n INTO TABLE(list_var) VALUES(12);

END PROCEDURE;

```

In **end\_of\_list**, the variable **n** holds the value that `cardinality()` returns, that is, the count of the items in the LIST. The LET statement increments **n**, so that the INSERT statement can insert a value at the last position of the LIST. The SELECT statement selects the collection from one row of the table into the collection variable **list\_var**. The INSERT statement inserts the element `12` at the end of the list.

## Syntax of the VALUES clause

The syntax of the VALUES clause is different when you insert into an SPL collection variable from when you insert into a collection column. The syntax rules for inserting literals into collection variables are as follows:

- Use parentheses after the VALUES keyword to enclose the complete list of values.
- If you are inserting into a simple collection, you do not need to use a type constructor or brackets.
- If you are inserting into a nested collection, you need to specify a literal collection.

## Select elements from a collection

Suppose you want your SPL routine to select elements from the collection stored in the collection variable, one at a time, so that you can handle the elements.

To move through the elements of a collection, you first need to declare a cursor using a FOREACH statement, just as you would declare a cursor to move through a set of rows. The following figure shows the FOREACH and END FOREACH statements, with no statements between them yet.

Figure 458. FOREACH and END FOREACH statements.

```

FOREACH cursor1 FOR
. . .
END FOREACH

```

The FOREACH statement is described in [The FOREACH loop on page 2022](#) and the *Informix® Guide to SQL: Syntax*.

The next topic, [The collection query on page 2038](#), describes the statements that are omitted between the FOREACH and END FOREACH statements.

The examples in the following sections are based on the **polygons** table of [Figure 447: Manipulate collections. on page 2033](#).

## The collection query

After you declare the cursor between the FOREACH and END FOREACH statements, you enter a special, restricted form of the SELECT statement known as a *collection query*.

A collection query is a SELECT statement that uses the FROM TABLE keywords followed by the name of a collection variable. The following figure shows this structure, which is known as a *collection-derived table*.

Figure 459. Collection-derived table.

```
FOREACH cursor1 FOR
    SELECT * INTO pnt FROM TABLE(vertexes)
    . . .
END FOREACH
```

The SELECT statement uses the collection variable **vertexes** as a collection-derived table. You can think of a collection-derived table as a table of one column, with each element of the collection being a row of the table. For example, you can visualize the SET of four points stored in **vertexes** as a table with four rows, such as the one that the following figure shows.

Figure 460. Table with four rows.

```
'(3.0,1.0)'  
'(8.0,1.0)'  
'(3.0,4.0)'  
'(8.0,4.0)'
```

After the first iteration of the FOREACH statement in the previous figure, the collection query selects the first element in **vertexes** and stores it in **pnt**, so that **pnt** contains the value `'(3.0,1.0)'`.

**Tip:** Because the collection variable **vertexes** contains a SET, not a LIST, the elements in **vertexes** have no defined order. In a real database, the value `'(3.0,1.0)'` might not be the first element in the SET.

## Add the collection query to the SPL routine

Now you can add the cursor defined with FOREACH and the collection query to the SPL routine, as the following example shows.

Figure 461. Cursor defined with FOREACH and the collection query.

```

CREATE PROCEDURE shapes()

  DEFINE vertexes SET( point NOT NULL );
  DEFINE pnt point;

  SELECT definition INTO vertexes FROM polygons
    WHERE id = 207;

  FOREACH cursor1 FOR
    SELECT * INTO pnt FROM TABLE(vertexes)
    . . .
  END FOREACH
  . . .
END PROCEDURE;

```

The statements shown above form the framework of an SPL routine that handles the elements of a collection variable. To decompose a collection into its elements, use a collection-derived table. After the collection is decomposed into its elements, the routine can access elements individually as rows of the collection-derived table. Now that you have selected one element in **pnt**, you can update or delete that element, as [Update a collection element on page 2042](#) and [Delete a collection element on page 2039](#) describe.

For the complete syntax of the collection query, see the SELECT statement in the *Informix® Guide to SQL: Syntax*. For the syntax of a collection-derived table, see the Collection-Derived Table segment in the *Informix® Guide to SQL: Syntax*.

 **Tip:** If you are selecting from a collection that contains no elements or zero elements, you can use a collection query without declaring a cursor. However, if the collection contains more than one element and you do not use a cursor, you will receive an error message.

 **Attention:** In the program fragment above, the database server would have issued a syntax error if the query (

```
SELECT * INTO pnt FROM TABLE(vertexes)
```

) within the FOREACH cursor definition had ended with a semicolon ( ; ) character as a statement terminator. Here the END FOREACH keywords are the logical statement terminator.

## Delete a collection element

After you select an individual element from a collection variable into an element variable, you can delete the element from the collection. For example, after you select a point from the collection variable **vertexes** with a collection query, you can remove the point from the collection.

The steps involved in deleting a collection element include:

1. Declare a collection variable and an element variable.
2. Select the collection from the database into the collection variable.
3. Declare a cursor so that you can select elements one at a time from the collection variable.

4. Write a loop or branch that locates the element that you want to delete.
5. Delete the element from the collection using a DELETE WHERE CURRENT OF statement that uses the collection variable as a collection-derived table.

The following figure shows a routine that deletes one of the four points in **vertexes**, so that the polygon becomes a triangle instead of a rectangle.

Figure 462. Routine that deletes one of the four points.

```
CREATE PROCEDURE shapes()

  DEFINE vertexes SET( point NOT NULL );
  DEFINE pnt point;

  SELECT definition INTO vertexes FROM polygons
     WHERE id = 207;

  FOREACH cursor1 FOR
    SELECT * INTO pnt FROM TABLE(vertexes)
    IF pnt = '(3,4)' THEN
      -- calls the equals function that
      -- compares two values of point type
      DELETE FROM TABLE(vertexes)
         WHERE CURRENT OF cursor1;
      EXIT FOREACH;
    ELSE
      CONTINUE FOREACH;
    END IF;
  END FOREACH
  . . .
END PROCEDURE;
```

In previous figure, the FOREACH statement declares a cursor. The SELECT statement is a collection-derived query that selects one element at a time from the collection variable **vertexes** into the element variable **pnt**.

The IF THEN ELSE structure tests the value currently in **pnt** to see if it is the point '(3,4)'. Note that the expression `pnt = '(3,4)'` calls the instance of the equal() function defined on the point data type. If the current value in **pnt** is '(3,4)', the DELETE statement deletes it, and the EXIT FOREACH statement exits the cursor.

**Tip:** Deleting an element from a collection stored in a collection variable does not delete it from the collection stored in the database. After you delete the element from a collection variable, you must update the collection stored in the database with the new collection. For an example that shows how to update a collection column, see [Update the collection in the database on page 2040](#).

The syntax for the DELETE statement is described in the *Informix® Guide to SQL: Syntax*.

## Update the collection in the database

After you change the contents of a collection variable in an SPL routine (by deleting, updating, or inserting an element), you must update the database with the new collection.

To update a collection in the database, add an UPDATE statement that sets the collection column in the table to the contents of the updated collection variable. For example, the UPDATE statement in the following figure shows how to update the **polygons** table to set the **definition** column to the new collection stored in the collection variable **vertexes**.

Figure 463. Update a collection in the database.

```
CREATE PROCEDURE shapes()

  DEFINE vertexes SET(point NOT NULL);
  DEFINE pnt point;

  SELECT definition INTO vertexes FROM polygons
    WHERE id = 207;

  FOREACH cursor1 FOR
    SELECT * INTO pnt FROM TABLE(vertexes)
  IF pnt = '(3,4)' THEN
    -- calls the equals function that
    -- compares two values of point type
    DELETE FROM TABLE(vertexes)
      WHERE CURRENT OF cursor1;
    EXIT FOREACH;
  ELSE
    CONTINUE FOREACH;
  END IF;
END FOREACH

  UPDATE polygons SET definition = vertexes
    WHERE id = 207;

END PROCEDURE;
```

Now the **shapes()** routine is complete. After you run **shapes()**, the collection stored in the row whose ID column is **207** is updated so that it contains three values instead of four.

You can use the **shapes()** routine as a framework for writing other SPL routines that manipulate collections.

The elements of the collection now stored in the **definition** column of row **207** of the **polygons** table are listed as follows:

```
'(3,1)'
'(8,1)'
'(8,4)'
```

## Delete the entire collection

If you want to delete all the elements of a collection, you can use a single SQL statement. You do not need to declare a cursor. To delete an entire collection, you must perform the following tasks:

- Define a collection variable.
- Select the collection from the database into a collection variable.
- Enter a DELETE statement that uses the collection variable as a collection-derived table.
- Update the collection from the database.

The following figure shows the statements that you might use in an SPL routine to delete an entire collection.

Figure 464. SPL routine to delete an entire collection.

```

DEFINE vertexes SET( INTEGER NOT NULL );

SELECT definition INTO vertexes FROM polygons
  WHERE id = 207;

DELETE FROM TABLE(vertexes);

UPDATE polygons SET definition = vertexes
  WHERE id = 207;

```

This form of the DELETE statement deletes the entire collection in the collection variable **vertexes**. You cannot use a WHERE clause in a DELETE statement that uses a collection-derived table.

After the UPDATE statement, the **polygons** table contains an empty collection where the **id** column is equal to 207.

The syntax for the DELETE statement is described in the *Informix® Guide to SQL: Syntax*.

## Update a collection element

You can update a collection element by accessing the collection within a cursor just as you select or delete an individual element.

If you want to update the collection `SET{100, 200, 300, 500}` to change the value 500 to 400, retrieve the SET from the database into a collection variable and then declare a cursor to move through the elements in the SET, as the following figure shows.

Figure 465. Update the collection element.

```

DEFINE s SET(INTEGER NOT NULL);
DEFINE n INTEGER;

SELECT numbers INTO s FROM orders
  WHERE order_num = 10;

FOREACH cursor1 FOR
  SELECT * INTO n FROM TABLE(s)
  IF ( n == 500 ) THEN
    UPDATE TABLE(s)(x)
      SET x = 400 WHERE CURRENT OF cursor1;
    EXIT FOREACH;
  ELSE
    CONTINUE FOREACH;
  END IF;
END FOREACH

```

The UPDATE statement uses the collection variable **s** as a collection-derived table. To specify a collection-derived table, use the TABLE keyword. The value `(x)` that follows `(s)` in the UPDATE statement is a *derived column*, a column name you supply because the SET clause requires it, even though the collection-derived table does not have columns.

Think of the collection-derived table as having one row and looking something like the following example:

|     |     |     |     |
|-----|-----|-----|-----|
| 100 | 200 | 300 | 500 |
|-----|-----|-----|-----|

In this example, `x` is a fictitious column name for the column that contains the value `500`. You only specify a derived column if you are updating a collection of built-in, opaque, distinct, or collection type elements. If you are updating a collection of row types, use a field name instead of a derived column, as [Update a collection of row types on page 2044](#) describes.

## Update a collection with a variable

You can also update a collection with the value stored in a variable instead of a literal value.

The SPL procedure in the following figure uses statements that are similar to the ones that [Figure 465: Update the collection element. on page 2042](#) shows, except that this procedure updates the SET in the `direct_reports` column of the `manager` table with a variable, rather than with a literal value. [Figure 435: Define the manager table. on page 2025](#) defines the `manager` table.

Figure 466. Update a collection with a variable.

```
CREATE PROCEDURE new_report(mgr VARCHAR(30),
  old VARCHAR(30), new VARCHAR(30) )

  DEFINE s SET (VARCHAR(30) NOT NULL);
  DEFINE n VARCHAR(30);

  SELECT direct_reports INTO s FROM manager
    WHERE mgr_name = mgr;

  FOREACH cursor1 FOR
    SELECT * INTO n FROM TABLE(s)
    IF ( n == old ) THEN
      UPDATE TABLE(s)(x)
        SET x = new WHERE CURRENT OF cursor1;
      EXIT FOREACH;
    ELSE
      CONTINUE FOREACH;
    END IF;
  END FOREACH

  UPDATE manager SET mgr_name = s
    WHERE mgr_name = mgr;

END PROCEDURE;
```

The UPDATE statement nested in the FOREACH loop uses the collection- derived table `s` and the derived column `x`. If the current value of `n` is the same as `old`, the UPDATE statement changes it to the value of `new`. The second UPDATE statement stores the new collection in the `manager` table.

## Update the entire collection

If you want to update all the elements of a collection to the same value, or if the collection contains only one element, you do not need to use a cursor. The statements in the following figure show how you can retrieve the collection into a collection variable and then update it with one statement.

Figure 467. Retrieve and update the collection.

```
DEFINE s SET (INTEGER NOT NULL);

SELECT numbers INTO s FROM orders
  WHERE order_num = 10;

UPDATE TABLE(s)(x) SET x = 0;

UPDATE orders SET numbers = s
  WHERE order_num = 10;
```

The first UPDATE statement in this example uses a derived column named **x** with the collection-derived table **s** and gives all the elements in the collection the value 0. The second UPDATE statement stores the new collection in the database.

## Update a collection of row types

To update a collection of ROW types, you can take these steps:

1. Declare a collection variable whose field data types match those of the ROW types in the collection.
2. Set the individual fields of the collection variable to the correct data values for the ROW type.
3. For each ROW type, update the entire row of the collection derived table using the collection variable.

The **manager** table in [Figure 435: Define the manager table. on page 2025](#) has a column named **projects** that contains a LIST of ROW types with the definition that the following figure shows.

Figure 468. LIST of ROW types definition.

```
projects LIST( ROW( pro_name VARCHAR(15),
  pro_members SET(VARCHAR(20) NOT NULL) ) NOT NULL)
```

To access the ROW types in the LIST, declare a cursor and select the LIST into a collection variable. After you retrieve each ROW type value in the **projects** column, however, you cannot update the **pro\_name** or **pro\_members** fields individually. Instead, for each ROW value that needs to be updated in the collection, you must replace the entire ROW with values from a collection variable that include the new field values, as the following figure shows.

Figure 469. Access the ROW types in the LIST.

```

CREATE PROCEDURE update_pro( mgr VARCHAR(30),
  pro VARCHAR(15) )

  DEFINE p LIST(ROW(a VARCHAR(15), b SET(VARCHAR(20)
    NOT NULL) ) NOT NULL);
  DEFINE r ROW(p_name VARCHAR(15), p_member SET(VARCHAR(20) NOT NULL) );
  LET r = ROW("project", "SET{'member'}");

SELECT projects INTO p FROM manager
  WHERE mgr_name = mgr;

FOREACH cursor1 FOR
  SELECT * INTO r FROM TABLE(p)
  IF (r.p_name == 'Zephyr') THEN
    LET r.p_name = pro;
    UPDATE TABLE(p)(x) SET x = r
      WHERE CURRENT OF cursor1;
    EXIT FOREACH;
  END IF;
END FOREACH

UPDATE manager SET projects = p
  WHERE mgr_name = mgr;

END PROCEDURE;

```

Before you can use a row-type variable in an SPL program, you must initialize the row variable with a LET statement or a SELECT INTO statement. The UPDATE statement nested in the FOREACH loop of the previous figure sets the **pro\_name** field of the row type to the value supplied in the variable **pro**.

 **Tip:** To update a value in a SET in the **pro\_members** field of the ROW type, declare a cursor and use an UPDATE statement with a derived column, as [Update a collection element on page 2042](#) explains.

## Update a nested collection

If you want to update a collection of collections, you must declare a cursor to access the outer collection and then declare a nested cursor to access the inner collection.

For example, suppose that the **manager** table has an additional column, **scores**, which contains a LIST whose element type is a MULTISET of integers, as the following figure shows.

Figure 470. Update a collection of collections.

```

scores      LIST(MULTISET(INT NOT NULL) NOT NULL);

```

To update a value in the MULTISET, declare a cursor that moves through each value in the LIST and a nested cursor that moves through each value in the MULTISET, as the following figure shows.

Figure 471. Update a value in the MULTISSET.

```

CREATE FUNCTION check_scores ( mgr VARCHAR(30) )
  SPECIFIC NAME nested;
  RETURNING INT;

  DEFINE l LIST( MULTISSET( INT NOT NULL ) NOT NULL );
  DEFINE m MULTISSET( INT NOT NULL );
  DEFINE n INT;
  DEFINE c INT;

  SELECT scores INTO l FROM manager
    WHERE mgr_name = mgr;

  FOREACH list_cursor FOR
    SELECT * FROM TABLE(l) INTO m;

    FOREACH set_cursor FOR
      SELECT * FROM TABLE(m) INTO n;
      IF (n == 0) THEN
        DELETE FROM TABLE(m)
          WHERE CURRENT OF set_cursor;
      ENDIF;
    END FOREACH;
    LET c = CARDINALITY(m);
    RETURN c WITH RESUME;
  END FOREACH

END FUNCTION
  WITH LISTING IN '/tmp/nested.out';

```

The SPL function selects each MULTISSET in the **scores** column into **l**, and then each value in the MULTISSET into **m**. If a value in **m** is 0, the function deletes it from the MULTISSET. After the values of 0 are deleted, the function counts the remaining elements in each MULTISSET and returns an integer.

**Tip:** Because this function returns a value for each MULTISSET in the LIST, you must use a cursor to enclose the EXECUTE FUNCTION statement when you execute the function.

## Insert into a collection

You can insert a value into a collection without declaring a cursor. If the collection is a SET or MULTISSET, the value is added to the collection but the position of the new element is undefined because the collection has no particular order. If the value is a LIST, you can add the new element at a specific point in the LIST or at the end of the LIST.

In the **manager** table, the **direct\_reports** column contains collections of SET type, and the **projects** column contains a LIST. To add a name to the SET in the **direct\_reports** column, use an INSERT statement with a collection-derived table, as the following figure shows.

Figure 472. Insert a value into a collection.

```

CREATE PROCEDURE new_emp( emp VARCHAR(30), mgr VARCHAR(30) )

  DEFINE r SET(VARCHAR(30) NOT NULL);

  SELECT direct_reports INTO r FROM manager
     WHERE mgr_name = mgr;

  INSERT INTO TABLE (r) VALUES(emp);

  UPDATE manager SET direct_reports = r
     WHERE mgr_name = mgr;

END PROCEDURE;

```

This SPL procedure takes an employee name and a manager name as arguments. The procedure then selects the collection in the **direct\_reports** column for the manager the user has entered, adds the employee name the user has entered, and updates the **manager** table with the new collection.

The INSERT statement in the previous figure inserts the new employee name that the user supplies into the SET contained in the collection variable **r**. The UPDATE statement then stores the new collection in the **manager** table.

Notice the syntax of the VALUES clause. The syntax rules for inserting literal data and variables into collection variables are as follows:

- Use parentheses after the VALUES keyword to enclose the complete list of values.
- If the collection is SET, MULTISET, or LIST, use the type constructor followed by brackets to enclose the list of values to be inserted. In addition, the collection value must be enclosed in quotes.

```
VALUES( "SET{ 1,4,8,9 }" )
```

- If the collection contains a row type, use ROW followed by parentheses to enclose the list of values to be inserted:

```
VALUES( ROW( 'Waters', 'voyager_project' ) )
```

- If the collection is a nested collection, nest keywords, parentheses, and brackets according to how the data type is defined:

```
VALUES( "SET{ ROW('Waters', 'voyager_project'),
           ROW('Adams', 'horizon_project') }")
```

For more information on inserting values into collections, see [Modify data on page 1901](#).

## Insert into a nested collection

If you want to insert into a nested collection, the syntax of the VALUES clause changes. Suppose, for example, that you want to insert a value into the **twin\_primes** column of the **numbers** table that [Figure 446: Handle collections in SPL programs. on page 2033](#) shows.

With the **twin\_primes** column, you might want to insert a SET into the LIST or an element into the inner SET. The following sections describe each of these tasks.

## Insert a collection into the outer collection

Inserting a SET into the LIST is similar to inserting a single value into a simple collection.

To insert a SET into the LIST, declare a collection variable to hold the LIST and select the entire collection into it. When you use the collection variable as a collection-derived table, each SET in the LIST becomes a row in the table. You can then insert another SET at the end of the LIST or at a specified point.

For example, the **twin\_primes** column of one row of numbers might contain the following LIST, as the following figure shows.

Figure 473. Sample LIST.

```
LIST( SET{3,5}, SET{5,7}, SET{11,13} )
```

If you think of the LIST as a collection-derived table, it might look similar to the following.

Figure 474. Thinking of the LIST as a collection-derived table.

```
{3,5}
{5,7}
{11,13}
```

You might want to insert the value "SET{17,19}" as a second item in the LIST. The statements in the following figure show how to do this.

Figure 475. Insert a value in the LIST.

```
CREATE PROCEDURE add_set()

  DEFINE l_var LIST( SET( INTEGER NOT NULL ) NOT NULL );

  SELECT twin_primes INTO l_var FROM numbers
     WHERE id = 100;

  INSERT AT 2 INTO TABLE (l_var) VALUES( "SET{17,19}" );

  UPDATE numbers SET twin_primes = l
     WHERE id = 100;

END PROCEDURE;
```

In the INSERT statement, the VALUES clause inserts the value SET {17,19} at the second position of the LIST. Now the LIST looks like the following figure.

Figure 476. LIST items.

```
{3,5}
{17,19}
{5,7}
{11,13}
```

You can perform the same insert by passing a SET to an SPL routine as an argument, as the following figure shows.

Figure 477. Passing a SET to an SPL routine as an argument.

```

CREATE PROCEDURE add_set( set_var SET(INTEGER NOT NULL),
  row_id INTEGER );

  DEFINE list_var LIST( SET(INTEGER NOT NULL) NOT NULL );
  DEFINE n SMALLINT;

  SELECT CARDINALITY(twin_primes) INTO n FROM numbers
    WHERE id = row_id;

  LET n = n + 1;

  SELECT twin_primes INTO list_var FROM numbers
    WHERE id = row_id;

  INSERT AT n INTO TABLE( list_var ) VALUES( set_var );

  UPDATE numbers SET twin_primes = list_var
    WHERE id = row_id;

END PROCEDURE;

```

In `add_set()`, the user supplies a SET to add to the LIST and an INTEGER value that is the **id** of the row in which the SET will be inserted.

## Insert a value into the inner collection

In an SPL routine, you can also insert a value into the inner collection of a nested collection. In general, to access the inner collection of a nested collection and add a value to it, perform the following steps:

1. Declare a collection variable to hold the entire collection stored in one row of a table.
2. Declare an element variable to hold one element of the outer collection. The element variable is itself a collection variable.
3. Select the entire collection from one row of a table into the collection variable.
4. Declare a cursor so that you can move through the elements of the outer collection.
5. Select one element at a time into the element variable.
6. Use a branch or loop to locate the inner collection you want to update.
7. Insert the new value into the inner collection.
8. Close the cursor.
9. Update the database table with the new collection.

As an example, you can use this process on the **twin\_primes** column of **numbers**. For example, suppose that **twin\_primes** contains the values that the following figure shows, and you want to insert the value **18** into the last SET in the LIST.

Figure 478. The twin\_primes list.

```
LIST( SET( {3,5}, {5,7}, {11,13}, {17,19} ) )
```

The following figure shows the beginning of a procedure that inserts the value.

Figure 479. Procedure that inserts the value.

```
CREATE PROCEDURE add_int()

  DEFINE list_var LIST( SET( INTEGER NOT NULL ) NOT NULL );
  DEFINE set_var SET( INTEGER NOT NULL );

  SELECT twin_primes INTO list_var FROM numbers
     WHERE id = 100;
```

So far, the **attaint** procedure has performed steps [1 on page 2049](#), [2 on page 2049](#), and [3 on page 2049](#). The first DEFINE statement declares a collection variable that holds the entire collection stored in one row of numbers.

The second DEFINE statement declares an element variable that holds an element of the collection. In this case, the element variable is itself a collection variable because it holds a SET. The SELECT statement selects the entire collection from one row into the collection variable, **list\_var**.

The following figure shows how to declare a cursor so that you can move through the elements of the outer collection.

Figure 480. Declare a cursor to move through the elements of the outer collection.

```
FOREACH list_cursor FOR
  SELECT * INTO set_var FROM TABLE( list_var);

FOREACH element_cursor FOR
```

## Executing routines

You can execute an SPL routine or external routine in any of these ways:

- Using a stand-alone EXECUTE PROCEDURE or EXECUTE FUNCTION statement that you execute from DB-Access
- Calling the routine explicitly from another SPL routine or an external routine
- Using the routine name with an expression in an SQL statement

An additional mechanism for executing routines supports only the **sysdbopen** and **sysdbclose** procedures, which the DBA can define. If a **sysdbopen** procedure whose owner matches the login identifier of a user exists in the database when the user connects to the database by the CONNECT or DATABASE statement, that routine is executed automatically. If no **sysdbopen** routine has an owner that matches the login identifier of the user, but a PUBLIC.**sysdbopen** routine exists, that routine is executed. This automatic invocation enables the DBA to customize the session environment for users at connection time. The **sysdbclose** routine is similarly invoked when the user disconnects from the database. (For more information about these session configuration routines, see the *Informix® Guide to SQL: Syntax* and the *Informix® Administrator's Guide*.)

An *external routine* is a routine written in C or some other external language.

## The EXECUTE statements

You can use EXECUTE PROCEDURE or EXECUTE FUNCTION to execute an SPL routine or external routine. In general, it is best to use EXECUTE PROCEDURE with procedures and EXECUTE FUNCTION with functions.

**i Tip:** For backward compatibility, the EXECUTE PROCEDURE statement allows you to use an SPL function name and an INTO clause to return values. However, *it is* recommended that you use EXECUTE PROCEDURE only with procedures and EXECUTE FUNCTION only with functions.

You can issue EXECUTE PROCEDURE and EXECUTE FUNCTION statements as stand-alone statements from DB-Access or from within an SPL routine or external routine. If the routine name is unique within the database, and if it does not require arguments, you can execute it by entering just its name and parentheses after EXECUTE PROCEDURE, as the following figure shows.

Figure 481. Execute a procedure.

```
EXECUTE PROCEDURE update_orders();
```

The INTO clause is never present when you invoke a procedure with the EXECUTE statement because a procedure does not return a value.

If the routine expects arguments, you must enter the argument values within parentheses, as the following figure shows.

Figure 482. Execute a procedure with arguments.

```
EXECUTE FUNCTION scale_rectangles(107, 1.9)
  INTO new;
```

The statement executes a function. Because a function returns a value, EXECUTE FUNCTION uses an INTO clause that specifies a variable where the return value is stored. The INTO clause must always be present when you use an EXECUTE statement to execute a function.

If the database has more than one procedure or function of the same name, HCL Informix® locates the right function based on the data types of the arguments. For example, the statement in the previous figure supplies INTEGER and REAL values as arguments, so if your database contains multiple routines named scale\_rectangles(), the database server executes only the scale\_rectangles() function that accepts INTEGER and REAL data types.

The parameter list of an SPL routine always has parameter names as well as data types. When you execute the routine, the parameter names are optional. However, if you pass arguments by name (instead of just by value) to EXECUTE PROCEDURE or EXECUTE FUNCTION, as in the following figure, Informix® resolves the routine-by-routine name and arguments only, a process known as *partial routine resolution*.

Figure 483. Execute a routine passing arguments by name.

```
EXECUTE FUNCTION scale_rectangles( rectid = 107,
  scale = 1.9 ) INTO new_rectangle;
```

You can also execute an SPL routine stored on another database server by adding a *qualified routine name* to the statement; that is, a name in the form `database@dbserver:owner_name.routine_name`, as in the following figure.

Figure 484. Execute an SPL routine stored on another database server.

```
EXECUTE PROCEDURE informix@davinci:bsmith.update_orders();
```

When you execute a routine remotely, the `owner_name` in the qualified routine name is optional.

## The CALL statement

You can call an SPL routine or an external routine from an SPL routine using the CALL statement. CALL can execute both procedures and functions. If you use CALL to execute a function, add a RETURNING clause and the name of an SPL variable (or variables) that will receive the value (or values) the function returns.

Suppose, for example, that you want the `scale_rectangles` function to call an external function that calculates the area of the rectangle and then returns the area with the rectangle description, as in the following figure.

Figure 485. Call an external function.

```
CREATE FUNCTION scale_rectangles( rectid INTEGER,
    scale REAL )
    RETURNING rectangle_t, REAL;

    DEFINE rectv rectangle_t;
    DEFINE a REAL;
    SELECT rect INTO rectv
        FROM rectangles WHERE id = rectid;
    IF ( rectv IS NULL ) THEN
        LET rectv.start = (0.0,0.0);
        LET rectv.length = 1.0;
        LET rectv.width = 1.0;
        LET a = 1.0;
        RETURN rectv, a;
    ELSE
        LET rectv.length = scale * rectv.length;
        LET rectv.width = scale * rectv.width;
        CALL area(rectv.length, rectv.width) RETURNING a;
        RETURN rectv, a;
    END IF;

END FUNCTION;
```

The SPL function uses a CALL statement that executes the external function `area()`. The value `area()` returns is stored in `a` and returned to the calling routine by the RETURN statement.

In this example, `area()` is an external function, but you can use CALL in the same manner with an SPL function.

## Execute routines in expressions

Just as with built-in functions, you can execute SPL routines (and external routines from SPL routines) by using them in expressions in SQL and SPL statements. A routine used in an expression is usually a function, because it returns a value to the rest of the statement.

For example, you might execute a function by a LET statement that assigns the return value to a variable. The statements in the following figure perform the same task. They execute an external function within an SPL routine and assign the return value to the variable `a`.

Figure 486. Execute an external function within an SPL routine.

```
LET a = area( rectv.length, rectv.width );

CALL area( rectv.length, rectv.width ) RETURNING a;
-- these statements are equivalent
```

You can also execute an SPL routine from an SQL statement, as the following figure shows. Suppose you write an SPL function, `increase_by_pct`, which increases a given price by a given percentage. After you write an SPL routine, it is available for use in any other SPL routine.

Figure 487. Execute an SPL routine from an SQL statement.

```
CREATE FUNCTION raise_price ( num INT )
  RETURNING DECIMAL;

  DEFINE p DECIMAL;

  SELECT increase_by_pct(price, 20) INTO p
    FROM inventory WHERE prod_num = num;

  RETURN p;

END FUNCTION;
```

The example selects the **price** column of a specified row of **inventory** and uses the value as an argument to the SPL function `increase_by_pct`. The function then returns the new value of **price**, increased by 20 percent, in the variable **p**.

## Execute an external function with the RETURN statement

You can use a RETURN statement to execute any external function from within an SPL routine. The following figure shows an external function that is used in the RETURN statement of an SPL program.

Figure 488. A RETURN statement to execute an external function from within an SPL routine.

```
CREATE FUNCTION c_func() RETURNS int
  LANGUAGE C;

CREATE FUNCTION spl_func() RETURNS INT;
  RETURN(c_func());
END FUNCTION;

EXECUTE FUNCTION spl_func();
```

When you execute the `spl_func()` function, the `c_func()` function is invoked, and the SPL function returns the value that the external function returns.

## Execute cursor functions from an SPL routine

A cursor function is a user-defined function that returns one or more rows of data and therefore requires a cursor to execute. A cursor function can be either of the following functions:

- An SPL function whose RETURN statement includes WITH RESUME
- An external function that is defined as an iterator function

The behavior of a cursor function is the same whether the function is an SPL function or an external function. However, an SPL cursor function can return more than one value per iteration, whereas an external cursor function (iterator function) can return only one value per iteration.

To execute a cursor function from an SPL routine, you must include the function in a FOREACH loop of an SPL routine. The following examples show different ways to execute a cursor function in a FOREACH loop:

```
FOREACH SELECT cur_func1(col_name) INTO spl_var FROM tbl1
  INSERT INTO tab2 VALUES (spl_var);
END FOREACH
```

```
FOREACH EXECUTE FUNCTION cur_func2() INTO spl_var
  INSERT INTO tab2 VALUES (spl_var);
END FOREACH
```

## Dynamic routine-name specification

Dynamic routine-name specification allows you to execute an SPL routine from another SPL routine, by building the name of the called routine within the calling routine. Dynamic routine-name specification simplifies how you can write an SPL routine that calls another SPL routine whose name is not known until runtime. The database server lets you specify an SPL variable instead of the explicit name of an SPL routine in the EXECUTE PROCEDURE or EXECUTE FUNCTION statement.

In the following figure, the SPL procedure **company\_proc** updates a large company sales table and then assigns an SPL variable named **salesperson\_proc** to hold the dynamically created name of an SPL procedure that updates another, smaller table that contains the monthly sales of an individual salesperson.

Figure 489. Dynamic routine-name specification.

```
CREATE PROCEDURE company_proc ( no_of_items INT,
  itm_quantity SMALLINT, sale_amount MONEY,
  customer VARCHAR(50), sales_person VARCHAR(30) )

DEFINE salesperson_proc VARCHAR(60);

-- Update the company table
INSERT INTO company_tbl VALUES (no_of_items, itm_quantity,
  sale_amount, customer, sales_person);

-- Generate the procedure name for the variable salesperson_proc
LET salesperson_proc = sales_person || "." || "tbl" ||
  current_month || "_" || current_year || "_proc" ;

-- Execute the SPL procedure that the salesperson_proc
-- variable specifies
EXECUTE PROCEDURE salesperson_proc (no_of_items,
  itm_quantity, sale_amount, customer)
END PROCEDURE;
```

In example, the procedure **company\_proc** accepts five arguments and inserts them into **company\_tbl**. Then the LET statement uses various values and the concatenation operator || to generate the name of another SPL procedure to execute. In the LET statement:

**sales\_person**

An argument passed to the **company\_proc** procedure.

**current\_month**

The current month in the system date.

**current\_year**

The current year in the system date.

Therefore, if a salesperson named Bill makes a sale in July 1998, **company\_proc** inserts a record in **company\_tbl** and executes the SPL procedure **bill.tbl07\_1998\_proc**, which updates a smaller table that contains the monthly sales of an individual salesperson.

## Rules for dynamic routine-name specification

You must define the SPL variable that holds the name of the dynamically executed SPL routine as CHAR, VARCHAR, NCHAR, or NVARCHAR type. You must also give the SPL variable a valid and non-NULL name.

The SPL routine that the dynamic routine-name specification identifies must exist before it can be executed. If you assign the SPL variable the name of a valid SPL routine, the EXECUTE PROCEDURE or EXECUTE FUNCTION statement executes the routine whose name is contained in the variable, even if a built-in function of the same name exists.

In an EXECUTE PROCEDURE or EXECUTE FUNCTION statement, you cannot use two SPL variables to create a variable name in the form *owner.routine\_name*. However, you can use an SPL variable that contains a fully qualified routine name, for example, *bill.proc1*. The following figure shows both cases.

Figure 490. SPL variable that contains a fully qualified routine name.

```
EXECUTE PROCEDURE owner_variable.proc_variable;
-- this is not allowed

LET proc1 = bill.proc1;
EXECUTE PROCEDURE proc1; -- this is allowed
```

## Privileges on routines

Privileges differentiate users who can create a routine from users who can execute a routine. Some privileges accrue as part of other privileges. For example, the DBA privilege includes permissions to create routines, execute routines, and grant these privileges to other users.

## Privileges for registering a routine

To register a routine in the database, an authorized user wraps the SPL commands in a CREATE FUNCTION or CREATE PROCEDURE statement. The database server stores a registered SPL routine internally. The following users qualify to register a new routine in the database:

- Any user with the DBA privilege can register a routine with or without the DBA keyword in the CREATE statement. For an explanation of the DBA keyword, see [DBA privileges for executing a routine on page 2059](#).
- A user who does not have the DBA privilege needs the Resource privilege to register an SPL routine. The creator is the owner of the routine.

A user who does not have the DBA privilege cannot use the DBA keyword to register the routine.

A DBA must give other users the Resource privilege needed to create routines. The DBA can also revoke the Resource privilege, preventing the user from creating further routines.

- Besides holding the DBA privilege or the Resource privilege on the database in which the UDR is registered, the user who creates a UDR must also hold the Usage privilege on the programming language in which the UDR is written.

These SQL statements can grant language-level Usage privileges for specific programming languages:

- `GRANT USAGE ON LANGUAGE C`
- `GRANT USAGE ON LANGUAGE JAVA`
- `GRANT USAGE ON LANGUAGE SPL`

Besides an individual user, the grantee of these privileges can also be a user-defined role, or the PUBLIC group. After language-level Usage privileges are granted to a role, any user who holds that role can enable all the access privileges of the role by using the SET ROLE statement of SQL to specify that role as the current role.

For external routines written in the C language or the Java™ language, if the IFX\_EXTEND\_ROLE configuration parameter is enabled, only users to whom the DBSA has granted EXTERNAL role has been granted can register, drop, or alter external UDRs or DataBlade® modules. This parameter is enabled by default. By setting the IFX\_EXTEND\_ROLE configuration parameter to OFF or to 0, the DBSA can disable the requirement of holding the EXTEND role for DDL operations on DataBlade® modules and external UDRs. This security feature has no effect, however, on SPL routines.

In summary, a user who holds the database-level and language-level discretionary access privileges that are identified above (and who also holds the EXTEND role, if IFX\_EXTEND\_ROLE is enabled and the UDR is an external routine) can reference UDRs in the following SQL statements:

- The DBA or a user can register a new UDR with the CREATE FUNCTION, CREATE FUNCTION FROM, CREATE PROCEDURE, CREATE PROCEDURE FROM, CREATE ROUTINE, or CREATE ROUTINE FROM statement.
- The DBA or the owner of an existing UDR can cancel the registration of that UDR with the DROP FUNCTION, DROP PROCEDURE, or DROP ROUTINE statement.
- The DBA or the owner of an existing UDR can modify the definition of that UDR with the ALTER FUNCTION, ALTER PROCEDURE, or ALTER ROUTINE statement.

## Privileges for executing a routine

The Execute privilege enables users to invoke a routine. The routine might be invoked by the EXECUTE or CALL statements, or by using a function in an expression. The following users have a default Execute privilege, which enables them to invoke a routine:

- By default, any user with the DBA privilege can execute any routine in the database.
- If the routine is registered with the qualified CREATE DBA FUNCTION or CREATE DBA PROCEDURE statements, only users with the DBA privilege have a default Execute privilege for that routine.
- If the database is not ANSI compliant, user **public** (any user with Connect database privilege) automatically has the Execute privilege to a routine that is not registered with the DBA keyword.
- In an ANSI-compliant database, the procedure owner and any user with the DBA privilege can execute the routine without receiving additional privileges.

## Grant and revoke the Execute privilege

Routines have the following GRANT and REVOKE requirements:

- The DBA can grant or revoke the Execute privilege to any routine in the database.
- The creator of a routine can grant or revoke the Execute privilege on that particular routine. The creator forfeits the ability to grant or revoke by including the AS *grantor* clause with the GRANT EXECUTE ON statement.
- Another user can grant the Execute privilege if the owner applied the WITH GRANT keywords in the GRANT EXECUTE ON statement.

A DBA or the routine owner must explicitly grant the Execute privilege to non-DBA users for the following conditions:

- A routine that was registered with the DBA keyword
- A routine in an ANSI-compliant database
- A routine in a database that is not ANSI-compliant, but with the **NODEFDAC** environment variable set to `yes`.
- 

An owner can restrict the Execute privilege on a routine even though the database server grants that privilege to public by default. To do this, issue the REVOKE EXECUTE ON PUBLIC statement. The DBA and owner can still execute the routine and can grant the Execute privilege to specific users, if applicable.

## Execute privileges with COMMUTATOR and NEGATOR functions

**!** **Important:** If you explicitly grant the Execute privilege on an SPL function that is the commutator or negator function of a UDR, you must also grant that privilege on the commutator or the negator function before the grantee can use either. You cannot specify COMMUTATOR or NEGATOR modifiers with SPL procedures.

The following example demonstrates both limiting privileges for a function and its negator to one group of users. Suppose you create the following pair of negator functions:

```
CREATE FUNCTION greater(y PERCENT, z PERCENT)
RETURNS BOOLEAN
NEGATOR= less(y PERCENT, z PERCENT);
. . .
CREATE FUNCTION less(y PERCENT, z PERCENT)
RETURNS BOOLEAN
NEGATOR= greater(y PERCENT, z PERCENT);
```

By default, any user can execute both the function and negator. The following statements allow only **accounting** to execute these functions:

```
REVOKE EXECUTE ON FUNCTION greater FROM PUBLIC;
REVOKE EXECUTE ON FUNCTION less FROM PUBLIC;
GRANT accounting TO mary, jim, ted;
GRANT EXECUTE ON FUNCTION greater TO accounting;
GRANT EXECUTE ON FUNCTION less TO accounting;
```

A user might receive the Execute privilege accompanied by the WITH GRANT OPTION authority to grant the Execute privilege to other users. If a user loses the Execute privilege on a routine, the Execute privilege is also revoked from all users who were granted the Execute privilege by that user.

For more information, see the GRANT and REVOKE statement descriptions in the *Informix® Guide to SQL: Syntax*.

## Privileges on objects associated with a routine

The database server checks the existence of any referenced objects and verifies that the user invoking the routine has the necessary privileges to access the referenced objects.

Objects referenced by a routine can include:

- Tables and columns
- Sequence objects
- User-defined data types
- Other routines executed by the routine

When a routine is run, the effective privilege is defined as the union of:

- The privileges of the user running the routine,
- The privileges that the owner has with the GRANT option.

By default, the database administrator has all the privileges in a database with the GRANT option. Therefore, users executing routines that are owned by database administrators can select from all of the tables in a given database.

A GRANT EXECUTE ON statement confers to the grantee any table-level privileges that the grantor received from a GRANT statement that contained the WITH GRANT keywords.

The owner of the routine, and not the user who runs the routine, owns the unqualified objects created in the course of executing the routine. For example, assume user **howie** registers an SPL routine that creates two tables, with the following SPL routine:

```
CREATE PROCEDURE promo()
. . .
  CREATE TABLE newcatalog
  (
    catlog_num INTEGER
    cat_advert VARCHAR(255, 65)
    cat_picture BLOB
  ) ;
  CREATE TABLE dawn.mailers
  (
    cust_num INTEGER
    interested_in SET(catlog_num INTEGER)
  );
END PROCEDURE;
```

User **julia** runs the routine, which creates the table **newcatalog**. Because no owner name qualifies table name **newcatalog**, the routine owner (**howie**) owns **newcatalog**. By contrast, the qualified name **dawn.maillist** identifies **dawn** as the owner of **maillist**.

## DBA privileges for executing a routine

If a DBA creates a routine using the DBA keyword, the database server automatically grants the Execute privilege only to other users with the DBA privilege. A DBA can, however, explicitly grant the Execute privilege on a DBA routine to a user who does not have the DBA privilege.

When a user executes a routine that was registered with the DBA keyword, that user assumes the privileges of a DBA for the duration of the routine. If a user who does not have the DBA privilege runs a DBA routine, the database server implicitly grants a temporary DBA privilege to the invoker. Before exiting a DBA routine, the database server implicitly revokes the temporary DBA privilege.

Objects created in the course of running a DBA routine are owned by the user who executes the routine, unless a statement in the routine explicitly names someone else as the owner. For example, suppose that **tony** registers the **promo()** routine with the DBA keyword, as follows:

```
CREATE DBA PROCEDURE promo()
. . .
  CREATE TABLE catalog
. . .
  CREATE TABLE libby.mailers
. . .
END PROCEDURE;
```

Although **tony** owns the routine, if **marty** runs it, then **marty** owns the **catalog** table, but user **libby** owns **libby.mailers** because their name qualifies the table name, making them the table owner.

A called routine does not inherit the DBA privilege. If a DBA routine executes a routine that was created without the DBA keyword, the DBA privileges do not affect the called routine.

If a routine that is registered without the DBA keyword calls a DBA routine, the caller must have Execute privileges on the called DBA routine. Statements within the DBA routine execute as they would within any DBA routine.

The following example demonstrates what occurs when a DBA and non-DBA routine interact. Suppose procedure `dbspc_cleanup()` executes another procedure `clust_catalog()`. Suppose also that the procedure `clust_catalog()` creates an index and that the SPL source code for `clust_catalog()` includes the following statements:

```
CREATE CLUSTER INDEX c_clust_ix ON catalog (catalog_num);
```

The DBA procedure `dbspc_cleanup()` invokes the other routine with the following statement:

```
EXECUTE PROCEDURE clust_catalog(catalog);
```

Assume **tony** registered `dbspc_cleanup()` as a DBA procedure and `clust_catalog()` is registered without the DBA keyword, as the following statements show:

```
CREATE DBA PROCEDURE dbspc_cleanup(loc CHAR)
CREATE PROCEDURE clust_catalog(catalog CHAR)
GRANT EXECUTE ON dbspc_cleanup(CHAR) to marty;
```

Suppose user **marty** runs `dbspc_cleanup()`. Because index **c\_clust\_ix** is created by a non-DBA routine, **tony**, who owns both routines, also owns **c\_clust\_ix**. By contrast, **marty** would own index **c\_clust\_ix** if `clust_catalog()` is a DBA procedure, as the following registering and grant statements show:

```
CREATE PROCEDURE dbspc_cleanup(loc CHAR);
CREATE DBA PROCEDURE clust_catalog(catalog CHAR);
GRANT EXECUTE ON clust_catalog(CHAR) to marty;
```

Notice that `dbspc_cleanup()` need not be a DBA procedure to call a DBA procedure.

## Find errors in an SPL routine

When you use `CREATE PROCEDURE` or `CREATE FUNCTION` to write an SPL routine with DB-Access, the statement fails when you select **Run** from the menu, if a syntax error occurs in the body of the routine.

If you are creating the routine in DB-Access, when you choose the **Modify** option from the menu, the cursor moves to the line that contains the syntax error. You can select **Run** and **Modify** again to check subsequent lines.

## Compile-time warnings

If the database server detects a potential problem, but the syntax of the SPL routine is correct, the database server generates a warning and places it in a listing file. You can examine this file to check for potential problems before you execute the routine.

The file name and path name of the listing file are specified in the WITH LISTING IN clause of the CREATE PROCEDURE or CREATE FUNCTION statement. For information about how to specify the path name of the listing file, see [Specify a DOCUMENT clause on page 2006](#).

If you are working on a network, the listing file is created on the system where the database resides. If you provide an absolute path name and file name for the file, the file is created at the location you specify.

For UNIX™, if you provide a relative path name for the listing file, the file is created in your home directory on the computer where the database resides. (If you do not have a home directory, the file is created in the **root** directory.)

For Windows™, if you provide a relative path name for the listing file, the default directory is your current working directory if the database is on the local computer. Otherwise the default directory is %INFORMIXDIR%\bin.

After you create the routine, you can view the file that is specified in the WITH LISTING IN clause to see the warnings that it contains.

## Generate the text of the routine

After you create an SPL routine, it is stored in the **sysprocbody** system catalog table. The **sysprocbody** system catalog table contains the executable routine, as well as its text.

To retrieve the text of the routine, select the **data** column from the **sysprocbody** system catalog table. The **datakey** column for a text entry has the code **T**.

The SELECT statement in the following figure reads the text of the SPL routine **read\_address**.

Figure 491. SELECT statement to read the text of the SPL routine.

```
SELECT data FROM informix.sysprocbody
WHERE datakey = 'T'           -- find text lines
AND procid =
  ( SELECT procid
    FROM informix.sysprocedures
    WHERE informix.sysprocedures.procname =
      'read_address' )
```

## Debug an SPL routine

After you successfully create and run an SPL routine, you can encounter logic errors. If the routine has logic errors, use the TRACE statement to help find them. You can trace the values of the following items:

- Variables
- Arguments
- Return values
- SQL error codes
- ISAM error codes

To generate a listing of traced values, first use the SQL statement SET DEBUG FILE to name the file that is to contain the traced output. When you create the SPL routine, include a TRACE statement.

The following methods specify the form of TRACE output.

**Statement**

**Action**

**TRACE ON**

Traces all statements except SQL statements. Prints the contents of variables before they are used. Traces routine calls and returned values.

**TRACE PROCEDURE**

Traces only the routine calls and returned values.

**TRACE *expression***

Prints a literal or an expression. If necessary, the value of the expression is calculated before it is sent to the file.

The following figure demonstrates how you can use the TRACE statement to monitor how an SPL function executes.

Figure 492. The TRACE statement.

```

CREATE FUNCTION read_many (lastname CHAR(15))
  RETURNING CHAR(15), CHAR(15), CHAR(20), CHAR(15),
    CHAR(2), CHAR(5);

DEFINE p_lname,p_fname, p_city CHAR(15);
DEFINE p_add CHAR(20);
DEFINE p_state CHAR(2);
DEFINE p_zip CHAR(5);
DEFINE lcount, i INT;

LET lcount = 1;

TRACE ON;      -- Trace every expression from here on
TRACE 'Foreach starts'; -- Trace statement with a literal

FOREACH
SELECT fname, lname, address1, city, state, zipcode
  INTO p_fname, p_lname, p_add, p_city, p_state, p_zip

  FROM customer
    WHERE lname = lastname
RETURN p_fname, p_lname, p_add, p_city, p_state, p_zip
  WITH RESUME;
LET lcount = lcount + 1;  -- count of returned addresses
END FOREACH

TRACE 'Loop starts';      -- Another literal
FOR i IN (1 TO 5)
  BEGIN
    RETURN i , i+1, i*i, i/i, i-1,i WITH RESUME;
  END
END FOR;

END FUNCTION;

```

With the TRACE ON statement, each time you execute the traced routine, entries are added to the file you specified in the SET DEBUG FILE statement. To see the debug entries, view the output file with any text editor.

The following list contains some of the output that the function in previous example generates. Next to each traced statement is an explanation of its contents.

#### Statement

##### Action

#### TRACE ON

Echoes TRACE ON statement.

#### TRACE Foreach starts

Traces expression, in this case, the literal string Foreach starts.

#### start select cursor

Provides notification that a cursor is opened to handle a FOREACH loop.

**select cursor iteration**

Provides notification of the start of each iteration of the select cursor.

**expression: (+lcount, 1)**

Evaluates the encountered expression, (lcount+1), to 2.

**let lcount = 2**

Echoes each LET statement with the value.

## Exception handling

You can use the ON EXCEPTION statement to trap any exception (or error) that the database server returns to your SPL routine or any exception that the routine raises. The RAISE EXCEPTION statement lets you generate an exception within the SPL routine.

In an SPL routine, you cannot use exception handling to handle the following conditions:

- Success (row returned)
- Success (no rows returned)

## Error trapping and recovering

The ON EXCEPTION statement provides a mechanism to trap any error.

To trap an error, enclose a group of statements in a statement block marked with BEGIN and END and add an ON EXCEPTION IN statement at the beginning of the statement block. If an error occurs in the block that follows the ON EXCEPTION statement, you can take recovery action.

The following figure shows an ON EXCEPTION statement within a statement block.

Figure 493. Trap errors.

```

BEGIN
DEFINE c INT;
ON EXCEPTION IN
(
-206, -- table does not exist
-217 -- column does not exist
) SET err_num

IF err_num = -206 THEN
CREATE TABLE t (c INT);
INSERT INTO t VALUES (10);
-- continue after the insert statement
ELSE
ALTER TABLE t ADD(d INT);
LET c = (SELECT d FROM t);
-- continue after the select statement.
END IF
END EXCEPTION WITH RESUME

INSERT INTO t VALUES (10); -- fails if t does not exist

LET c = (SELECT d FROM t); -- fails if d does not exist
END

```

When an error occurs, the SPL interpreter searches for the innermost ON EXCEPTION declaration that traps the error. The first action after trapping the error is to reset the error. When execution of the error action code is complete, and if the ON EXCEPTION declaration that was raised included the WITH RESUME keywords, execution resumes automatically with the statement *following* the statement that generated the error. If the ON EXCEPTION declaration did not include the WITH RESUME keywords, execution exits the current block entirely.

## Scope of control of an ON EXCEPTION statement

The scope of the ON EXCEPTION statement extends from the statement that immediately follows the ON EXCEPTION statement, and ends at the end of the statement block in which the ON EXCEPTION statement is issued. If the SPL routine includes no explicit statement blocks, the scope is all subsequent statements in the routine.

For the exceptions specified in the IN clause (or for all exceptions, if no IN clause is specified), the scope of the ON EXCEPTION statement includes all statements that follow the ON EXCEPTION statement within the same statement block. If other statement blocks are nested within that block, the scope also includes all statements in the nested statement blocks that follow the ON EXCEPTION statement, and any statements in statement blocks that are nested within those nested blocks.

The following pseudocode shows where the exception is valid within the routine. That is, if error 201 occurs in any of the indicated blocks, the action labeled a201 occurs.

Figure 494. ON EXCEPTION statement scope of control.

```

CREATE PROCEDURE scope()
  DEFINE i INT;
  . . .
  BEGIN          -- begin statement block A
    . . .
    ON EXCEPTION IN (201)
    -- do action a201
  END EXCEPTION
  BEGIN          -- nested statement block aa
    -- do action, a201 valid here
  END
  BEGIN          -- nested statement block bb
    -- do action, a201 valid here
  END
  WHILE i < 10
    -- do something, a201 is valid here
  END WHILE

  END          -- end of statement block A
  BEGIN          -- begin statement block B
    -- do something
    -- a201 is NOT valid here
  END
END PROCEDURE;

```

## User-generated exceptions

You can generate your own error using the RAISE EXCEPTION statement, as the following figure shows.

Figure 495. The RAISE EXCEPTION statement.

```

BEGIN
  ON EXCEPTION SET esql, eisam  -- trap all errors
  IF esql = -206 THEN          -- table not found
    -- recover somehow
  ELSE
    RAISE exception esql, eisam; -- pass the error up
  END IF
END EXCEPTION
  -- do something
END

```

In the example, the ON EXCEPTION statement uses two variables, **esql** and **eisam**, to hold the error numbers that the database server returns. The IF clause executes if an error occurs and if the SQL error number is -206. If any other SQL error is caught, it is passed out of this BEGINEND block to the last BEGINEND block of the previous example.

## Simulate SQL errors

You can generate errors to simulate SQL errors, as the following figure shows. If the user is **pault**, then the SPL routine acts as if that user has no update privileges, even if the user really does have that privilege.

Figure 496. Simulate SQL errors.

```
BEGIN
  IF user = 'pault' THEN
    RAISE EXCEPTION -273; -- deny Paul update privilege
  END IF
END
```

## RAISE EXCEPTION to exit nested code

The following figure shows how you can use the RAISE EXCEPTION statement to break out of a deeply nested block.

Figure 497. The RAISE EXCEPTION statement.

```
BEGIN
  ON EXCEPTION IN (1)
  END EXCEPTION WITH RESUME -- do nothing significant (cont)

  BEGIN
    FOR i IN (1 TO 1000)
      FOREACH select ..INTO aa FROM t
        IF aa < 0 THEN
          RAISE EXCEPTION 1; -- emergency exit
        END IF
      END FOREACH
    END FOR
    RETURN 1;
  END

  --do something; -- emergency exit to
  -- this statement.

  TRACE 'Negative value returned';
  RETURN -10;
END
```

If the innermost condition is true (if **aa** is negative), then the exception is raised and execution jumps to the code following the END of the block. In this case, execution jumps to the TRACE statement.

Remember that a BEGINEND block is a *single* statement. If an error occurs somewhere inside a block and the trap is outside the block, the rest of the block is skipped when execution resumes, and execution begins at the next statement.

Unless you set a trap for this error somewhere in the block, the error condition is passed back to the block that contains the call and back to any blocks that contain the block. If no ON EXCEPTION statement exists that is set to handle the error, execution of the SPL routine stops, creating an error for the routine that is executing the SPL routine.

## Check the number of rows processed in an SPL routine

Within SPL routines, you can use the DBINFO function to find out the number of rows that have been processed in SELECT, INSERT, UPDATE, DELETE, EXECUTE PROCEDURE, and EXECUTE FUNCTION statements.

The following figure shows an SPL function that uses the DBINFO function with the 'sqlca.sqlerrd2' option to determine the number of rows that are deleted from a table.

Figure 498. Determine the number of rows deleted from a table.

```
CREATE FUNCTION del_rows ( pnumb INT )
RETURNING INT;

DEFINE nrows INT;

DELETE FROM sec_tab WHERE part_num = pnumb;
LET nrows = DBINFO('sqlca.sqlerrd2');

RETURN nrows;

END FUNCTION;
```

To ensure valid results, use this option after SELECT and EXECUTE PROCEDURE or EXECUTE FUNCTION statements have completed executing. In addition, if you use the 'sqlca.sqlerrd2' option within cursors, make sure that all rows are fetched before the cursors are closed, to ensure valid results.

## Summary

SPL routines provide many opportunities for streamlining your database process, including enhanced database performance, simplified applications, and limited or monitored access to data. You can also use SPL routines to handle extended data types, such as collection types, row types, opaque types, and distinct types. For syntax diagrams of SPL statements, see the *Informix® Guide to SQL: Syntax*.

## Create and use triggers

This section describes each component of the CREATE TRIGGER statement, illustrates some uses for triggers, and describes the advantages of using an SPL routine as a triggered action.

In addition, this section describes INSTEAD OF trigger that can be defined on views.

An SQL trigger is a mechanism that resides in the database. It is available to any user who has permission to use it. An SQL trigger specifies that when a data-manipulation language (DML) operation (an INSERT, SELECT, DELETE, or UPDATE statement) occurs on a particular table, the database server automatically performs one or more additional actions. For triggers defined on views, the triggered action on the base tables of the view replaces the triggering event. For triggers on tables or views, the triggered actions can be INSERT, DELETE, UPDATE, EXECUTE PROCEDURE or EXECUTE FUNCTION statements.

HCL Informix® also supports user-defined routines written in C or in Java™ as triggered actions.

For information on how to write a C UDR to obtain metadata information about trigger events, see the *Informix® DataBlade® API Programmer's Guide*.

## When to use triggers

Because a trigger resides in the database and anyone who has the required privilege can use it, a trigger lets you write a set of SQL statements that multiple applications can use. It lets you avoid redundant code when multiple programs need to perform the same database operation.

You can use triggers to perform the following actions, as well as others that are not found in this list:

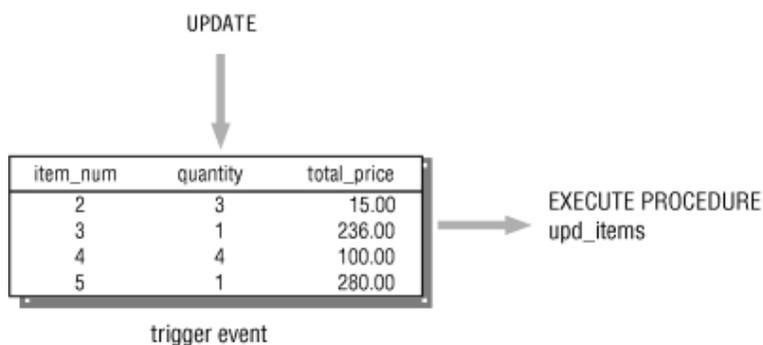

- Create an audit trail of activity in the database. For example, you can track updates to the orders table by updating corroborating information to an audit table.
- Implement a business rule. For example, you can determine when an order exceeds a customer's credit limit and display a message to that effect.
- Derive additional data that is not available within a table or within the database. For example, when an update occurs to the **quantity** column of the **items** table, you can calculate the corresponding adjustment to the **total\_price** column.
- Enforce referential integrity. When you delete a customer, for example, you can use a trigger to delete corresponding rows that have the same customer number in the **orders** table.

## How to create a trigger

You use the CREATE TRIGGER statement to define a new trigger. The CREATE TRIGGER statement is a data-definition statement that associates SQL statements, called the *triggered action*, with a precipitating event on a table. When the event occurs, it triggers the associated SQL statements, which are stored in the database.

In this example, the triggering event is an UPDATE statement that references the **quantity** column of the **items** table. The following figure illustrates the relationship of the DML operation that activates the trigger, called the trigger event, to the triggered action.

Figure 499. Trigger event and triggered action

The CREATE TRIGGER statement consists of clauses that perform the following actions:

- Declare a name for the trigger .
- Specify the DML operation on a specified table or view as the triggering event.
- Define the SQL operations that this event triggers.

An optional clause, called the REFERENCING clause, is discussed in [FOR EACH ROW triggered actions on page 2072](#).

To create a trigger, use DB-Access or one of the SQL APIs. This section describes the CREATE TRIGGER statement as you enter it with the interactive Query-language option in DB-Access. In an SQL API, you precede the statement with the symbol or keywords that identify it as an embedded statement.

## Declare a trigger name

The trigger name identifies the trigger, and must be unique among trigger names within the database. The trigger name follows the words CREATE TRIGGER in the statement. Like any SQL identifier, can be up to 128 bytes in length, beginning with a letter and consisting of letters, digits, and the underscore ( `_` ) symbol. In the following example, the portion of the CREATE TRIGGER statement that is shown declares the name **upqty** for the trigger:

```
CREATE TRIGGER upqty      -- declare trigger name
```

## Specify the trigger event

The *trigger event* is the type of DML statement that activates the trigger. When a statement of this type is performed on the table, the database server executes the SQL statements that make up the triggered action. For tables, the trigger event can be an INSERT, SELECT, DELETE, or UPDATE statement. For UPDATE or SELECT trigger event, you can specify one or more columns in the table to activate the trigger. If you do not specify any columns, then an UPDATE or SELECT of any column in the table activates the trigger. You can define multiple INSERT, DELETE, UPDATE and SELECT triggers on the same table, and multiple INSERT, DELETE, and UPDATE triggers on the same view.

You can only create a trigger on a table or view in the current database. Triggers cannot reference a remote table or view.

In the following excerpt from a CREATE TRIGGER statement, the trigger event is defined as an update of the **quantity** column in the **items** table:

```
CREATE TRIGGER upqty
  UPDATE OF quantity ON items      -- an UPDATE trigger event
```

This portion of the statement identifies the table on which you define the trigger. If the trigger event is an insert or delete operation, only the type of statement and the table name are required, as the following example shows:

```
CREATE TRIGGER ins_qty
  INSERT ON items                  -- an INSERT trigger event
```

## Define the triggered actions

The *triggered actions* are the SQL statements that are performed when the trigger event occurs. The triggered actions can consist of INSERT, DELETE, UPDATE, EXECUTE FUNCTION and EXECUTE PROCEDURE statements. In addition to specifying what actions are to be performed, however, you must also specify when they are to be performed in relation to the triggering statement. You have the following choices:

- Before the triggering statement executes
- After the triggering statement executes
- For each row that is affected by the triggering statement

A single trigger on a table can define actions for each of these times.

To define a triggered action, specify when it occurs and then provide the SQL statement or statements to execute. You specify when the action is to occur with the keywords BEFORE, AFTER, or FOR EACH ROW. The triggered actions follow, enclosed in parentheses. The following triggered-action definition specifies that the SPL routine upd\_items\_p1 is to be executed before the triggering statement:

```
BEFORE(EXECUTE PROCEDURE upd_items_p1) -- a BEFORE action
```

## A complete CREATE TRIGGER statement

To define a complete CREATE TRIGGER statement, combine the trigger-name clause, the trigger-event clause, and the triggered-action clause. The following CREATE TRIGGER statement is the result of combining the components of the statement from the preceding examples. This trigger executes the SPL routine upd\_items\_p1 whenever the **quantity** column of the **items** table is updated.

```
CREATE TRIGGER upqty
  UPDATE OF quantity ON items
  BEFORE(EXECUTE PROCEDURE upd_items_p1);
```

If a database object in the trigger definition, such as the SPL routine upd\_items\_p1 in this example, does not exist when the database server processes the CREATE TRIGGER statement, it returns an error.

## Triggered actions

To use triggers effectively, you need to understand the relationship between the triggering statement and the resulting triggered actions. You define this relationship when you specify the time that the triggered action occurs; that is, BEFORE, AFTER, or FOR EACH ROW.

## BEFORE and AFTER triggered actions

Triggered actions that occur before or after the trigger event execute only once. A BEFORE triggered action executes before the *triggering statement*, that is, before the occurrence of the trigger event. An AFTER triggered action executes after the action of the triggering statement is complete. BEFORE and AFTER triggered actions execute even if the triggering statement does not process any rows.

Among other uses, you can use BEFORE and AFTER triggered actions to determine the effect of the triggering statement. For example, before you update the **quantity** column in the **items** table, you could call the SPL routine `upd_items_p1` to calculate the total quantity on order for all items in the table, as the following example shows. The procedure stores the total in a global variable called **old\_qty**.

```
CREATE PROCEDURE upd_items_p1()
  DEFINE GLOBAL old_qty INT DEFAULT 0;
  LET old_qty = (SELECT SUM(quantity) FROM items);
END PROCEDURE;
```

After the triggering update completes, you can calculate the total again to see how much it has changed. The following SPL routine, `upd_items_p2`, calculates the total of **quantity** again and stores the result in the local variable **new\_qty**. Then it compares **new\_qty** to the global variable **old\_qty** to see if the total quantity for all orders has increased by more than 50 percent. If so, the procedure uses the `RAISE EXCEPTION` statement to simulate an SQL error.

```
CREATE PROCEDURE upd_items_p2()
  DEFINE GLOBAL old_qty INT DEFAULT 0;
  DEFINE new_qty INT;
  LET new_qty = (SELECT SUM(quantity) FROM items);
  IF new_qty > old_qty * 1.50 THEN
    RAISE EXCEPTION -746, 0, 'Not allowed - rule violation';
  END IF
END PROCEDURE;
```

The following trigger calls `upd_items_p1` and `upd_items_p2` to prevent an extraordinary update on the **quantity** column of the **items** table:

```
CREATE TRIGGER up_items
  UPDATE OF quantity ON items
  BEFORE(EXECUTE PROCEDURE upd_items_p1())
  AFTER(EXECUTE PROCEDURE upd_items_p2());
```

If an update raises the total quantity on order for all items by more than 50 percent, the `RAISE EXCEPTION` statement in `upd_items_p2` terminates the trigger with an error. When a trigger fails in a database that has transaction logging, the database server rolls back the changes that both the triggering statement and the triggered actions make. For more information on what happens when a trigger fails, see the `CREATE TRIGGER` statement in the *Informix® Guide to SQL: Syntax*.

## FOR EACH ROW triggered actions

A FOR EACH ROW triggered action executes once for each row that the triggering statement affects. For example, if the triggering statement has the following syntax, a FOR EACH ROW triggered action executes once for each row in the **items** table in which the **manu\_code** column has a value of `'KAR'`:

```
UPDATE items SET quantity = quantity * 2
WHERE manu_code = 'KAR';
```

If the triggering event does not process any rows, a FOR EACH ROW triggered action does not execute.

For a trigger on a table, if the triggering event is a SELECT statement, the trigger is called a Select trigger, and the triggered actions execute after all processing on the retrieved row is complete. The triggered actions might not execute immediately; however, because a FOR EACH ROW action executes for every instance of a row that the query returns. For example, in a SELECT statement with an ORDER BY clause, all rows must be qualified against the WHERE clause before they are sorted and returned.

## The REFERENCING clause

When you create a FOR EACH ROW triggered action, you must usually indicate in the triggered action statements whether you are referring to the value of a column before or after the effect of the triggering statement. For example, imagine that you want to track updates to the **quantity** column of the **items** table. To do this, create the following table to record the activity:

```
CREATE TABLE log_record
(item_num      SMALLINT,
ord_num       INTEGER,
username      CHARACTER(8),
update_time   DATETIME YEAR TO MINUTE,
old_qty       SMALLINT,
new_qty       SMALLINT);
```

To supply values for the **old\_qty** and **new\_qty** columns in this table, you must be able to refer to the old and new values of **quantity** in the **items** table; that is, the values before and after the effect of the triggering statement. The REFERENCING clause enables you to do this.

The REFERENCING clause lets you create two prefixes that you can combine with a column name, one to reference the old value of the column, and one to reference its new value. These prefixes are called *correlation names*. You can create one or both correlation names, depending on your requirements. You indicate which one you are creating with the keywords OLD and NEW. The following REFERENCING clause creates the correlation names **pre\_upd** and **post\_upd** to refer to the old and new values in a row:

```
REFERENCING OLD AS pre_upd NEW AS post_upd
```

The following triggered action creates a row in **log\_record** when **quantity** is updated in a row of the **items** table. The INSERT statement refers to the old values of the **item\_num** and **order\_num** columns and to both the old and new values of the **quantity** column.

```
FOR EACH ROW(INSERT INTO log_record
VALUES (pre_upd.item_num, pre_upd.order_num, USER,
CURRENT, pre_upd.quantity, post_upd.quantity));
```

The correlation names defined in the REFERENCING clause apply to all rows that the triggering statement affects.

**Important:** If you refer to a column name that is not qualified by a correlation name, the database server makes no special effort to search for the column in the definition of the triggering table. You must always use a correlation name with a column name in SQL statements in a FOR EACH ROW triggered action, unless the statement is valid

independent of the triggered action. For more information, see the CREATE TRIGGER statement in the *Informix® Guide to SQL: Syntax*.

## The WHEN condition

As an option for triggers on tables, you can precede a triggered action with a WHEN clause to make the action dependent on the outcome of a test. The WHEN clause consists of the keyword WHEN followed by the condition statement given in parentheses. In the CREATE TRIGGER statement, the WHEN clause follows the keywords BEFORE, AFTER, or FOR EACH ROW and precedes the triggered-action list.

When a WHEN condition is present, if it evaluates to *true*, the triggered actions execute in the order in which they appear. If the WHEN condition evaluates to *false* or *unknown*, the actions in the triggered-action list do not execute. If the trigger specifies FOR EACH ROW, the condition is evaluated for each row also.

In the following trigger example, the triggered action executes only if the condition in the WHEN clause is true; that is, if the post-update unit price is greater than two times the pre-update unit price:

```
CREATE TRIGGER up_price
  UPDATE OF unit_price ON stock
  REFERENCING OLD AS pre NEW AS post
  FOR EACH ROW WHEN(post.unit_price > pre.unit_price * 2)
  (INSERT INTO warn_tab
   VALUES(pre.stock_num, pre.manu_code, pre.unit_price,
           post.unit_price, CURRENT));
```

For more information on the WHEN condition, see the CREATE TRIGGER statement in the *Informix® Guide to SQL: Syntax*.

## SPL routines as triggered actions

Probably the most powerful feature of triggers is the ability to call an SPL routine as a triggered action. The EXECUTE PROCEDURE or EXECUTE FUNCTION statement, which calls an SPL routine, lets you pass data from the triggering table to the SPL routine and also to update the triggering table with data returned by the SPL routine. SPL also lets you define variables, assign data to them, make comparisons, and use procedural statements to accomplish complex tasks within a triggered action.

## Pass data to an SPL routine

You can pass data to an SPL routine in the argument list of the EXECUTE PROCEDURE or EXECUTE FUNCTION statement. The EXECUTE PROCEDURE statement in the following example passes values from the **quantity** and **total\_price** columns of the **items** table to the SPL routine **calc\_totpr**:

```
CREATE TRIGGER upd_totpr
  UPDATE OF quantity ON items
  REFERENCING OLD AS pre_upd NEW AS post_upd
```

```
FOR EACH ROW(EXECUTE PROCEDURE calc_totpr(pre_upd.quantity,
    post_upd.quantity, pre_upd.total_price) INTO total_price);
```

Passing data to an SPL routine lets you use data values in the operations that the routine performs.

## Using SPL

The EXECUTE PROCEDURE statement in the preceding trigger calls the SPL routine that the following example shows. The procedure uses SPL to calculate the change that needs to be made to the **total\_price** column when **quantity** is updated in the **items** table. The procedure receives both the old and new values of **quantity** and the old value of **total\_price**. It divides the old total price by the old quantity to derive the unit price. It then multiplies the unit price by the new quantity to obtain the new total price.

```
CREATE PROCEDURE calc_totpr(old_qty SMALLINT, new_qty SMALLINT,
    total MONEY(8)) RETURNING MONEY(8);
    DEFINE u_price LIKE items.total_price;
    DEFINE n_total LIKE items.total_price;
    LET u_price = total / old_qty;
    LET n_total = new_qty * u_price;
    RETURN n_total;
END PROCEDURE;
```

In this example, SPL lets the trigger derive data that is not directly available from the triggering table.

## Update nontriggering columns with data from an SPL routine

Within a triggered action, the INTO clause of the EXECUTE PROCEDURE statement lets you update nontriggering columns in the triggering table. The EXECUTE PROCEDURE statement in the following example calls the **calc\_totpr** SPL procedure that contains an INTO clause, which references the column **total\_price**:

```
FOR EACH ROW(EXECUTE PROCEDURE calc_totpr(pre_upd.quantity,
    post_upd.quantity, pre_upd.total_price) INTO total_price);
```

The value that is updated into **total\_price** is returned by the RETURN statement at the conclusion of the SPL procedure. The **total\_price** column is updated for each row that the triggering statement affects.

## Trigger routines

You can define specialized SPL routines, called *trigger routines*, that can be invoked only from the FOR EACH ROW section of the triggered action. Unlike ordinary UDRs that EXECUTE FUNCTION or EXECUTE PROCEDURE routines can call from the triggered action list, trigger routines include their own REFERENCING clause that defines correlation names for the old and new column values in rows that the triggered action modifies. These correlation names can be referenced in SPL statements within the trigger routine, providing greater flexibility in how the triggered action can modify data in the table or view.

Trigger routines can also use trigger-type Boolean operators, called DELETING, INSERTING, SELECTING, and UPDATING, to identify what type of trigger has called the trigger routine. Trigger routines can also invoke the **mi\_trigger\*** routines, which are

sometimes called *trigger introspection routines*, to obtain information about the context in which the trigger routine has been called.

Trigger routines are invoked by EXECUTE FUNCTION or EXECUTE PROCEDURE statements that include the WITH TRIGGER REFERENCES keywords. These statements must call the trigger routine from the FOR EACH ROW section of the triggered action, rather than from the BEFORE or AFTER sections.

For information about syntax features that the CREATE FUNCTION, CREATE PROCEDURE, EXECUTE FUNCTION, and EXECUTE PROCEDURE statements of SQL support for defining and executing trigger routines, see your *Informix® Guide to SQL: Syntax*. For more information about the **mi\_trigger\*** routines, see your *Informix® DataBlade® API Programmer's Guide*.

## Triggers in a table hierarchy

When you define a trigger on a supertable, any subtables in the table hierarchy also inherit the trigger. Consequently when you perform operations on tables in the hierarchy, triggers can execute for any table in the hierarchy that is a subtable of the table on which a trigger is defined.

## Select triggers

When the CREATE TRIGGER statement defines as its triggering event any query on a specific table (

```
SELECT ON table
```

or

```
SELECT ON column-list ON table
```

), the resulting trigger object is a *Select trigger* on the specified *table*. The same trigger can also be activated by queries on a view that includes triggering columns from *table* as its base table. SELECT statements cannot, however, be the trigger events for INSTEAD OF triggers on a view.

If the CREATE TRIGGER statement also includes a *column-list* in the definition of an enabled Select trigger event, and the Projection list of a subsequent query on the specified table does not include any of the specified columns, that query cannot be a triggering event for the Select trigger.

### Warning:

Select triggers are not reliable for auditing. Do not attempt to create a Select trigger on a table, or on a subset of its columns, for the purpose of performing application-specific auditing. In general, it is not possible, to track the number of SELECT actions on a table by creating a Select trigger to insert an audit record into an audit table each time a user queries a certain table.

For example, suppose that you define a Select trigger on the table `AuditedTable` and that a user who holds Select privileges on `AuditedTable` issues the following query:

```
SELECT a.* FROM (SELECT * FROM AuditedTable) AS a;
```

The database server issues no error, but the SELECT trigger on `AuditedTable` will not be activated by this query. A query that included a set operator, such as UNION or INTERSECT, or any other syntax that Select triggers do not support, would be similarly invisible to an audit-record strategy that is based on Select triggers.

Because of the numerous restrictions on the execution of Select triggers, as partially listed in this chapter, the resulting Select trigger actions will typically correspond to only a subset (that might be empty) of whatever logical Select events you are attempting to enumerate.

## SELECT statements that execute triggered actions

When you create a select trigger, only certain types of select statements can execute the actions defined on that trigger. A select trigger executes for the following types of SELECT statements only:

- Stand-alone SELECT statements
- Collection subqueries in the select list of a SELECT statement
- SELECT statements embedded in user-defined routines
- Views

### Stand-alone SELECT statements

Suppose you define the following Select trigger on a table:

```
CREATE TRIGGER hits_trig SELECT OF col_a ON tab_a
REFERENCING OLD AS hit
FOR EACH ROW (INSERT INTO hits_log
VALUES (hit.col_a, CURRENT, USER));
```

A Select trigger executes when the triggering column appears in the select list of a stand-alone SELECT statement. The following statement executes a triggered action on the **hits\_trig** trigger for each instance of a row that the database server returns:

```
SELECT col_a FROM tab_a;
```

### Collection subqueries in the projection list of a query

A Select trigger executes when the triggering column appears in a collection subquery that occurs in the projection list of another SELECT statement. The following statement executes a triggered action on the **hits\_trig** trigger for each instance of a row that the collection subquery returns:

```
SELECT MULTISET(SELECT col_a FROM tab_a) FROM ...
```

### SELECT statements embedded in user-defined routines

A select trigger that is defined on a SELECT statement embedded in a user defined routine (UDR) executes a triggered action in the following instances only:

- The UDR appears in the select list of a SELECT statement
- The UDR is invoked with an EXECUTE PROCEDURE statement

Suppose you create a routine **new\_proc** that contains the statement `SELECT col_a FROM tab_a`. Each of the following statements executes a triggered action on the **hits\_trig** trigger for each instance of a row that the embedded SELECT statement returns:

```
SELECT new_proc() FROM tab_b;
EXECUTE PROCEDURE new_proc;
```

## Views

Select triggers execute a triggered action for views whose base tables contain a reference to a triggering column. You cannot, however, define a Select trigger on a view.

Suppose you create the following view:

```
CREATE VIEW view_tab AS
SELECT * FROM tab_a;
```

The following statements execute a triggered action on the **hits\_trig** trigger for each instance of a row that the view returns:

```
SELECT * FROM view_tab;

SELECT col_a FROM tab_a;
```

## Restrictions on execution of Select triggers

The following types of SELECT statements do not trigger any actions when they reference a table or column on which an enabled Select trigger is defined.

- No triggering column is referenced in the Projection list (for example, a column that appears only in the WHERE clause of a SELECT statement does not execute a Select trigger).
- The SELECT statement references a remote table.
- The SELECT statement calls an aggregate function or an OLAP window aggregation function.
- The SELECT statement includes a set operator (UNION, UNION ALL, INTERSECT, MINUS, or EXCEPT)
- The SELECT statement includes the DISTINCT or UNIQUE keyword.
- The UDR expression that contains the SELECT statement is not in the Projection list.
- The SELECT statement appears within an INSERT INTO statement.
- The SELECT statement appears within a scroll cursor.
- The trigger is a cascading Select trigger.

A cascading Select trigger is a trigger whose actions includes an SPL routine that itself has a triggering SELECT statement. The actions of a cascading Select trigger do not execute, however, and the database server does not return an error.

## Select triggers on tables in a table hierarchy

When you define a select trigger on a supertable, any subtables in the table hierarchy also inherit the trigger.

For information about overriding and disabling inherited triggers, see [Triggers in a table hierarchy on page 2076](#).

## Re-entrant triggers

A *re-entrant trigger* refers to a case in which the triggered action can reference the triggering table. In other words, both the triggering event and the triggered action can operate on the same table. For example, suppose the following UPDATE statement represents the triggering event:

```
UPDATE tab1 SET (col_a, col_b) = (col_a + 1, col_b + 1);
```

The following triggered action is legal because column **col\_c** is not a column that the triggering event has updated:

```
UPDATE tab1 SET (col_c) = (col_c + 3);
```

In the preceding example, a triggered action on **col\_a** or **col\_b** would be illegal because a triggered action cannot be an UPDATE statement that references a column that was updated by the triggering event.

**Important:** Select triggers cannot be re-entrant triggers. If the triggering event is a SELECT statement, the triggered action cannot operate on the same table.

For a list of the rules that describe those situations in which a trigger can and cannot be re-entrant, see the CREATE TRIGGER statement in the *Informix® Guide to SQL: Syntax*.

## INSTEAD OF triggers on views

A view is a synthetic table that you create with the CREATE VIEW statement and define with a SELECT statement. Each view consists of the set of rows and columns that the SELECT statement in the view definition returns each time you refer to the view in a query. To insert, update, or delete rows in the base tables of a view, you can define an INSTEAD OF trigger.

Unlike a trigger on a table, the INSTEAD OF trigger on a view causes HCL Informix® to ignore the triggering event, and instead perform only the triggered action.

For information on the CREATE VIEW statement and the INSTEAD OF trigger syntax and rules, including an example of an INSTEAD OF trigger that will insert rows on a view, see the *Informix® Guide to SQL: Syntax*.

## INSTEAD OF trigger to update on a view

After you create one or more tables (like those named **dept** and **emp** in the following example), and then created a view (like the one named **manager\_info**) from **dept** and **emp**, you can use an INSTEAD OF trigger to update that view.

The following CREATE TRIGGER statement creates **manager\_info\_update**, an INSTEAD OF trigger that is designed to update rows within the **dept** and **emp** tables through the **manager\_info** view.

```
CREATE TRIGGER manager_info_update
  INSTEAD OF UPDATE ON manager_info
  REFERENCING NEW AS n
  FOR EACH ROW
  (EXECUTE PROCEDURE updtab (n.empno, n.empname, n.deptno,));

CREATE PROCEDURE updtab (eno INT, ename CHAR(20), dno INT,)
  DEFINE deptcode INT;
  UPDATE dept SET manager_num = eno where deptno = dno;
  SELECT deptno INTO deptcode FROM emp WHERE empno = eno;
  IF dno !=deptcode THEN
    UPDATE emp SET deptno = dno WHERE empno = eno;
  END IF;
END PROCEDURE;
```

After the tables, view, trigger, and SPL routine have been created, the database server treats the following UPDATE statement as a triggering event:

```
UPDATE manager_info
  SET empno = 3666, empname = Steve
  WHERE deptno = 01;
```

This triggering UPDATE statement is not executed, but this event causes the trigger action to be executed instead, invoking the updtab() SPL routine. The UPDATE statements in the SPL routine update values into both the **emp** and **dept** base tables of the **manager\_info** view.

## Trace triggered actions

If a triggered action does not behave as you expect, place it in an SPL routine and use the SPL TRACE statement to monitor its operation. Before you start the trace, you must direct the output to a file with the SET DEBUG FILE TO statement.

## Example of TRACE statements in an SPL routine

The following example shows TRACE statements that you add to the SPL routine **items\_pct**. The SET DEBUG FILE TO statement directs the trace output to the file that the path name specifies. The TRACE ON statement begins tracing the statements and variables within the procedure.

```
CREATE PROCEDURE items_pct(mac CHAR(3))
  DEFINE tp MONEY;
  DEFINE mc_tot MONEY;
  DEFINE pct DECIMAL;
  SET DEBUG FILE TO 'pathname';

  TRACE 'begin trace';
  TRACE ON;
  LET tp = (SELECT SUM(total_price) FROM items);
  LET mc_tot = (SELECT SUM(total_price) FROM items
  WHERE manu_code = mac);
```

```

LET pct = mc_tot / tp;
IF pct > .10 THEN
    RAISE EXCEPTION -745;
END IF
TRACE OFF;
END PROCEDURE;

CREATE TRIGGER items_ins
INSERT ON items
REFERENCING NEW AS post_ins
FOR EACH ROW(EXECUTE PROCEDURE items_pct (post_ins.manu_code));

```

## Example of TRACE output

The following example shows sample trace output from the **items\_pct** procedure as it appears in the file that was named in the SET DEBUG FILE TO statement. The output reveals the values of procedure variables, procedure arguments, return values, and error codes.

```

trace expression :begin trace
trace on
expression:
  (select (sum total_price)
   from items)
evaluates to $18280.77 ;
let tp = $18280.77
expression:
  (select (sum total_price)
   from items
   where (= manu_code, mac))
evaluates to $3008.00 ;
let mc_tot = $3008.00
expression:(/ mc_tot, tp)
evaluates to 0.16
let pct = 0.16
expression:(> pct, 0.1)
evaluates to 1
expression:(- 745)
evaluates to -745
raise exception :-745, 0, ''
exception : looking for handler
SQL error = -745 ISAM error = 0 error string = ''
exception : no appropriate handler

```

For more information about how to use the TRACE statement to diagnose logic errors in SPL routines, see [Create and use SPL routines on page 1998](#).

## Generate error messages

When a trigger fails because of an SQL statement, the database server returns the SQL error number that applies to the specific cause of the failure.

When the triggered action is an SPL routine, you can generate error messages for other error conditions with one of two reserved error numbers. The first one is error number -745, which has a generalized and fixed error message. The second one is error number -746, which allows you to supply the message text, up to a maximum of 70 bytes.

## Summary

To introduce triggers, this chapter discussed the following topics:

- The components of the CREATE TRIGGER statement
- Types of DML statements that can be triggering events
- Types of SQL statements that can be triggered actions
- How to create BEFORE and AFTER triggered actions and how to use them to determine the impact of the triggering statement
- How to create a FOR EACH ROW triggered action and how to use the REFERENCING clause to refer to the values of columns both before and after the action of the triggering statement
- INSTEAD OF triggers on views, whose triggering event is ignored, but whose triggered actions can modify the base tables of the view
- The advantages of using SPL routines as triggered actions
- Special features of calls to trigger routines as triggered actions
- How to trace triggered actions if they behave unexpectedly
- How to generate two types of error messages within a triggered action.

# Index

## Special Characters

- [()], brackets
  - array subscripts 791
  - range delimiters 1155
  - substring operator 843, 1225, 1633, 1677
- Brackets ([])
  - range delimiters 1155
- !=, not equal, relational operator 1790
- ?, question mark
  - as placeholder in PREPARE 1963
- .jar filename extension 250
- 'VERSION' table 1609
- (\_), underscore
  - in SQL identifiers 1719
- (;), semicolon
  - list separator 1735, 1746
- (:), colon
  - cast (::) operator 1674, 1677
  - list separator 1716, 1721, 1735, 1741, 1746
- (!=), not equal to
  - relational operator 1677
- ('), single quotation
  - string delimiter 1712
- ('), single quotation symbols
  - string delimiter 1719
- ("), double quotation marks
  - string delimiter 1641
- ("), double quotation symbols
  - delimited SQL identifiers 1719
  - string delimiter 1625, 1644, 1651
- ( ), parentheses
  - delimiters in expressions 1665
- { }, braces
  - collection delimiters 1412, 1641, 1644
  - comment indicators 3, 1473
  - pathname delimiters 1681
  - specifying empty collection 1248
- (@), at symbol 1452
- (/), slash
  - DATE separator 1636, 1665, 1707
  - division operator 1661, 1677
  - pathname delimiter 1683, 1713, 1741
- (\), backslash
  - invalid as delimiter 1709
  - pathname delimiter 1684, 1737
- (#), sharp
  - comment indicator 1679
- (%), percentage
  - pathname indicator 1716
- (< >), less than symbol 1429
- (< >), less than
  - angle (< >) brackets 1633
  - relational operator 1677, 1709
- (> < >), greater than
  - angle (< >) brackets 1633
  - relational operator 1554, 1677
- (> < >), greater than symbol 1429
- (|), pipe character 218, 652, 857, 857, 1035
- (|), vertical bar
  - absolute value delimiter 1640
  - concatenation (||) operator 1677
  - field delimiter 1709
- (||), concatenation operator 1193, 1215
- (\$), dollar sign
  - currency symbol 1643, 1712
  - pathname indicator 1746
- (\_), underscore

- in SQL identifiers 1458
- (-), double hyphen, comment indicator 3
- (-), hyphen
  - DATE separator 1707
  - subtraction operator 1661, 1677
  - symbol in syscolauth 1549, 1567
  - symbol in sysfragauth 1581
  - symbol in systabauth 1608
  - unary operator 1662, 1677
- (-), hyphen symbol
  - DATETIME separator 1414
  - INTERVAL separator 1418
- (-), minus sign
  - binary operator 1193
  - INTERVAL literals 1418
  - unary operator 1418
- (,), comma
  - decimal point 1712
  - list separator 1644, 1648, 1716
  - thousands separator 1643
- ::, cast operator 1217
- (:), colon symbol
  - DATETIME separator 1414
  - INTERVAL separator 1418
- (!), exclamation point 1429
  - in smart-large-object filename 1301
- (?), question mark
  - as placeholder in PREPARE 682, 687
  - as wildcard 1155
  - dynamic parameters 502
  - generating unique large-object filename 1301
  - variables in PUT 704
- (.), decimal point
  - DATETIME separator 1414
  - INTERVAL separator 1410
  - literal numbers 1419, 1428
- (.), period
  - DATE separator 1707, 1707
  - decimal point 1638, 1643, 1712
  - execution symbol 1679
  - membership operator 1677
  - nested dot notation 1669
- (.), period symbol
  - DATETIME separator 1414
  - DECIMAL values 1420
  - dot notation 1222
  - INTERVAL separator 1418
  - MONEY values 1420

AVOID\_STAR\_JOIN keyword, in optimizer directives 1483

AVOID\_STMT\_CACHE keyword  
in optimizer directives 1487

## B

B abbreviation for byte 1358

B-tree access method 1560, 1586, 1719

B-tree index 1584  
btree\_ops operator class 290  
default operator class 290  
enforcing constraints 111  
uses 266

B-tree secondary-access method 266, 286

B18030-2000 code set 863

Background mode 1132

Backslash (\) symbol 1709

Backslash (\)  
as escape character 218, 1035, 1155

Backup  
file prefix 1729

Bandwidth 1730

BARGROUP keyword  
in ALTER USER statement 172  
in CREATE DEFAULT USER statement 209  
in CREATE USER statement 447

Base-100 format 1178

BASE64 encoding of encrypted data 897, 1283

BASED keyword  
in CREATE TRUSTED CONTEXT statement 444

Batch file 1134

BATCHEDREAD\_TABLE configuration parameter 1173

BATCHEDREAD\_TABLE session environment option 1173

BEFORE keyword  
in ALTER FRAGMENT statement 27, 47  
in ALTER SECURITY LABEL COMPONENT statement 91  
in ALTER TABLE statement 105, 107  
in CREATE TRIGGER statement 419, 425

BEGIN keyword 1115  
in Statement Block segment 1522

BEGIN WORK statement 176, 1937

BETWEEN keyword  
in Condition segment 1145, 1149  
in OLAP window expressions 1405  
using in WHERE clause 1788  
using to specify a range of rows 1790

BETWEEN operator 1677

BigDecimal data type of Java 1179, 1514

BIGINT data type 1176, 1631  
coltype code 1568  
length (syscolumns) 1572

BIGSERIAL data type 1631  
coltype code 1568  
inserting values 645  
invalid default 350  
last BIGSERIAL value inserted 1856  
last inserted value 1278  
length (syscolumns) 1572  
value range 1176

bin subdirectory 1681

Binary operator 197, 1210

Binding style 1624

Bit-hashing function 834

BITAND function 1211, 1212

BITANDNOT function 1211, 1214

BITNOT function 1211, 1215

BITOR function 1211, 1213

Bitshift functions 1268, 1269

Bitwise functions 1211

BITXOR function 1211, 1213

Blank characters  
DATETIME separator 1414  
in index names 515  
in literal numbers 1419  
in WHERE clause string literals 814

Casts from TEXT 1653

cdr utility 809

cdrserver shadow column 102

cdrserver, replication column name 372

cdrsession

- DBINFO function 1276

cdftime shadow column 102

cdftime, replication column name 372

CEIL function 1254, 1256

Chaining synonyms 334

CHAR data type

- built-in casts 1673
- converting to a DATE value 1842
- converting to a DATETIME value 1844
- defined 1164
- in INSERT 1428
- in relational expressions 1788
- substrings of 1787
- syntax 1170
- truncation signalled 1949

CHAR keyword

- in CREATE EXTERNAL TABLE statement 214

CHAR\_LENGTH function 1293, 1294

CHARACTER data type 1634

- syntax 1170

Character data types

- Boolean comparisons 1655
- casting between 1672
- changing a column length or data type 147
- data strings 1626
- fixed and varying length 1164, 1172
- listed 1656
- localized collation 1173
- multibyte characters 1172
- syntax 1170

Character string

- CHARACTER VARYING data type 1634
- CLOB data type 1635
- converting to a DATE value 1842
- converting to a DATETIME value 1844
- DATETIME literals 1665
- LVARCHAR data type 1642
- NCHAR data type 1645
- NVARCHAR data type 1645
- VARCHAR data type 1655
- with DELIMITED set 1719

CHARACTER VARYING data type

- defined 1634
- syntax 1170

CHARACTER\_LENGTH function 1293, 1294

Character-based applications 1738, 1753

CHARINDEX function 1347

Check constraints

- creation-time value 1706, 1708
- defining 360
- reject files 223
- syschecks data 1565
- syscheckudrdep data 1566
- syscoldepend data 1568
- sysconstraints data 1574

Check constraints, definition of 1925

CHECK keyword

- in ALTER TABLE statement 117
- in CREATE TABLE statement 360
- in CREATE VIEW statement 452, 457

Child table 116, 125, 663

chkenv utility 1679

- error message 1682
- syntax 1682

CHR function 1343

Chunks 1660

CLASS keyword, in Routine Modifier segment 1507

Class libraries, shared 1770

CLASS\_ORIGIN keyword, in GET DIAGNOSTICS statement 587

CLEANUP keyword in SET ENVIRONMENT USE\_DWA statement 957

CLIEN\_LABEL environment variable 1700

Client APIs 1426

CLIENT\_LOCALE environment variable 863, 1416, 1416, 1707

CLIENT\_LOCALE environment variables 1173

CLIENT\_TZ keyword

- in SET ENVIRONMENT statement 1240

Client/server

- DataBlade API 1660
- default database 1736
- INFORMIXSQLHOSTS environment variable 1737
- shared memory communication segments 1737
- stacksize for client session 1738

CLIENTBINVAL data type 779, 1164

CLOB data type

- casting unavailable 1635
- code-set conversion 1635
- collation 1635
- copying to a file 1301
- copying to a smart large object 1303
- creating from a file 1299
- defined 1635
- handle values 1226
- inserting data 1635
- multibyte characters 1635
- size limit 1182
- storing 156, 378
- syscolattns data 1566
- unloading 1031, 1034
- unreferenced 1028

CLOB keyword

- in Data Type segment 1180

CLOB TEXT 1653

CLOSE DATABASE statement 182

CLOSE DATABASE statement, effect on database locks 1981

CLOSE statement 1745

- closing a collection cursor 182
- closing a select cursor 181
- closing an insert cursor 181
- cursors affected by transaction end 182
- syntax 179

CLUSTER keyword

- in ALTER INDEX statement 84
- in CREATE INDEX statement 256
- in SET ENVIRONMENT statement 900, 916

Cluster transaction scope 916

CLUSTER\_TXN\_SCOPE configuration parameter 916

CLUSTER\_TXN\_SCOPE environment option 916

CLUSTER\_TXN\_SCOPE keyword, in SET ENVIRONMENT statement 916

Clustered index 85, 256

Clustering 1560, 1584, 1588

Clustering, specifying support for 1495

CMCONFIG environment variable 1699

COALESCE function 1231

Code points, ASCII 1431

Code set 863, 1172

Code sets

- conversion 1686, 1686
- EBCDIC 1624
- ISO 8859-1 1579

CODESET keyword

- in SELECT statement 857

Collation 1653

- CLOB data type 1635
- code-set order 1173
- GL\_COLLATE table 1609
- in NLSCASE INSENSITIVE databases 1173
- localized 862, 1173
- NCHAR data type 1645
- NVARCHAR data type 1645
- server\_attribute data 1624
- with relational operators 1431

COLLATION keyword, in SET COLLATION statement 862

Collection constructors

- example 1248, 1249
- restrictions 1248

Collection cursor

- closing 182
- DECLARE for ESQL/C variable 480
- declaring 1110
- defined 480
- in SPL 1110
- inserting into 569, 705, 705
- INTO clause 569
- opening 682

Collection data type 1189, 1189

- allocating memory 16
- casting matrix 1676
- defined 1668
- defining a column 1189
- deleting 493
- element, searching for with IN 1152
- empty 1668
- IN operator 1152
- LIST 1189, 1641
- loading 657
- MULTISET 1189, 1644
- returning number of elements 1269
- selecting from 798
- SET 1189, 1651
- sysattrtypes data 1562
- sysxtddesc data 1618

- sysxdtypes data 1618, 1619
- unloading 1031
- updating 1444
- COLLECTION data type
  - coltype code 1568
- Collection data types
  - accessing 1822, 1827
  - counting elements in 1845, 1845
  - description of 1827
  - element, searching for with IN 1828
  - simple 1827
  - updating 1919, 1919
  - using the CARDINALITY function 1845
- collection delimiters 1651, 1668
- COLLECTION keyword
  - in ALLOCATE COLLECTION statement 16
  - in DEALLOCATE COLLECTION statement 464
  - untyped collection variable 798
- Collection subquery
  - description of 1888
  - ITEM keyword 1889, 1889
  - using ITEM keyword in 1889
- Collection Subquery segment 1141
- Collection types
  - in an SPL routine 2007
  - in DELETE statement 1904
- Collection values, inserting into columns 1911
- Collection variable
  - accessing 1444
  - accessing values 1444
  - associating cursor with 480
  - cursor for 569
  - deallocating memory for 464
  - defining, restrictions on 2013
  - in SELECT statement 798
  - manipulating values 1444
  - nested 1827, 1828
  - opening a cursor 682
  - selecting 1828
  - selecting from 798
  - selecting, inserting elements 480
  - untyped 16, 464
  - updating 569, 1444
  - with DESCRIBE INPUT statement 504
  - with DESCRIBE statement 499
- Collection variable)
  - cursor for 1111
- collection-derived table
  - using in SPL 2042
- Collection-derived table 1436, 1891
  - accessing elements in a collection 1891
  - collection cursor 483, 569, 705
  - collection variables with 1444
  - description of 1888, 2038
  - FOREACH statement 1112
  - in SELECT statement 1444
  - INSERT statement with 483, 652
  - restrictions on 1891
  - ROW data types
    - selecting fields 799
  - row types in 1440
  - row variables with 1448
  - SELECT statement with 798
    - fields from row variable 799
  - TABLE keyword 1436, 1444, 1448
  - UPDATE statement with 1053, 1444, 1448
  - where allowed 1448
- Collection-Derived Table segment 1436
- Collections
  - accessing a nested collection 1448
  - accessing elements 1438
  - allocating memory 16
  - constructors 1248
  - deleting elements from 493
  - example of deleting elements 1445
  - example of inserting elements 1447
  - example of updating 1446
  - generating values for 1248
  - inserting values into 646
  - nested 1413
  - restrictions when accessing elements 1439
  - restrictions when defining 1191
  - restrictions with inserting null values 646
  - selecting from 798
  - specifying literal values 1413
  - untyped 16

## M

- M abbreviation for megabyte 1358
- Machine notes 1738
- Machine-independent integer types 1572
- Magnetic storage media 1564
- mail utility, accessing from an SPL routine 1132
- Mail, sending from SPL routines 1132
- Mantissa 1419
- Mantissa precision 1622, 1638
- Map file for C++ programs 1735
- Mapped User 965
- MATCHED keyword in MERGE statement 663
- MATCHES 1653

**MATCHES** keyword  
   in Condition segment 1145, 1154  
   in SELECT statement 815  
   using in WHERE clause 1788  
   wildcard characters 815  
**MATCHES** operator 1633, 1677  
**MATCHES** relational operator  
   in WHERE clause 1795  
**matches()** operator function 1155  
**Materialized table expression** 794  
**Materialized view** 452  
**MAX** function 1367, 1376  
**MAX** function, as aggregate function 1835  
**MAX** keyword  
   in ALLOCATE DESCRIPTOR statement 17, 19  
   in START VIOLATIONS TABLE statement 1011  
**MAX ROWS** keywords, in START VIOLATIONS TABLE statement 1011  
**MAX** window function 1400  
**MAX\_PDQPRIORITY** configuration parameter 934, 992  
**MAXERRORS** keyword  
   in CREATE EXTERNAL TABLE statement 218  
**MAXLEN** keyword, in CREATE OPAQUE TYPE statement 283  
**MAXVALUE** keyword  
   in ALTER SEQUENCE statement 98  
   in CREATE SEQUENCE statement 329  
**MDY** function 1304, 1313  
**MEDIUM** keyword 1555, 1573, 1576  
**MEDIUM** keyword, in UPDATE STATISTICS statement 1054, 1582  
**MEDIUM** mode 1065  
**Membership (.)** operator 1222  
**Membership** operator 1677  
**Memory**  
   allocating for collection variable 16  
   allocating for query 914, 931  
   allocating for ROW variable 19  
   deallocating cursors 574  
   deallocating for collection variable 464  
   deallocating for cursors 859  
   deallocating for row variable 466  
   deallocating prepared objects 574, 861  
**MERGE** statement 663, 1616  
   using Insert join 1907  
   using Update join 1915  
**MERGE** statements  
   using Delete join 1905  
**Message file**  
   specifying subdirectory with DBLANG 1711  
**MESSAGE\_LENGTH** keyword, in GET DIAGNOSTICS statement 587  
**MESSAGE\_TEXT** keyword, in GET DIAGNOSTICS statement 587  
**Messages**  
   chaining 1744  
   error in syserrors 1579  
   optimized transfers 1744  
   reducing requests 1745  
   trace message template 1613  
   warning in syserrors 1579  
**mi\_collection\_card()** function 1641, 1644, 1651  
**mi\_collection\*** functions 1510  
**mi\_db\_error\_raise()** function 1579  
**mi\_trigger\*()** functions 427  
**Microsoft C compiler** 1731  
**MIN** function 1367, 1376  
**MIN** function, as aggregate function 1835  
**MIN** window function 1400  
**Minus (-)** sign  
   binary operator 1193  
**MINUS** operator  
   in SELECT statement 768, 836, 839, 840  
   restrictions on use 837  
**Minus sign (-)**  
   INTERVAL literals 1418  
   unary operator 1418  
**minus()** operator function 1210  
**MINUTE** keyword 1191, 1410, 1410  
**MINVALUE** keyword  
   in ALTER SEQUENCE statement 98  
   in CREATE SEQUENCE statement 329  
**Missing arguments** 1434  
**MITRACE\_OFF** configuration parameter 1612, 1613  
**Mixed-case characters, converting to** 1343  
**mkdir** utility 1711  
**MOD** function 1254, 1258  
**MODE ANSI** keywords, specifying transactions 1937  
**MODE** keyword  
   in ALTER TABLE statement 141  
   in CREATE DATABASE statement 201  
   in CREATE TABLE statement 341, 392  
   in LOCK TABLE statement 659  
   in SET LOCK MODE statement 982  
**MODERATE INTEG** keywords  
   ALTER TABLE statement 1660  
   CREATE TABLE statement 1660  
   in ALTER TABLE statement 156, 378  
**MODERATE** keyword  
   in ALTER TABLE statement 156  
**Modifiers**

## T

T abbreviation for terabyte 1358

tabid 1549, 1609

tabid column 40

### Table

- adding a constraint 119, 121
- adding a constraint to a column with data 153
- alias in DELETE 492
- alias in SELECT 791
- alias in UPDATE 1042
- build 967
- changing a column data type 1671
- child 356
- compressed 391
- consumed 26, 31
- creating 335
- creating a synonym for 330
- default privileges 632
- defining fragmentation strategy 382
- deleting all rows 1025
- dependencies, in sysdepend 1575
- derived 794, 1143, 1439
- description of 1768
- diagnostic 1616
- diagnostics 409, 663, 1020
- diagnostics table 1024
- dropping 531
- dropping a synonym 530
- dropping a system table 533
- extent size 1609
- external 213, 213, 237, 409, 857, 1474
- fragmented 22, 1582, 1584
- hash 967
- hashing parameters 1607
- hierarchy 1582, 1584, 1591, 1646, 1760, 1830
- in relational model 1768
- inheritance 411, 418
- inheritance hierarchy 369, 1040
- inheritance, sysinherits data 1591
- isolating 377
- joins in Condition segment 818
- loading data
  - with onload utility 1937
- loading data with the LOAD statement 652
- lock 1982
- lock mode 1609, 1722
- locking
  - with ALTER INDEX 85
  - with LOCK TABLE 659
- nonfragmented 42, 1719
- nonlogging 401
- not in the current database 1794

- operations on a 1769
- parent 356
- permanent 404
- privileges
  - granting 597
- privileges on 371, 733
- protected 40, 649
- qualifiers 1452
- query result table 341
- raw 1041
- renaming 717
- separate from large object storage 1659
- static 1005
- structure in superstores\_demo database 1757
- surviving 26, 31
- synonyms in sysyntable 1606
- systables data 1609
- system catalog 409
- system catalog tables 1559
- target 1011, 1016, 1024
- temporary 397, 409, 855, 1057, 1716, 1717
- temporary in SE 1717
- temporary table name 398
- typed 307, 370
- unlocking 1036
- untyped 370
- untyped, and unnamed ROW 1648
- updating statistics 1057
- version value 1609
- violations 409, 663, 1014, 1616
- violations table 1024
- virtual 1436
- waiting for a locked table 982
- Table expression 794, 1143, 1439
- Table format, in SET Database Object Mode statement 875
- Table hierarchy
  - triggers in 2076
  - UPDATE statements 1920
